| **Attribute** | Enter the required or optional attribute. |
| **Values** | Enter the value(s) associated with the attribute. Separate multiple values for a single attribute with a semicolon. No spaces are required. |
| **Insert Files** | Opens a dialog box that allows you to use a text file with the appropriate attributes and values. |
| **Enter** | Adds the entered attribute and value(s) to the **Entry List** section of the dialog box, and clears the **Attribute** and **Value** fields. Continue entering attributes and values until all required and desired optional attributes are on the Entry List. |

| | |
|---|---|
| **Operation Section** | **Add**, **Delete**, or **Replace**. Choose **Add** to add a new value to an existing attribute. Choose **Delete** to permanently remove an attribute from the listed object. Attributes containing data cannot be deleted. Also, attempting to delete required attributes results in an error. Choose **Replace** to replace an existing value with another, or to change listed values for an existing attribute. |
| **Entry List Section** | Displays existing attributes and values for an object. |
| **Edit** | Opens a dialog box you can use to changes the selected entry from the Entry List. |
| **Synchronous** | If selected (the default), requires LDP to wait for a response from the destination server before continuing. If you clear this check box, LDP continues before a response is received. Clear this check box when slow WAN connections are causing LDP commands to time out. |
| **Extended** | Select this check box if the object being modified is part of an extended control. |
| **Run** | Sends the edited values in the Entry List to Active Directory. |

**Modify RDN**

Opens a dialog box you can use to change the relative distinguished name of an object. This option is designed to modify leaf objects only. If you rename the container portion of the distinguished name, then the object moves to the container that is named.

| Option | Description |
|---|---|
| **Old DN** | Enter the current distinguished name of the object. |
| **New DN** | Enter the new distinguished name for the object. |
| **Delete Old** | If selected (the default), removes the old distinguished name from the LDAP directory. |
| **Synchronous** | If selected (the default), requires LDP to wait for a response from the destination server before continuing. If you clear this check box, LDP continues before a response is received. Clear this check box when slow WAN connections are causing LDP commands to time out. |
| **Extended rename** | Select this check box if the object being renamed is part of an extended control. |
| **Run** | Sends the change to Active Directory. |

**Search**

Opens a dialog box that you can use to create a customized search filter and to perform the search on the directory information tree. The search base must be specified as a distinguished name, and the filter must be a valid LDAP filter. Items returned from a search are separated by **>>** characters.

| Option | Description |
|---|---|
| **Base DN** | Enter a distinguished name to specify where the search starts. |
| **Filter** | Enter the search criteria separated by LDAP search filters. Enter attributes and values to find an object or set of objects.<br><br>Note: LDAP search filters are defined in RFC 2254, and in the Knowledge Base Article Q255602 "Browsing and Querying Using the LDP Utility" at Microsoft Product Support Services. |
| **Scope Section** | Specifies how many levels the search encompasses. |
| **Base** | Searches the base object only. |
| **One Level** | Searches objects immediately subordinate to the base object, but does not search the base object. |

| | |
|---|---|
| **Subtree** | Searches the entire subtree, from the base object down to all child objects. |
| **Options Button** | Opens the **Search Options** dialog box. You can use it to apply filters that allow some entries and exclude others from the search, and that allow you to control the way the search is processed. See the **Options** menu for more details. |
| **Run** | Click this button to send the search request to Active Directory. |

**Compare**

Opens a dialog box you can use to compare the value of an attribute of an object with a specified value. The result returned is either true or false.

| Option | Description |
|---|---|
| **DN** | Enter the full distinguished name of the object whose value(s) will be compared. |
| **Attribute** | Enter attribute to be compared. |
| **Values** | Enter the value(s) that will be compared with the existing value in Active Directory. Separate multiple values for a single attribute with a semicolon. No spaces are required. |
| **Synchronous** | If selected (the default), requires LDP to wait for a response from the destination server before continuing. If you clear this check box, LDP continues before a response is received. Clear this check box when slow WAN connections are causing LDP commands to time out. |
| **Run** | Starts the comparison. |

**Extended Op**

Opens a dialog box you can use to submit an extended operation to an LDAP Directory by specifying an LDAP object identifier (OID) and an applicable value.

| Option | Description |
|---|---|
| **Oid** | Enter the object ID number. |
| **Data** | Enter the value of the object identifier (OID) attribute. |
| **Controls** | See **Controls Option** under the **Options** menu. |
| **Send** | Submits the extended operation to Active Directory. |

**GetLastError**

Calls the LDAP **Getlasterror** function.

**Security**

Opens a dialog box you can use to submit an extended operation to an LDAP directory by specifying an LDAP object identifier (OID) and an applicable value.

| Option | Description |
|---|---|
| **Security Descriptor** | Opens a dialog box you can use to view access permissions on an object. |
| **User Rights** | Not implemented yet. |

**Replication**

Opens a dialog box you can use to submit an extended operation to an LDAP directory by specifying an LDAP object identifier (OID) and an applicable value.

| Option | Description |
|---|---|
| **View Metadata** | Opens a dialog box you can use to view replication metadata of an object. This command is useful to identify whether the objects are up to date and replicated between domain controllers. |

**Process Pending**

Opens a dialog box that shows the list of requests that are not finished processing.

**View Menu**

The **View** menu options:

| Option | Description |
|---|---|
| **Status Bar** | Shows or hides the status bar located along the bottom of the LDAP window. |
| **Tree** | Opens a dialog box you can use to specify the base object in the navigation pane. You can enter a default base object in the **General Options** dialog box in the **Auto Base DN Query** field. By default, this field is blank and no object is listed in the navigation pane. |
| **Enterprise Configuration** | Opens the **Live Enterprise Tree** dialog box, which shows a graphic display of all domains and domain controllers in the enterprise. The dialog box indicates whether the domain controllers are online or offline by marking offline domain controllers with a red "X". |
| **Auto Refresh (min):** | Enter the number of minutes for LDP to wait before refreshing the display. |
| **Refresh** | Manually refreshes the display. |

**Options Menu**

**Options** menu options:

**Bind Options**

| Option | Description |
|---|---|
| **Function Type** | Specifies a category of authentication for LDP to use when choosing authentication methods. |
| **Generic** | Specifies to use a standard authentication protocol. |
| **Simple** | Specifies to use no authentication protocol and to send the password in clear text. |
| **Extended** | Not available. |
| **Method** | Selects the type of authentication that LDP uses when passing credentials. |
| **Synchronous** | Specifies that the authenticating server must respond immediately to requests. This option works only with simple authentication. |
| **Use auth. identit** | Allows the use of alternate authentication credentials. All authentication methods except simple require synchronous calls. |

**Search Options**

| Option | Description |
|---|---|
| **Time Limit** | Enter the number of milliseconds that the search can take on the server. By default the maximum is 120 seconds. |
| **Size Limit** | Enter the maximum number of bytes that the search can return. Entering a null value does not place a maximum size on the data returned. |
| **Timeout (s)** | Enter the number of seconds that LDP waits for the LDAP server to respond to a search request. |
| **Timeout (ms)** | Enter the number of milliseconds that LDP waits for the LDAP server to respond to a search request. |
| **Page Size** | Enter the maximum size, in bytes, of each page of returned data. |
| **Attributes** | Specifies which attributes to return in the search. Separate multiple attributes with a semicolon. Use the wildcard character (*****) to indicate all attributes. |

| | |
|---|---|
| **Search Call Type** | Specifies a call type to use in the search. If the search will take some time, you can select **async** to allow you to perform other tasks while waiting for the search to complete. |
| **Attributes Only** | Select this check box to return only attributes of objects. The distinguished name is not returned. |
| **Chase Referrals** | Performs a search for objects found in external LDAP directories. By default, the objects' trusts of external LDAP directories return only a referral instead of the actual object. |
| **Display Results** | Displays a detailed list of objects returned by the search. By default, only a success or failure and the number of objects found display. |
| **Sort Keys** | Opens the **Sort Keys Option** dialog box. See **Sort Keys** under the **Options** menu. |
| **Controls** | Opens the **Controls Option** dialog box. |

**Pending Options**

Opens a dialog box you can use to place filters on the list of processes that have not yet completed.

| Option | Description |
|---|---|
| **All search results** | Specifies that all search results display. |
| **Blocking** | Clear this check box to set a time limit. |
| **Time Limit (sec):** | Enter a time limit in seconds. |
| **Time Limit (millisec):** | Enter a time limit milliseconds. |

**General Options**

**Value Parsing Section**

| Option | Description |
|---|---|
| **Binary** | Displays the LDAP information in its native numerical format. |
| **String** | Converts the LDAP information from its native format to ASCII characters so that it is more readable when displayed. This is the default setting. Values that are too long to be converted are still displayed in binary form. |
| **LDAP Version Section** | Specifies which version of LDAP the server is using. The default is version 3. |
| **DN Processing Section** | Converts the distinguished names, displayed in component parts, by extending the data types that LDP returns when performing a command. |

**Buffer Size Section**

| Option | Description |
|---|---|
| **Page** | Enter the number of returned lines to display per command. |
| **Line** | Enter the number of returned characters to display per command. |
| **Auto default NC query** | Specifies that LDP queries the default naming context when a connection to the LDAP server is made. The default naming context is the RootDSE. This setting is used when the distinguished name value in the **View\|Tree** dialog box is left blank. |

**Virtual List View (VLV) Section**

| Option | Description |
|---|---|

| | |
|---|---|
| **Auto VLV browse when container size is greater than:** | Select this check box to display a virtual list view whenever the object count is greater than the value displayed in the field. The default value is 100. |

**Connection Options**

Opens a dialog box you can use to change the value of any option.

| Option | Description |
|---|---|
| **Option Name** | Enter the name of the option whose value will be reset. |
| **Value** | Enter the new value for the specified option. |
| **Set** | Sends the information to the LDAP directory. |

**TLS Options**

| Option | Description |
|---|---|
| **StartTLS** or **StopTLS** | Starts or stops a secure session with the LDAP server that uses Transport Level Security (TLS). |

**Controls Option**

In the **Controls** dialog box, enter values to extend the functionality of LDAP.

The object identifier must be specified when implementing a control. To obtain a list of object identifiers, view the supportedControls property in the RootDSE of a domain controller. Individual controls are described in the Understanding LDAP white paper on the Microsoft Web site

Note

- Only server controls can be sent to a server. Client controls work only with LDAP APIs.
- To view a list of extended LDAP controls, see the Knowledge Base article Q222560 "Windows 2000 Extended LDAP Controls" at Microsoft Product Support Services.

**Sort Keys Option**

Sort Keys is a type of control that formats the display of search results. To format the display of your search results, in the **Sort Keys** dialog box, enter an attribute type.

For more information find sortKeyRequestControl in the Understanding LDAP white paper on the Microsoft Web site.

Utilities Menu

**Utilities** menu options:

| Option | Description |
|---|---|
| **Large Integer Converter** | To convert long integers into high and low parts, enter a value in the **String** field. |

Note

- LDP can connect to only one LDAP server at a time. Using the **Connect** command while connected to a server disconnects the current session.

# Ldp Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**LDP Examples**
**Example 1: Add a new object to an LDAP directory**
To add a user to Active Directory by using LDP:

1. On the **Browse** menu, click **Add**.

2. In the **Add** dialog box, in the **Dn** input box, enter the distinguished name of the new object.

3. In the **Edit Entry** section, add the new attributes and values. Click **Enter** after typing in each attribute and associated value:

| Attribute | Value |
|---|---|
| userAccountControl | 512 |
| ObjectClass | User |
| SamAccountName | Testuser2 |

4. To add the attribute or value combination to the Entry List box, click **Edit**.

5. To add the information to Active Directory using LDAP APIs when all the attributes are entered, click **Run**.

**Example 2: Search an LDAP directory**
To search Active Directory by using LDP:

- On the **Browse** menu, click **Search**.

  The **Search** dialog box opens.

In the following searches, the LDAP directory is Active Directory. For user names, it contains a **givenName** attribute for first names, and an attribute of **sn** for last names.

- To search for all users that have a first name of John and a last name of either Smith or Jones, type the following in the **Filter** field:

  **(&(objectClass=user)(givenName=John)(|(sn=Smith)(sn=Jones))))**

- To search for users that have a last name of Jones, but filter out those users that have a first name of John or Jane, and also filter out users that have not logged on at least 100 times, type the following in the **Filter** field. (The exclamation point (!) is the NOT operator.)

  **(&(objectClass=user)(sn=Jones)(!givenName=John)(!givenName=Jane)(!logonCount<=100))**

  **Note**

  - To search for reserved characters as part of an attribute value, you must precede the reserved character with an escape character. Use the following escape characters to represent the associated characters:

| Character | Escape characters |
|---|---|

| | |
|---|---|
| * | 2a |
| ( | 28 |
| ) | 29 |
| \ | 5c |
| NUL | 00 |

- To search for all of the users whose display names end in a close parenthesis character, type the following in the **Filter** field:

  **(&(objectClass=user)(displayName=*\29))**

- To search for all users who have a surname that starts with the letter J, type the following in the **Filter** field. (Queries support the wildcard character (*****).)

  **(&(objectClass=user)(sn=j*))**

- To search for users whose home directories are G:\Accounting, type the following in the **Filter** field. (The attribute name is **home-directory**.)

  **(&(objectClass=user)(home-directory=G:\5cACCOUNTING*))**

**Example 3: Control the returns on a search of an LDAP directory**
In this example, you use the **Search Options** dialog box to control which attributes are displayed in a search. Just a few attributes are displayed; the rest are filtered and do not display in the details window of LDP.

To control which attributes display:

- In the **Attributes** input box, type the attributes to display:

  **"memberof;range:1-20"objectClass;objectGUID**

  **Notes**

  - Separate attributes with a semicolon. No spaces are necessary. All other attributes will be filtered out of the display.

  - A range is specified for the **memberof** attribute. Because a semicolon is used, the entire section must be separated from the rest of the attributes by quotation marks.

All searches display only the **memberof**, **objectClass**, and **objectGUID** attributes in the details pane. To return all attributes, replace any existing list of attributes with the wildcard character (*****).

**Example 4: View replication metadata for an object**
To list the replication metadata for an object in Active Directory:

1. On the **Browse** menu, click **Replication|View Metadata**.

   The **View Metadata** dialog box opens.

2. In the **Object Dn** field, enter the distinguished name of the object, then click **OK**.

   The output will look similar to the output in the following table.

| AttID | Ver | Loc.USN | Originating DSA | Org.USN | Org.Time/Date |
|---|---|---|---|---|---|

| | | | | | |
|---|---|---|---|---|---|
| 0 | 1 | 3693 | 9fad4c38-2d76-44b2-84f6-f2fe384f8450 | 3693 | 2000-12-29 09:15.02 |
| 3 | 1 | 3693 | 9fad4c38-2d76-44b2-84f6-f2fe384f8450 | 3693 | 2000-12-29 09:15.02 |
| d | 1 | 3693 | 9fad4c38-2d76-44b2-84f6-f2fe384f8450 | 3693 | 2000-12-29 09:15.02 |
| 20001 | 1 | 3693 | 9fad4c38-2d76-44b2-84f6-f2fe384f8450 | 3693 | 2000-12-29 09:15.02 |
| 20002 | 1 | 3693 | 9fad4c38-2d76-44b2-84f6-f2fe384f8450 | 3693 | 2000-12-29 09:15.02 |

# Movetree.exe

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Movetree command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Movetree.exe: Active Directory Object Manager**
This command-line tool enables administrators to move Active Directory objects such as contacts between domains in a single forest. Operations such as these are performed to support domain consolidation or organizational restructuring operations.

### Important

- Use the Active Directory Migration Tool (ADMT) included on your Windows Server 2003 CD-ROM to move Active Directory objects such as user, computer, group, and OU. MoveTree should **only** be used in special cases to handle objects (such as contacts) which cannot currently be migrated by ADMT.

**Corresponding UI**
To move users or groups within a Windows Server 2003 domain (for example, from one organizational unit to another), use Active Directory Users and Computers, a Microsoft Management Consolesnap-in that is part of Windows Server 2003.

Note

- You must install Adminpak.msi before you can see the Active Directory Users and Computers snap-in in Administrative Tools.

**Concepts**
For more information about Active Directory, see the Active Directory Overview.

System Requirements

The following are the system requirements for MoveTree:

- Windows XP Professional or Windows Server 2003
- Administrator rights

**Files Required**

- Movetree.dll
- Movetree.exe

# Movetree Remarks

Updated: December 28, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MoveTree Remarks**
**Before Using MoveTree**
Before using MoveTree take the following steps to maintain peak performance:

1. Review all Group Policy objects that apply to a particular organizational unit, and make a note of the Group Policy settings they contain.

2. Recreate the Group Policy objects, linked to the moved organizational unit in the new domain, with the desired settings.

3. Make sure to remove the Group Policy objects linked from the old domain.

**MoveTree Limitations**
While MoveTree can move some Active Directory objects between domains, certain objects cannot be moved. MoveTree is also unable to move certain associated data that may exist externally to Active Directory. For details about limitations, see the following sections.

**Local and Domain Global Group Limitations**
Local and Domain Global groups are moved during a MoveTree operation, but their members are not. This is because of group membership rules. Therefore, it is important to save and recreate the memberships of Domain Local and Global groups to maintain the existing resource access permissions.

**Universal Group Limitations**
Universal groups including their members, are moved during a MoveTree operation.

**Computer Objects Limitations**
Computer objects are not moved during a MoveTree operation. Use Netdom Overview, another Windows Support Tool, to move computer accounts between domains and to join computers to domains.

**Associated Data**
Associated data that is not moved during a MoveTree operation includes policies, profiles, logon scripts, and users' personal data. Use additional scripts or management tools, such as the Remote Administration Scripts (included in the *Windows 2000 Resource Kit*), in conjunction with MoveTree to perform these additional steps.

### Important

- Remote Administration Scripts in the *Windows 2000 Resource Kit* are examples only. They might require code modification to be used with Windows Server 2003 operating systems. Use this feature only with the assistance of Microsoft Product Support professionals.

MoveTree cannot move the following objects:

- System objects (identified by the objectClass being marked as systemOnly)

- Objects in the configuration or schema naming contexts

- Objects in the special containers in the domain: Builtin, ForeignSecurityPrincipal, System, LostAndFound

- Domain controllers or any object whose parent is a domain controller

- Any object with the same name as an object that already exists in the target domain

MoveTree can fail because of some of the following error conditions:

- The source domain controller cannot transfer the RID role owner.

- The source object is locked due to another operation in progress. (For example, if another user is currently creating child objects under the source object that is selected for the move operation.)
- Either the source or destination domain have invalid credentials.
- The destination knows the source object is deleted but the source does not. (For example, the source object had been deleted on a different domain controller, but because of replication latency the source domain controller has not yet received the deletion event.)
- There is a failure at the destination domain controller (for example, Disk Full).
- A Security Accounts Manager (SAM) constraint is met. (For example, Duplicate SAM Account Name or source object password length does not meet the password restrictions in the target domain.)
- The source and destination have a schema mismatch.

When a MoveTree Operation Is Paused or Halted

During a MoveTree operation, if the process is paused or halted, then any objects that have yet to be moved remain in an *orphan* container in the *Lost And Found* container in the source domain. The *Lost And Found* container can be viewed in the Active Directory Users and Computers snap-in (a Windows administrative tool) when the Advanced View menu option is selected. The *orphan* container is named using the globally unique identifier (GUID) of the parent container being moved and can be readily identified; it will contain the objects that were selected for the MoveTree operation.

For example, if you are moving the organizational unit Sales, which has an object GUID of {123-abc}, and the MoveTree operation is halted, then the tree structure looks like this:

```
Lost + Found
         {123-abc}
               Sales
```

**MoveTree ErrorLevels**
MoveTree returns ErrorLevel 0 for success and ErrorLevels 1 through 5 for different kinds of failure. These values can be used as criteria for branching when the tool is used in a batch file; see Movetree Examples in the *MoveTree Examples* topic.

The following table describes MoveTree error levels.

| Error Level | Meaning |
|---|---|
| 0 | Success |
| 1 | Error – command-line syntax |
| 2 | Error – directory conflict (duplicate names, insufficient privilege, name conflict, immovable object) |
| 3 | Error - network error (DC unavailable) |
| 4 | Error – system resource (Low VM, disk space) |
| 5 | Error – internal processing error |

# Movetree Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MoveTree Syntax**

MoveTree uses the following syntax:

**movetree** {**/start** | **/continue** | **/check**} **/s** *SrcDSA* **/d** *DstDSA* **/sdn** *SrcDN* **/ddn** *DstDN* [**/u** [*Domain*\]*UserName* **/p** *Password*] [**/verbose**]

**Parameters**

**/start**

Starts a MoveTree operation. This command includes a **/check** operation by default. MoveTree tries to continue the operation until it is complete. If there is a network fault or if the destination domain controller becomes unavailable, then MoveTree pauses the operation. If an operation has been paused, it can be continued by using the **/continue** command.

**/continue**

Continues the execution of a previously paused or failed MoveTree operation. This allows the MoveTree operation to continue even if a network fault or a domain controller error has interrupted the initial operation. Specifying **/sdn** *SrcDN* is optional for this command.

**/check**

Performs a test run of the MoveTree operation checking the whole tree without moving any objects. This enables the administrator to determine if there is sufficient disk space on the destination server, if there are any conflicts with object names or if there are any objects that could not be moved (such as Domain Local or Global groups). The administrator can then take remedial action before performing the actual move.

The **/check** command returns an error if any of the following conditions are met:

- The user does not have the necessary permissions to create objects in the destination container.
- The destination server does not have sufficient disk space to continue the operation.
- A relative distinguished name conflict exists on the destination server.
- There is a samAccountName conflict for any object that would be moved.
- Any objects cannot be moved because they are built-in accounts, or they are either a Domain Local or a Global group.
- Any computer objects would be moved. To move computer accounts and join the computers to the domain, use Netdom Overview, a Windows Support Tool.

**/s *SrcDSA***

Specifies the fully qualified primary DNS name of the source server in the domain from which the objects are being moved (for example, server1.marketing.microsoft.com). Required for all MoveTree commands.

**/d *DstDSA***

Specifies the fully qualified primary DNS name of the destination server in the domain to which the objects are being moved (for example, server2.sales.microsoft.com). Required for all MoveTree commands.

**/sdn *SrcDN***

Specifies the distinguished name of the source subtree (the object being moved) (for example, OU=Promotions,DC=Marketing,DC=Microsoft,DC=Com). Required for the **/start**, **/startnocheck**, and **/check** commands; optional for **/continue**.

**/ddn *DstDN***

Specifies the distinguished name of the destination subtree (to which the object is being moved) (for example, OU=Promotions,DC=Sales,DC=Microsoft,DC=Com). Required for all MoveTree commands.

**/u [*Domain*\]*UserName* /p *Password***

Runs MoveTree under the credentials of an alternate user name and password. Optionally, *Domain* can be specified as well. If these optional arguments are not provided, MoveTree uses the credentials of the currently logged-on user.

**/verbose**

Runs MoveTree in verbose mode, which displays more details about the operation as it runs. Optional.

**/? or /help**

Displays this information on a command-line syntax screen.

# Movetree Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MoveTree Examples**
These examples assume the following scenario:

In the Marketing domain, there is a Server1 server and a Promotions organizational unit. In the Sales domain, there is a Server2 server. You want to move the Promotions organizational unit from the Marketing domain to the Sales domain, and to rename the new organizational unit Sales Promotions.

**Example 1: Perform a Test MoveTree Operation**
You want to move the Promotions organizational unit from the Marketing domain to the Sales domain and to rename the Promotions organizational unit Sales Promotions. To do a test run, and only perform the move if the test executes without errors, type the following at the command line:

```
movetree /start /s server1.marketing.microsoft.com /d server2.sales.microsoft.com/sdn
OU=Promotions,DC=Marketing,DC=Microsoft,DC=Com /ddn OU=Sales Promotions,DC=Sales,DC=Microsoft,DC=Com
```

**Example 2: Move Tree Without Test**
To move the Promotions organizational unit from the Marketing domain to the Sales domain and then rename the Promotions organizational unit to Sales Promotions without doing a test run first, type the following at the command line:

```
movetree /startnocheck /s server1.marketing.microsoft.com /d server2.sales.microsoft.com /sdn
OU=Promotions,DC=Sales,DC=Microsoft,DC=Com /ddn OU=Sales Promotions,DC=Sales,DC=Microsoft,DC=Com
```

**Example 3: Resume a Failed MoveTree Operation**
A previous MoveTree operation between Server1 in the Marketing domain and Server2 in the Sales domain failed while the objects were being moved into the Sales Promotion organizational unit. To resume the failed operation, type the following at the command line:

```
movetree /continue /s server1.marketing.microsoft.com /d server2.sales.microsoft.com /ddn OU=Sales
Promotions,DC=Sales,DC=Microsoft,DC=Com
```

**Example 4: Test a MoveTree Operation**
Eventually you want to move the Promotions organizational unit from the Marketing domain to the Sales domain, renaming it Sales Promotions. To do a test run and get verbose output to study before you perform the actual move, using the credentials Microsoft\administrator with the password "********", type the following at the command line:

```
movetree /check /s server1.marketing.microsoft.com /d server2.sales.microsoft.com /sdn
OU=Promotions,DC=Sales,DC=Microsoft,DC=Com /ddn OU=Sales Promotions,DC=Sales,DC=Microsoft,DC=Com /verbose /u
Microsoft\administrator /p ********
```

**Example 5: Use MoveTree in a Batch File**
You want to move the Promotions organizational unit from the Marketing domain to the Sales domain and rename the Promotions organizational unit Sales Promotions. To use a batch file to do a test run, and only perform the move if the test executes without errors, create a batch file with the following content:

```
movetree /check
 /s server1.marketing.microsoft.com
 /d server2.sales.microsoft.com
 /sdn OU=Promotions,DC=Marketing,DC=Microsoft,DC=Com
 /ddn OU=Sales Promotions,DC=Sales,DC=Microsoft,DC=Com
if errorlevel 0 goto start
goto exit
:start
movetree /start
 /s server1.marketing.microsoft.com
 /d server2.sales.microsoft.com
 /sdn OU=Promotions,DC=Marketing,DC=Microsoft,DC=Com
 /ddn OU=Sales Promotions ,DC=Sales,DC=Microsoft,DC=Com
:exit
```

For more information about errors in MoveTree, see Movetree Remarks in *MoveTree Remarks*.

# Ntfrsutl Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Ntfrsutl command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Ntfrsutl.exe: File Replication Utility**
This command-line tool dumps the internal tables, thread and memory information for the NT File Replication Service (NTFRS). It runs against local and remote servers.

The recovery setting for NTFRS in Service Control Manager (SCM) can be critical to locating and keeping important log events on the computer. This tool provides a convenient method of reviewing those settings.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
The File Replication Service (FRS) is a key element of the Microsoft Distributed File System (DFS) technologies, and was first introduced in Windows 2000. It is used by Active directory for SYSVOL replication, and by DFS for automatic replication of content between 'alternate targets'.

NTFRS creates text-based log files in the *Systemroot*\debug folder for troubleshooting NTFRS replication problems. NTFRS builds two types of text-based log files.

- The Ntfrsapi.log file contains events that take place during promotion and demotion of a server, namely, the creation of the NTFRS registry keys.

- The Ntfrs_nnnn.log debug log files store transaction and event details in the Ntfrs_nnnn.log through Ntfrs_0005.log files. The most recent NTFRS transactions and events are written to the log with the highest version number in existence at the time.

The Registry entries that control NTFRS logging reside in the HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Ntfrs\Parameters registry key.

The number of log files residing in the Debug folder is determined by the Debug Log File entry. Once the log entries are written (determined by the Debug Maximum Log Messages registry entry) , a new log file, Ntfrs_000n-1.log is created. Once the correct number of logs is created (determined by the Debug Log File registry entry), the lowest-version log file is deleted and the remaining log file names are decremented by 1 to make room for a new log file.

**System Requirements**
To access the internal NTFRS information, the user needs specified levels of access to the following registry keys on the target server.

```
       HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Ntfrs\Parameters\
Access Checks\
```

# Ntfrsutl Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NTFRSUtl Examples**

Example 1: Determine NTFRS Polling Interval

In this example, you want to determine the polling interval for file replication. At the command prompt, type:

```
C:\Program Files\SupportTools>ntfrsutl poll wrkstn-1
```

Your output will look similar to the one below:

```
Current Interval:      5 minutes
Short Interval  :      5 minutes
Long Interval   :     60 minutes
```

You can see that the tool ran successfully providing the local interval information that was requested.

Example 2: Determine NTFRS API Version Information

In this example, you want to find information about the current NTFRS application program interface (API). At the command prompt, type:

```
C:\Program Files\SupportTools>ntfrsutl version
```

Your output will look similar to the one below:

```
NtFrsApi Version Information
   NtFrsApi Major      : 0
   NtFrsApi Minor      : 0
   NtFrsApi Compiled on: Mar 27 2002 18:20:58
NtFrs Version Information
   NtFrs Major        : 0
   NtFrs Minor        : 0
   NtFrs Compiled on  : Mar 27 2002 18:21:38
   Latest changes:
   Windows Server 2003 Server
OS Version 5.1 (3620) -
SP (0.0) SM: 0x0112  PT: 0x03
Processor:  INTEL Level: 0x0006  Revision: 0x0803  Processor num/mask: 1/0000000
1
```

The information provided NTFRS versions as well as operating system versions and processor information.

NTFRSUtl Syntax 1

NTFRSUtl Syntax 2

DS

Sets

Version

Poll

**NTFRSUtl Syntax 1**

Enumerates the idtable/configtable/inlog/outlog of the service.

**Syntax**

- **ntfrsutl**[**idtable**|**configtable**|**inlog**|**outlog**] [*Computer*]

**Parameters**

***Computer***

Connects to the NTFRS service on the specified computer.

**NTFRSUtl Syntax 2**

Lists the NTFRS memory usage of the service.

**Syntax**

- **ntfrsutl**[**memory**|**threads**|**stage**] [*Computer*]

**Parameters**

***Computer***

Connects to the NTFRS service on the specified computer.

**DS**

Lists the NTFRS service's view of the DS.

**Syntax**

- **ntfrsutl ds**[*Computer*]

**Parameters**

***Computer***

Connects to the NTFRS service on the specified computer.

**Sets**

Lists the active replication sets.

**Syntax**

- ntfrsutl sets [*Computer*]

**Parameters**

***Computer***

Connects to the NTFRS service on the specified computer.

**Version**

List the API and NTFRS service versions.

**Syntax**

- **ntfrsutl version**[*Computer*]

**Parameters**

***Computer***

Connects to the NTFRS service on the specified computer.

**Poll**
Lists the current polling intervals.

**Syntax**
**ntfrsutl poll**[**/quickly**[=[*N*]]][**/slowly**[=[*N*]]][**/now**][*Computer*]

**Parameters**
**/quickly[ =[ *N*]]**
Polls quickly.

| | |
|---|---|
| **quickly** | Polls quickly until stable configuration is retrieved. |
| **quickly=** | Polls quickly every default minutes. |
| **quickly=***N* | Polls quickly every *N* minutes. |

**/slowly[ =[ *N*]]**
Polls slowly.

| | |
|---|---|
| **slowly** | Polls slowly until stable configuration is retrieved. |
| **slowly=** | Polls slowly every default minutes. |
| **slowly=***N* | Polls slowly every *N* minutes. |

**/now**
Polls now.

***Computer***
Connects to the NTFRS service on the specified computer.

# Repadmin Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Repadmin command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Repadmin.exe: Replication Diagnostics Tool**
This command-line tool assists administrators in diagnosing replication problems between Windows domain controllers.

Administrators can use Repadmin to view the replication topology (sometimes referred to as RepsFrom and RepsTo) as seen from the perspective of each domain controller. In addition, Repadmin can be used to manually create the replication topology (although in normal practice this should not be necessary), to force replication events between domain controllers, and to view both the replication metadata and up-to-dateness vectors.

Repadmin.exe can also be used for monitoring the relative health of an Active Directory forest. The operations **replsummary**, **showrepl**, **showrepl /csv**, and **showvector /latency** can be used to check for replication problems.

Usually, the Knowledge Consistency Checker (KCC) manages the replication topology for each naming context held on domain controllers.

| **Important** |
| --- |
| During the normal course of operations, there is no need to create the replication topology manually. Incorrect use of this tool can adversely impact the replication topology. The primary use of this tool is to monitor replication so that problems such as offline servers or unavailable LAN/WAN connections can be identified. |

**Corresponding UI**
Repadmin is used to troubleshoot replication issues in Active Directory. Many of the actions performed at the command line with Repadmin can be accomplished by using Replmon Overview.

**Concepts**
For more information about replication, see Active Directory Replication Technologies.

**System Requirements**
The following are the system requirements for Repadmin:

- Windows XP Professional, Windows Server 2003, or Windows Server 2003 with Service Pack 1 (SP1)
- Administrator rights on the domain controller

**File Required**

- Repadmin.exe

# Repadmin Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Repadmin Remarks**

**Repadmin Terminology**

The following terminology is used in discussing Repadmin syntax:

- *NamingContext* refers to the directory partitions that Active Directory comprises. Naming contexts include the three Read/Write naming contexts — domain, schema, and configuration — and the optional Read-only naming contexts that are present on domain controllers that are global catalog servers. A naming context can also be an application directory partition. A naming context is specified as a distinguished name, which indicates its hierarchical relationship to the forest root domain (for example, DC=MyDomain,DC=Microsoft,DC=Com).

- *GUID* (globally unique identifier) refers to the 128-bit number used to uniquely identify objects stored in the directory (for example, fa1a9e6e-2e14-11d2-aa9b-bbfc0a30094c). The GUID is sometimes referred to in the syntax line as a universally unique identifier (UUID). For the purposes of Repadmin, these two terms are synonymous.

- *DN* is an X.500 distinguished name (for example, CN=Server1,CN=Servers,CN=Default-First-Site-Name,CN=Sites,CN=Configuration,DC=Microsoft,DC=Com).

Difference Between the objectGUID and the InvocationID

In the Repadmin Examples, DC object GUID and DC InvocationID returned by **showrepl** and other commands show identical hexadecimal values. However, these two values identify different objects. DC object GUID is a unique identifier for the NTDS Settings object on the domain controller. The value of DC object GUID does not change unless Active Directory is removed from the domain controller and subsequently reinstalled. DC Invocation ID identifies the directory database on the domain controller. This value changes during the process to restore Active Directory from backup. When a domain controller is first installed, the values for these two identifiers are the same; however, each time Active Directory is restored from backup, the Invocation ID value changes.

# Repadmin Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Repadmin Examples**

**Example 1: Display the replication partners of a server**

The following example uses the **showrepl** operation of Repadmin to display the replication partners of Server1. This command is also used to find the objectGUID and InvocationID for a server for use with other operations.

No parameters are required for the **showrepl** operation. A remote connection is assumed; therefore, the server name (*DC* in the syntax) is included.

Type the following at the command prompt:

```
repadmin /showrepl server1.microsoft.com
```

Press Enter and the following output is displayed:

```
repadmin /showrepl server1.microsoft.com
Building7a\server1
DC Options : IS_GC
Site OPtions: (none)
DC object GUID : 405db077-1e28-4825-b225-c5bb9af6f50b
DC invocationID: 405db077-1e28-4825-b225-c5bb9af6f50b

==== INBOUND NEIGHBORS ======================================

CN=Schema,CN=Configuration,DC=microsoft,Dc=com
    Building7b\server2 via RPC
         objectGuid: e55c6c75-75bb-485a-a0d3-020a44c3afe7
         last attempt @ 2002-09-09 12:25.35 was successful.

CN=Configuration,DC=microsoft,Dc=com
    Building7b\server2 via RPC
          objectGuid: e55c6c75-75bb-485a-a0d3-020a44c3afe7
         last attempt @ 2002-09-09 12:25.10 was successful.

DC=microsoft,Dc=com
     Building7b\server2 via RPC
          objectGuid: e55c6c75-75bb-485a-a0d3-020a44c3afe7
          last attempt @ 2001-09-09 12:25.11 was successful.
```

**Example 2: Initiate a replication event between two replication partners**

The following example uses the **replicate** operation of Repadmin to make Server2 initiate replication of the domain directory partition for microsoft.com from Server1. In this example, Server1 is the source server and Server2 is the destination server.

The required parameters for the **replicate** operation are the name of the server that will receive changes (*DestDC* in the syntax), the name of the directory partition (*NamingContext* in the syntax), and the name of the server that will send the changes (*SrcDC* in the syntax).

Type the following at the command prompt:

```
repadmin /replicate server2.microsoft.com server1.microsoft.com dc=microsoft,dc=com
```

Press Enter and the following output is displayed:

```
server2.microsoft.com
Sync from server1.microsoft.com to server2.microsoft.com completed successfully.
```

**Example 3: Initiate a replication event for a specified directory partition with all of its replication partners**

The following example uses the **syncall** operation of Repadmin to make Server1 initiate replication of the domain directory partition for microsoft.com from all of its source replication partners in the same site and to make all of the source replication partners initiate replication for microsoft.com from all of their source replication partners in the same site, and so on.

The required parameter for the **syncall** operation is the server name (*DC* in the syntax). The name of the directory partition (*NamingContext* in the syntax) that will be synchronized is also included in this example. If this name is not included, only the configuration partition is synchronized.

Type the following at the command prompt:

```
repadmin /syncall server1.microsoft.com dc=microsoft,dc=com
```

Press Enter and the following output is displayed:

```
repadmin /syncall server1 dc=microsoft,dc=com
Syncing partition: dc=microsoft,dc=com
CALLBACK MESSAGE: The following replication is in progress:
    From: fea22f1d-a456-4f70-aa06-bedbda29e7eb._msdcs.microsoft.com
    To  : 5c02bcaf-86d9-4bed-811e-d17a5cebf8bb._msdcs.microsoft.com
CALLBACK MESSAGE: The following replication completed successfully:
    From: fea22f1d-a456-4f70-aa06-bedbda29e7eb._msdcs.microsoft.com
    To  : 5c02bcaf-86d9-4bed-811e-d17a5cebf8bb._msdcs.microsoft.com
CALLBACK MESSAGE: SyncAll Finished.
SyncAll terminated with no errors.
```

**Example 4: Display the highest Update Sequence Number on a server**

The following example uses the **showutdvec** operation of Repadmin to show the highest USNs for a specified directory partition on each replication partner. In this example, there are only two replication partners and the directory partition is the domain directory partition for the microsoft.com domain.

The only required parameter for the **showutdvec** operation is the distinguished name of the directory partition (*NamingContext* in the syntax). A remote connection is assumed so a server name (*DC_LIST* in the syntax) is also included.

Type the following at the command prompt:

```
repadmin /showutdvec . dc=microsoft,dc=com server2.microsoft.com
```

Press Enter and the following output is displayed:

```
repadmin running command /showutdvec against server localhost

Caching GUIDs.
..
Building7b\Server1    @ USN    295458 @ Time 2002-09-09 19:33:42
Building7b\Server2    @ USN    338194 @ Time 2002-09-09 19:38:16
```

**Example 5: View unreplicated changes between two servers**

The following example uses the **showchanges** operation of Repadmin to view changes that have not yet replicated between Server1 and Server2. In this example Server1 is the source server and is sending the changes while Server2 is the destination server and is receiving the changes.

This is one implementation of the **showchanges** operation. For another implementation of this operation see Example 6: Create a file to determine what changes have occurred over a period of time.

The required parameters for this version of the **showchanges** operation are the objectGuid of the directory partition on the source server (referred to as *SourceDCObjectGUID* in the syntax line) and the name of the directory partition (referred to in the syntax line as *NamingContext*). A remote connection is assumed so the destination server name (referred to in the syntax line as *DestDC*) is also included.

Type the following at the command prompt:

```
repadmin /showchanges server2.microsoft.com 5c02bcaf-86d9-4bed-811e-d17a5cebf8bb dc=microsoft,dc=com
```

Press Enter and the following output is displayed:

```
server2.microsoft.com
```

```
Building starting position from destination server rktlabdc2.rktlabdom.com

==== SOURCE DC: 5c02bcaf-86d9-4bed-811e-d17a5cebf8bb._msdcs.microsoft.com ====

No Changes
```

**Example 6: Create a file to determine what changes have occurred over a period of time**

The following example uses the **showchanges** operation of Repadmin to create a file that records replication changes. By running the **showchanges** operation later you can compare the file created earlier to the current replication state.

This is one implementation of the **showchanges** operation. For another implementation of this operation see Example 5: View unreplicated changes between two servers.

The only required parameter for this version of the **showchanges** operation is the name of the directory partition (*NamingContext* in the syntax) on which the check should be performed. In this example, the check is performed remotely so the server name (*SourceDC* in the syntax) is included as well as the **/cookie:** parameter, along with the name of the file to be created.

Type the following at the command prompt:

```
repadmin /showchanges dc=microsoft,dc=com server2.microsoft.com /cookie:microsoft.txt
```

Press Enter and the following output is displayed:

```
pDcList->szSp.. server2
Using cookie from file test.txt (132 bytes)

==== SOURCE DC: server2 ====

    1> dnsRecord: <32 byte blob>
New cookie written to file microsoft.txt (132 bytes)
```

**Example 7: Display the connection objects for a server**

The following example uses the **showconn** operation of Repadmin to show connection objects for a server.

No parameters are required for **showconn** operation. In this example, a remote connection is assumed so the server name (*DC_LIST* in the syntax) is specified. All connection objects for Server2 are shown.

Type the following at the command prompt:

```
repadmin /showconn server2.microsoft.com
```

Press Enter and the following output is displayed:

```
repadmin running command /showconn against server server2.microsoft.com

```

**Example 8: Display the replication signature for a server**

The following example uses the **showsig** operation of Repadmin to show the replication signature for a server.

No parameters are required for the **showsig** operation. In this example, a remote connection is assumed so the server name (*DC_LIST* in the syntax) is specified.

Type the following at the command prompt:

```
repadmin /showsig server1.microsoft.com
```

Press Enter and the following output is displayed:

```
server1.microsoft.com
Building7a\server1

Current DC invocationID: 415db077-1e28-4588-b255-c5bb9af6f50b (current)

No retired signatures.
```

**Example 9: Display the context handles for the replication process**
The following example uses the **showctx** operation of Repadmin to show the open connections to the server that are established by remote servers.

No parameters are required for the **showctx** operation. This example specifies the server name (*DC_LIST* in the syntax) on which the check should be performed.

Type the following at the command prompt:

```
repadmin /showctx server2.microsoft.com
```

Press Enter and the following output is displayed:

```
server1.microsoft.com
Caching GUIDs.
..
3 open context handles.

NTDSAPI client @ 10.193.36.209 (PID 1528) (Handle 0x20b8a38)
    bound, refs=1, last used 2002-09-09 14:21:41

Building7a\Server1 @ 10.193.36.210 (PID 460) (Handle 0x20b8c40)
    bound, refs=1, last used 2002-09-09 14:23:22

NTDSAPI client @ 10.193.36.210 (PID 2976) (Handle 0x20bb960)
    bound, refs=2, last used 2002-09-09 14:23:28
```

**Example 10: Showing the replication status of a forest using replsummary and wildcard characters.**
The following example uses the **replsummary** operation and a wildcard character to show a summary of the replication status for all the domain controllers in the forest with a name beginning with 'FOURTH'.

Type the following at the command prompt:

```
repadmin /replsummary FOURTH*
```

Press Enter and the following output is displayed:

```
repadmin /replsummary FOURTH*
Replication Summary Start Time: 2002-09-18 14:54:49

Beginning data collection for replication summary, this may take awhile:

Source DC           largest delta  fails/total  %%  error
 FOURTH-CLT-DC-01             54m:57s    0 /   9    0

 FOURTH-DC-26                  08m:16s    0 / 108    0
 FOURTH-DC-30                  55m:13s    0 /  47    0
 FOURTH-DC-31                  41m:23s    0 /  56    0
 FOURTH-SVC-DC-40              57m:02s    0 /   9    0
 FOURTH-TK-DC-27               07m:02s    0 /  54    0
 FOURTH-TK-DC-28               08m:01s    1 / 161    0  (8461) The replication operation
was preempted.
 FOURTH-TK-DC-29               55m:10s    0 / 115    0

Experienced the following operational errors trying to retrieve replication
information:
          58 - fourth-dc-08.fourthcoffee.com
```

**Example 11: Showing the attributes of a specific object.**
The following example uses the **showattr** operation to show the attributes of a specific object in the Active Directory.

Type the following at the command prompt:

```
repadmin /showattr fsmo_dnm: ncobj:config: /subtree /filter:(objectClass=crossRef)
/atts:nCName,dnsRoot,net,dnsRoot,net,biosname,systemFlags /homeserver:FOURTH-DC-26
```

Press Enter and the following output is displayed:

```
repadmin running command /showattr against server aseanl-test2.fourthcoffee.com

DN: CN=Enterprise Configuration,CN=Partitions,CN=Configuration,DC=fourthcoffee,DC=com
    1> nCName: CN=Configuration,DC=fourthcoffee,DC=com

# Repadmin Syntax

Updated: October 17, 2012

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### Repadmin.exe Syntax

Repadmin uses the following general syntax:

**repadmin** *Operation Parameters* [**/rpc**] [**/ldap**][**/u:***Domain**User*] [**/pw:**{*Password* | *****}]

**/rpc**
This parameter forces Repadmin to use an RPC session for network communications.

**/ldap**
This parameter forces Repadmin to use an LDAP session for network communications if posable. If the LDAP connection fails then Repadmin attempts to connect using an RPC session. This is the default behavior for Repadmin.

**/u**
Specifies the user name that has permissions to perform operations in Active Directory.

**/pw**
Specifies the password for the user name entered with the **/u** parameter.

#### The DC_LIST Parameter

This section explains the syntax of the semi-global *dc_list* parameter

{*dc_name***|** * |*partial_server_name**| **site:***site_name* **|gc: |fsmo**_*type*:[*name*]}

***dc_name***
Specifies the host name of a domain controller.

*****
Standard wildcard character. When this is used it returns all domain controllers in the enterprise. Improper use can cause a significant increase in network traffic.

***partial_server_name****
Partial wildcard character matching. For example, if given the partial domain controller name "woodgrovebank*", the wildcard character would return woodgrovebank-dc1 and woodgrovebank-dc2, but not woodgrove-diff-name.

**site: *site_name***
The **site:** parameter takes the name of an Active Directory site (*site_name*), and returns all domain controllers in that site.

**gc:**
Queries all Global Catalog Servers in the enterprise.

**fsmo_ *type*:[*name*]**
Specifies a group of domain controllers to query by operations master (also know as flexible single master operations or FSMO) type. Valid operations master types follow.

| Operations Master Type | Description |
|---|---|
| **fsmo_pdc**:[*name*] | Runs the repadmin.exe command against the PDC Emulator. The *name* parameter takes a naming context. |
| **fsmo_rid**:[*name*] | Runs the repadmin.exe command against the RID operations master. The *name* parameter takes a naming context. |
| **fsmo_im**:[*name*] | Runs the repadmin.exe command against the IM operations master. The *name* parameter takes a naming context. |
| **fsmo_istg**:[*name*] | Runs the repadmin.exe command against the ISTG operations master. The *name* parameter takes a site DN. |

| | |
|---|---|
| **fsmo_dnm**: | Runs the repadmin.exe command against the DNM operations master. |
| **fsmo_schema**: | Runs the repadmin.exe command against the Schema operations master. |

**Operations**

Repadmin bind

Repadmin bridgeheads

Repadmin checkprop

Repadmin dsaguid

Repadmin failcache

Repadmin istg

Repadmin kcc

Repadmin latency

Repadmin notifyopt

Repadmin options

Repadmin queue

Repadmin querysites

Repadmin regkey

Repadmin removelingeringobjects

Repadmin replicate

Repadmin replsingleobj

Repadmin replsummary

Repadmin showattr

Repadmin showcert

Repadmin showchanges

Repadmin showconn

Repadmin showctx

Repadmin showism

Repadmin showmsg

Repadmin showncsig

Repadmin showobjmeta

Repadmin showoutcalls

Repadmin showproxy

Repadmin showrepl

Repadmin showsig

Repadmin showtime

Repadmin showtrust

Repadmin showutdvec

Repadmin showvalue

Repadmin siteoptions

Repadmin syncall

Repadmin viewlist

Repadmin oldhelp

**Repadmin bind**
Connects to, and displays the replication features for, a directory partition on a domain controller.

**repadmin /bind** [*DC_LIST*]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

**Repadmin bridgeheads**
Lists the bridgehead servers for a specified site.

**repadmin /bridgeheads** [*DC_LIST*] [**/verbose**]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

**/verbose**
Lists detailed information.

**Repadmin checkprop**
Compares properties of specified domain controllers to determine if they are up-to-date with each other. The source domain controller contains the original information that needs to be checked. The destination domain controller data is compared to the source domain controller data.

**repadmin /checkprop** [*DC_LIST*] *NamingContext OriginatingDCInvocationID OriginatingUSN*

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

***NamingContext***
Specifies the distinguished name of the directory partition on the source domain controller.

***OriginatingDCInvocationID***
Specifies the unique hexadecimal number that identifies an object on a source domain controller. The InvocationID can be retrieved by using the **showrepl** operation.

***OriginatingUSN***
Specifies the USN for the object on the source domain controller. The USN is for the object whose InvocationID is already listed.

**Repadmin dsaguid**
Returns a server name when given a GUID.

**repadmin /dsaguid** [*DC_LIST*] [*GUID*]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

***GUID***
Specifies the unique hexadecimal number that identifies the domain controller. The GUID can be retrieved by using the **showrepl** operation.

**Repadmin failcache**
Displays a list of failed replication events detected by the Knowledge Consistency Checker (KCC).

**repadmin /failcache** [*DC_LIST*]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space. See above for detailed syntax.

**Repadmin istg**
Returns the server name of the ISTG server for a specified site.

**repadmin /istg** [*DC_LIST*] [**/verbose**]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

**/verbose**
Lists detailed information.

**Repadmin kcc**
Forces the KCC to recalculate replication topology for a specified domain controller. By default this recalculation occurs every 15 minutes.

**repadmin /kcc** [*DC_LIST*] [**/async**]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space. See above for detailed syntax.

**/async**
Specifies that replication will be asynchronous. This means that Repadmin starts the replication event, but it does not expect an immediate response from the destination domain controller. Use this parameter to start **kcc** and not wait for it to finish.

**Repadmin latency**
Displays the amount of time between replications using the ISTG Keep Alive timestamp.

**Notes**

- These time stamps are not used in Windows Server 2003 Native Mode, and results are inaccurate.
- In Windows Server 2003 Native Mode, the **repadmin /showutdvec /latency** is used in place of the operation.

**repadmin /latency** [*DC_LIST*] [**/verbose**]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

**/verbose**
Lists detailed information.

**Repadmin notifyopt**
Displays and sets the notification timing settings for replication of a specified directory partition.

**repadmin /notifyopt** [*DC_LIST*] *NamingContext* [**/first:***Value*] [**/subs:***Value*]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

***NamingContext***
Specifies the distinguished name of the directory partition on the source domain controller.

***first***
The number of seconds after a change is made before the domain controller notifies its first replication partner that there is a change.

***subs***
Once the first replication partner is notified of a change, the **subs** parameter specifies the number of seconds to wait before notifying the next replication partner.

**Repadmin options**
Changes default Knowledge Consistency Checker (KCC) behavior on the NTDS Settings object of a domain controller.

Syntax for **/options** is available by typing:

**repadmin /experthelp**

| **Important** |
| --- |
| Setting these options might impair or disable the ability of the KCC to calculate the topology automatically. These options are intended for use by advanced administrators for special situations. If you set these options, document the settings carefully to ensure that the KCC functions as expected and can be restored to default functionality if necessary. |

**repadmin /options** [*DC*] [{+|-}IS_GC] [{+|-}DISABLE_INBOUND_REPL]

[{+|-}DISABLE_OUTBOUND_REPL] [{+|-}DISABLE_NTDSCONN_XLATE]

**Parameters**
***DC***
Specifies the host name of the domain controller on which to set the NTDS Settings options.

**{+|-}IS_GC**
Adds or removes the global catalog.

**{+|-}DISABLE_INBOUND_REPL**
Stops (+) or restarts (-) inbound replication.

**{+|-}DISABLE_OUTBOUND_REPL**
Stops (+) or restarts (-) outbound replication.

**{+|-}DISABLE_NTDSCONN_XLATE**
Prevents connections from forming replication partnerships.

**Repadmin queue**
Displays tasks waiting in the replication queue.

**repadmin /queue** [*DC_LIST*]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller, or a list of domain controllers separated by a space. See above for detailed syntax.

**Repadmin querysites**
Uses routing information to determine cost of a route from a specified site to another specified site or sites.

**repadmin /querysites** *FromSiteRDN ToSite1RDN* [*ToSite2RDN*...

**Parameters**
**Note**

- The Relative Distinguished Names (RDNs) used in this command are case-sensitive.

***FromSiteRDN***
Specifies the RDN of the site from which the cost is calculated.

***ToSiteRDN***

Specifies the RDN of the site to which the cost is calculated.

**Note**

- The **querysites** parameter does not allow the use of alternate credentials.

**Repadmin regkey**

Changes the value of an entry in a registry key. This command is available only in the version of Repadmin that is included with Windows Support Tools in Windows Server 2003 Service Pack 1 (SP1). This command can be applied only on domain controllers running Windows Server 2003 with SP1.

**repadmin /regkey** [*DC_LIST*]{**+**|**-**}*value*]

**Parameters**

***DC_LIST***

Specifies the host name of a domain controller, a list of domain controllers separated by a space, or * for all domain controllers in the forest. See above for detailed syntax.

**{+|-}*value*]**

Specifies enabling (+) or disabling (-) the registry entry specified in *value*. The following table describes the value that can be applied on domain controllers running Windows Server 2003 with SP1.

| Value | Description |
|---|---|
| **strict** | The **Strict Replication Consistency** entry in **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters** |

**Repadmin removelingeringobjects**

Uses an authoritative domain controller to compare the directory of a domain controller (destination) that is suspected of having lingering objects against the directory of a domain controller (source) that is designated as a reference source for up-to-date values for the domain of the destination. When the advisory mode parameter is used, this command provides a list of found lingering objects. When the advisory mode parameter is not used, this command removes lingering objects from the destination domain controller.

Syntax for **/removelingeringobjects** is available by typing:

**repadmin /experthelp**

| **Important** |
|---|
| To use the **repadmin /removelingeringobjects** command, both source and destination domain controllers must be running Windows Server 2003. |

**repadmin /removelingeringobjects** *Destination_DC_List SourceDCGUID NamingContextDN* **/advisory_mode**

**Parameters**

| **Note** |
|---|
| "Destination" in the context of this syntax does not indicate a destination replication partner, but rather a source replication partner that is suspected of having lingering objects. The term "destination" identifies the server as the focus of the lingering object removal process. |

***Destination_DC_List***

Specifies the host name of a destination domain controller, a list of domain controllers separated by a space, or * for all domain controllers in the enterprise. See above for detailed syntax.

***SourceDCGUID***

Specifies the GUID of the source (reference) domain controller that will be used to identify objects that are outdated (lingering) on the destination. Obtain the GUID by running **repadmin /showrepl** against the source domain controller that you are using as the reference server.

***NamingContextDN***

Specifies the distinguished name of the directory partition from which the lingering objects are to be removed.

**advisory_mode**
Prints a list of objects that are found in the directory of the destination domain controller that are not found in the directory of the source domain controller. Objects are not removed if this parameter is used.

#### Repadmin replicate

Starts a replication event for the specified directory partition between the source and destination domain controllers. The source UUID can be determined when viewing the replication partners by using the Repadmin showrepl operation.

**Syntax 1**

- **repadmin /replicate** *Destination_DC_LIST Source_DC_NAME* [**/force**] [**/async**] [**/full**] [**/addref**]

**Syntax 2**

- **repadmin /replicate** *Destination_DC_LIST* [**/force**] [**/async**] [**/full**] [**/addref**] [**/allsources**]

**Parameters**

***Destination_DC_LIST***
Specifies the host name of the destination domain controller (Directory Server Agent) with which you want to replicate. See above for detailed syntax on the *DC_LIST* parameter. This parameter cannot be used with **/allsource**.

***Source_DC_NAME***
Specifies the host name of the source domain controller with which you want to replicate. This parameter accepts a GUID, GUID-based DNS name, or the name of a server object.

**/force**
This parameter is used to override the Disable Replication option on a server.

**/async**
Specifies that the replication will be asynchronous. This means that Repadmin starts the replication event, but it does not expect an immediate response from the destination domain controller. Use this parameter when there are slow links between domain controllers.

**/full**
Forces a full replication of all objects from the destination domain controller.

**/addref**
Directs the source to check for a notification entry on the source. If the source does not have a notification entry for this destination, one is added.

**/allsources**
A given destination can have multiple sources for the same naming context. Directs the destination to sync with all sources instead of just one. This parameter cannot be used with *Destination_DC_LIST*

**/readonly**
This parameter is ignored by the **/replicate** operation.

#### Repadmin replsingleobj

Replicates a single object between any two domain controllers that have partitions in common. The two domain controllers do not have a replication agreement. Replication agreements can be shown by using the Repadmin **/showrepl** command.

- **repadmin /replsingleobject** [*DC_LIST*] *DsaSourceGUID ObjectDN*

**Parameters**

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***DsaSourceGUID***
Specifies the unique hexadecimal number that identifies the object that will be replicated. The objectGUID can be retrieved by using the **showrepl** operation.

***ObjectDN***
Specifies the distinguished name of the object.

#### Repadmin replsummary

The **replsummary** operation quickly and concisely summarizes the replication state and relative health of a forest.

**repadmin /replsummary** [*DC_LIST*] [**/bysrc**] [**/bydest**] [**/errorsonly**] [**/sort**:{*delta* | *partners* | *failures* | *error* | *percent*}]

**Parameters**

***DC_LIST***

Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

**/bysrc**

This parameter shows the output of the **repadmin.exe/replsummary** command, from the perspective of the replication source, in the form of a table. This means that a given source server is "pulled on" by multiple client computers. The table is sorted in order of the source computers that are having the most problems, across all the clients in the forest. This parameter does not display the destination domain controller.

**/bydest**

This parameter shows the output of the **repadmin.exe/replsummary** command, from the perspective of the replication destination, in the form of a table. This means that the "client" is pulling the changes from a replication source or "server", and the table shows the inbound systems, and what problems they are having with their partners. The table is sorted in the order of the inbound systems that are having the most problem with inbound replication, across all the possible partners in the forest. This parameter does not display the source domain controller.

**/errorsonly**

Shows only the domain controllers where the partner error is non-zero.

**/sort:{*delta*| *partners*| *failures*| *error*| *percent*}**

Sorts the **replsummary** table by the specified column heading.

**Notes**

- The **/bysrc** and **/bydest** parameters may be specified at the same time. If this is done, then Repadmin displays the **/bysrc** table first and the **/bydest** table next.
- If the parameters **/bysrc** and **/bydest** are both absent, Repadmin picks the best one, and displays the one with the least number of partner errors.

**Repadmin showattr**

The **/showattr** operation displays the attributes of an object.

**repadmin /showattr** *DC_LIST* [*OBJ_LIST*] [*OBJ_LIST_OPTIONS*] [**/atts:***attribute,attribute,...*] [**/allvalues**] [**/long**] [**/nolongblob**] [**/nolongblob**] [**/nolongfriendly**] [**/dumpallblob**]

**Parameters**

***DC_LIST***

Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax. This is a required parameter.

***OBJ_LIST***

This parameter takes a DN or a special keyword that expands into a DN. The keywords are:

- **Ncobj:config:**
- **Ncobj:schema:**
- **Ncobj:domain:** This key word is the domain partition DN of the home server.
- **Dsaobj:** This keyword is the NTDS settings object of the home server.

***OBJ_LIST_OPTIONS***

The OBJ_LIST_OPTION parameter is required to perform a generic LDAP search from the command line. The parameter requires a Base DN, with the ability to use a search modifier option. The valid search modifier options are as follow:

- **/filter:**<ldap_filter>

- **/base**
- **/subtree**
- **/onelevel**

See the LDAP documentation for the LDAP filter syntax.

**/atts:<*attributes,attributes,...***
Returns only the attributes specified. Separate each listed attribute with a comma.

**/allvalues**
For an attribute, the tool only displays 20 values unless this flag is specified, in which case it shows all values.

**/long**
Displays one value per line.

**/nolongblob**
This parameter is ignored by the **/showattr** operation.

**/nolongfriendly**
This parameter is ignored by the **/showattr** operation.

**/friendlyblob[:*attributeattribute...*]**
If any attributes are specified, only those attributes named are displayed in friendly format. Otherwise all known blobs are formatted.

**/nolongfriendly**
Does not format blobs.

**/dumpallblob**
Dumps the blob in a default byte-by-byte format if there is not a friendly formatted interpretation available for it.

**/nodumpallblob**
Does not show the blob if there is not a formatted interpretation available.

**Note**

- A blob in this context means an attribute that is not a simple type, like a string or an integer. A blob is a complex structured type that is stored as binary bytes. In order to make sense of the blob, a program must interpret it and format it. A friendly blob is a blob that the program knows about and can format in an understandable way. The program has a list of blobs that it understands.

#### Repadmin showcert

Displays the server certificates loaded on a specified domain controller.

**repadmin /showcert** *DC_LIST*

#### Parameters

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax. This is a required parameter.

#### Repadmin showchanges

Displays changes from a specified directory partition or changes to a specified object. Syntax 1 saves changes to a directory partition. If this information is saved to a file the **getchanges** operation can be run again for comparison. Syntax 2 lists changes to a specified object.

#### Syntax

**repadmin/showchanges** *SourceDC NamingContext* [**/cookie:***File*] [**/atts:***attribute,attribute,...*]

#### Syntax

**repadmin /showchanges** *DestDC SourceDCObjectGUID NamingContext* [**/verbose**] [**/statistics**] [**/noincremental**]

[**/objectsecurity**] [**/ancestors**] [**/atts:** *attribute1,attribute2,...*] [**/filter:** *ldap filter*]

**Parameters**

***DestDC***
Specifies the host name of the destination domain controller from which to enumerate the host domain controllers.

***SourceDC***
Specifies the host name of the domain controller that hosts the directory partition whose changes you want to view.

***NamingContext***
Specifies the distinguished name of the directory partition.

**/cookie:** ***File***
Specifies a name for the file to which list changes are saved.

**/atts:** ***attribute1attributes...***
Returns only the attributes specified. Separate each listed attribute with a comma.

***SourceDCObjectGUID***
Specifies the unique hexadecimal number that identifies the object whose changes will be listed. The objectGUID can be retrieved by using the **showrepl** operation.

**/verbose**
Lists detailed information.

**/statistics**
Displays a summary of information about changes instead of a list of individual changes.

**/noincremental**
Returns changes in value change format, which lists current values for attributes as well what attributes have been added or deleted. If not specified, changes are returned in attribute change format, which shows only the current value of the attribute.

**/objectsecurity**
Overrides the need for the Get Changes right to the directory partition. By default this right is needed to run the *GetChanges* parameter. However, only changes that the currently logged on user has the rights to view are displayed.

**/ancestors**
Returns changes in USN order.

**/filter:** ***ldap filter***
Returns only those changes that meet the filter requirements.

**Note**

- The information from Syntax 1 can be saved to a file for later comparison.

**Repadmin showconn**

Displays the connection objects for a specified domain controller. Default is local site.

**repadmin /showconn** [*DC_LIST*] [*ServerRDN* | *ContainerDN* | *DC_GUID*] [**/From:***ServerRDN*] [**/intersite**]

**Parameters**

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***ServerRDN***
Specifies the RDN of a server.

***ContainerDN***
Specifies the distinguished name of a container.

***DC_GUID***
Specifies the unique hexadecimal number that identifies the domain controller. The GUID can be retrieved by using the **showrepl** operation.

**/From:** ***ServerRDN***

Displays only the connection objects that exist to the specified server. By default all connection objects are displayed.

**/intersite**
Displays only those connection objects that are between sites.

#### Repadmin showctx

Displays a list of computers that have opened sessions with a specified domain controller.

**repadmin /showctx** [*DC_LIST*] [**/nocache**]

**Parameters**

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

**/nocache**
Specifies that GUIDs are left in hexadecimal form. By default, GUIDs are translated into strings.

#### Repadmin showism

Displays intersite messaging routes calculated by the Intersite Messaging Service. This operation cannot be executed remotely.

**repadmin /showism** [*TransportDN*] [**/verbose**]

**Parameters**

***TransportDN***
Specifies whether the mail server is using SMTP or RPC to send messages.

**/verbose**
Lists detailed information.

**Note**

- The **repadmin.exe/showism** cannot be executed against a remote server.

#### Repadmin showmsg

Displays the error message for a given error number.

**repadmin /showmsg** {*Win32Error* | *DSEventID* **/NTDSMSG**}

**Parameters**

***Win32Error***
Returns a short description of the given Win32 error code.

***DSEventID* /NTDSMSG**
Returns the actual event log text for the specified event ID.

#### Repadmin showncsig

Each domain controller has a naming context signature list. **repadmin.exe/showncsig** displays a list of the removed application partition GUIDs. An application partition can be configured to be held or not held on a particular domain controller using **ntdsutil**.

**repadmin /showncsig** [*DC_LIST*]

**Parameters**

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

#### Repadmin showobjmeta

Displays the replication metadata for a specified object stored in Active Directory, such as attribute ID, version number, originating and local Update Sequence Number (USN), and originating server's GUID and Date and Time stamp. By comparing the replication metadata for the same object on different domain controllers, an administrator can determine whether replication has taken place.

**repadmin /showobjmeta** [*DC_LIST*] *ObjectDN* [**/nocache**] [**/linked**]

**Parameters**

***DC_LIST***

Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***ObjectDN***
Specifies the distinguished name of the object.

**/nocache**
Specifies that GUIDs are left in hexadecimal form. By default, GUIDs are translated into strings.

**/linked**
Displays metadata associated with, but not stored with, the specified object.

#### Repadmin showoutcalls

Displays calls that have not yet been answered, made by the specified server to other servers.

▸ **repadmin /showoutcalls** [*DC_LIST*]

#### Parameters

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

#### Repadmin showproxy

Lists cross domain move proxy objects. When an object is moved to another domain, a marker is left in the old domain indicating that the object used to be there. This is called the proxy.

#### Syntax

▸ **repadmin /showproxy** [*DC_LIST*] [*NamingContext*] [**matchstring**]

#### Syntax

▸ **repadmin /showproxy** [*DC_LIST*] [*ObjectDN*] [**matchstring**] **/movedobject**

#### Parameters

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***NamingContext***
Specifies the distinguished name of the directory partition on the source domain controller.

***ObjectDN***
Specifies the distinguished name of the object.

**matchstring**
Specifies a filter for the output. Type a string of characters that must be present in the distinguished name in order to display the object.

***movedobject***
Displays a history of information from the original domain on a moved object after it has reached the new domain.

#### Repadmin showrepl

Displays the replication partners for each directory partition on the specified domain controller. Helps the administrator build a visual representation of the replication topology and see the role of each domain controller in the replication process.

▸ **repadmin /showrepl** [*DC_LIST*] [*SourceDCObjectGUID*] [*NamingContext*] [**/verbose**] [**/nocache**] [**/repsto**] [**/conn**] [**/csv**] [**/all**] [**/errorsonly**] [**/intersite**]

#### Parameters

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***SourceDCObjectGUID***
Specifies the unique hexadecimal number that identifies the object whose replication events will be listed.

***NamingContext***
Specifies the distinguished name of the directory partition.

**/verbose**
Lists detailed information.

**/nocache**
Specifies that GUIDs are left in hexadecimal form. By default, GUIDs are translated into strings.

**/repsto**
Lists the domain controllers that pull replication information from the specified directory partition. To see the outbound neighbors, specify **/repsto** or **/all**.

**/conn**
Displays the connection objects associated with each link.

**/csv**
Displays the output of the **repadmin showrepl** operation in a Comma Separated Variable (CSV) format for viewing and analysis in Microsoft Excel. Repadmin supports redirection of screen output to a file.

**/all**
Displays all replication partners.

**/errorsonly**
Only shows the partnership if it has an error associated with it.

**/intersite**
Only shows this partnership if the source server is in a different site than our own.

#### Repadmin showsig

Displays the retired invocation IDs on a domain controller. A domain controller changes its invocation ID on being restored or when re-hosting an application partition.

**repadmin /showsig** [*DC_LIST*]

#### Parameters

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

#### Repadmin showtime

Converts a directory service time value to string format for both the local and the UTC time zones.

**repadmin /showtime** [*DSTimeValue*]

#### Parameters

***DSTimeValue***
Specifies the time value that needs to be converted.

### Note

- With parameters omitted, **repadmin /showtime** displays the current system time in both the directory service format and string format.

#### Repadmin showtrust

Lists all domains trusted by a specified domain.

**repadmin /showtrust** [*DC_LIST*]

#### Parameters

***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

#### Repadmin showutdvec

Displays the highest Update Sequence Number (USN) for the specified domain controller. This information shows how up-to-date a replica is with its replication partners.

**repadmin /showutdvec** *DC_LIST NamingContext* [**/nocache**] [**/latency**]

**Parameters**

***DC_LIST***

Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***NamingContext***

Specifies the distinguished name of the directory partition.

**/nocache**

Specifies that GUIDs are left in hexadecimal form. By default GUIDs are translated into strings.

**/latency**

Sorts the information by the time required to complete the replication. By default the information is sorted by USN.

**Repadmin showvalue**

Displays the values of the type, last modified time, originating DC, and distinguished name of a specified object.

**repadmin /showvalue** [*DC_LIST*] *ObjectDN* [*AttributeName*] [*ValueDN*] [**/nocache**]

**Parameters**

***DC_LIST***

Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***ObjectDN***

Specifies the distinguished name of the object.

***AttributeName***

Specifies a single attribute whose value you want to display.

***ValueDN***

Specifies the distinguished name of the attribute that is displayed.

**/nocache**

Specifies that GUIDs are left in hexadecimal form. By default, GUIDs are translated into strings.

**Repadmin siteoptions**

Changes default Knowledge Consistency Checker (KCC) behavior in a site.

Syntax for **/siteoptions** is available by typing:

**repadmin /experthelp**

| **Important** |
| --- |
| Setting these options might impair or disable the ability of the KCC to calculate the topology automatically. These options are intended for use by advanced administrators for special situations. If you set these options, document the settings carefully to ensure that the KCC functions as expected and can be restored to default functionality if necessary. |

**repadmin /siteoptions** [*DC*] [**/site:***SiteName*]

[{+|-}IS_AUTO_TOPOLOGY_DISABLED]

[{+|-}IS_TOPL_CLEANUP_DISABLED] [{+|-}IS_TOPL_MIN_HOPS_DISABLED]

[{+|-}IS_TOPL_DETECT_STALE_DISABLED]

[{+|-}IS_INTER_SITE_AUTO_TOPOLOGY_DISABLED]

[{+|-}IS_GROUP_CACHING_ENABLED] [{+|-}FORCE_KCC_WHISTLER_BEHAVIOR] [{+|-}FORCE_KCC_W2K_ELECTION] [{+|-}IS_RAND_BH_SELECTION_DISABLED]

[{+|-}IS_SCHEDULE_HASHING_ENABLED]

[{+|-}IS_REDUNDANT_SERVER_TOPOLOGY_ENABLED]

{+|-}W2K3_IGNORE_SCHEDULES {+|-}W2K3_BRIDGES_REQUIRED

**Parameters**

***DC***

Specifies the host name of the domain controller on which to set the site options.

***SiteName***

The site that the option setting affects.

**{+|-}IS_AUTO_TOPOLOGY_DISABLED**

When enabled, prevents the KCC from generating intrasite connections on all servers in the site. Disable this option if you use manual connections and do not want the KCC to build connections automatically.

**{+|-}IS_TOPL_CLEANUP_DISABLED**

When enabled, prevents the KCC from removing connection objects that it does not need. Disable this option if you want to take responsibility for removing old redundant connections. Alternatively, to control or augment the topology, you can use manual connections, which the KCC does not delete.

**{+|-}IS_TOPL_MIN_HOPS_DISABLED**

When enabled, prevents the KCC from generating optimizing connections in the ring topology of intrasite replication. Optimizing connections reduce the replication latency in the site and disabling them is not recommended.

**{+|-}IS_TOPL_DETECT_STALE_DISABLED**

Prevents the KCC from excluding servers that are unreachable from the topology; that is, the KCC does use an alternate server to reroute replication. Use this option only if network communication is very unstable and brief outages are expected.

**{+|-}IS_INTER_SITE_AUTO_TOPOLOGY_DISABLED**

Prevents the KCC that functions as the intersite topology generator (ISTG) from generating connections for intersite replication. Use this option when you want to create manual intersite connections (disable the ISTG) but retain the KCC to generate intrasite connections.

**{+|-}IS_GROUP_CACHING_ENABLED**

Disables Universal Group Membership Caching in the site.

**{+|-}FORCE_KCC_WHISTLER_BEHAVIOR**

Implements KCC operation that is consistent with Windows Server 2003 forest functional level. This option can be set if all domain controllers in the site are running Windows Server 2003.

**{+|-}FORCE_KCC_W2K_ELECTION**

Off by default. When enabled, implements the Windows 2000 Server method of ISTG selection.

**{+|-}IS_RAND_BH_SELECTION_DISABLED**

Implements the Windows 2000 Server method of selecting a single bridgehead server per directory partition and transport.

**{+|-}IS_SCHEDULE_HASHING_ENABLED**

Spreads replication start times randomly across the entire schedule interval rather than just the first quarter of the interval.

**{+|-}IS_REDUNDANT_SERVER_TOPOLOGY_ENABLED**

Creates redundant connections between sites before a failure takes place. When enabled, disables KCC failover. Requires that automatic detection of failed connections also be disabled (+IS_TOPL_DETECT_STALE_DISABLED).

**{+|-}W2K3_IGNORE_SCHEDULES**

When the forest functional level Windows Server 2003 or Windows Server 2003 interim is in effect, provides KCC control of the ability to ignore schedules (replication occurs at the designated intervals and is always available).

**{+|-}W2K3_BRIDGES_REQUIRED**

When the forest functional level Windows Server 2003 or Windows Server 2003 interim is in effect, provides KCC control of the ability to enable or disable site link bridging.

For more information about using site options, see Planning Chapter 3, "Planning the Physical Structure for a Branch Office Deployment" in the Windows Server 2003 Active Directory Branch Office Guide on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=28523).

**Repadmin syncall**

Synchronizes a specified domain controller with all replication partners.

▸ **repadmin /syncall** *DC* [*NamingContext*] [*Flags*]

**Parameters**

***DC***
Specifies the host name of the domain controller to synchronize with all replication partners.

***NamingContext***
Specifies the distinguished name of the directory partition.

***Flags***
Performs specific actions during the replication.

| Flag | Description |
|---|---|
| **/a** | Abort if any server is unavailable. |
| **/A** | Sync all naming contexts that are held on the home server. |
| **/d** | Identify servers by distinguished name in messages. |
| **/e** | Enterprise, cross sites. |
| **/h** | Print this help screen. |
| **/i** | Iterate indefinitely. |
| **/l** | Perform showrepl on each server pair in path instead of syncing. |
| **/j** | Synchronize adjacent servers only. |
| **/p** | Pause for possible user abort after every message. |
| **/P** | Push changes outward from home server. |
| **/q** | Run in quiet mode, suppress call back messages. |
| **/Q** | Run in very quiet mode, report fatal errors only. |
| **/s** | Do not synchronize. |
| **/S** | Skip initial server response check. |

**Repadmin viewlist**
Displays a list of domain controllers.

**repadmin /viewlist** [*DC_LIST*] [*OBJ_LIST*]

**Parameters**
***DC_LIST***
Specifies the host name of a domain controller or a list of domain controllers separated by a space that the object will be replicated to. See above for detailed syntax.

***OBJ_LIST***
this parameter takes a DN or a special keyword that expands into a DN. The keywords are:

- **Ncobj:config:**
- **Ncobj:schema:**
- **Ncobj:domain:**, This key word is the domain partition DN of the home server.
- **Dsaobj:**, This keyword is the NTDS settings object of the home server

**Repadmin oldhelp**
This displays a list of the operations that have been deprecated in this version of Repadmin.

# Replmon Overview

Updated: April 18, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Replmon graphical user interface (GUI) tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

The Replmon graphical user interface tool was removed from Windows Server 2008 and later. Repadmin is still available for troubleshooting replication. For more information on using Repadmin, see Monitoring and Troubleshooting Active Directory Replication Using Repadmin and Getting Over Replmon.

**Replmon.exe: Active Directory Replication Monitor**
This GUI tool enables administrators to view the low-level status of Active Directory replication, force synchronization between domain controllers, view the topology in a graphical format, and monitor the status and performance of domain controller replication.

You can use ReplMon to do the following:

- See when a replication partner fails.
- View the history of successful and failed replication changes for troubleshooting purposes.
- View the properties of directory replication partners.
- Create your own applications or scripts written in Microsoft Visual Basic Scripting Edition (VBScript) to extract specific data from Active Directory.
- View a snapshot of the performance counters on the computer, and the registry configuration of the server.
- Generate status reports that include direct and transitive replication partners, and detail a record of changes.
- Find all direct and transitive replication partners on the network.
- Display replication topology.
- Poll replication partners and generate individual histories of successful and failed replication events.
- Force replication.
- Trigger the Knowledge Consistency Checker (KCC) to recalculate the replication topology.
- Display changes that have not yet replicated from a given replication partner.
- Display a list of the trust relationships maintained by the domain controller being monitored.
- Display the metadata of an Active Directory object's attributes.
- Monitor replication status of domain controllers from multiple forests.

**Corresponding UI**
ReplMon provides its own user interface. See Replmon UI for more information.

**Concepts**

For more information about deploying and using Active Directory, see the Active Directory Overview Web site.

**System Requirements**
The following are the system requirements for ReplMon:

- ReplMon must be installed on a computer running Windows Server 2003. The computer can be a domain controller, member server, member workstation, or standalone computer.

**Files Required**

- Comctl32.ocx
- Comdlg32.ocx
- Ctl3d32.dll
- Iadstools.dll — component DLL that hosts the functions used by ReplMon
- Replmon.exe
- Tabctl32.ocx

### For More Information

Installing ReplMon in a directory other than the default might result in errors. For more information, see "Intalling Replmon" in Replmon Remarks. For information about the IADsTools, see IADsTools Documentation (iadstools.doc) in the Program Files\Support Tools directory.

### Note

- You need Microsoft Word or a compatible viewer to view Iadstools.doc. You can download a free version of Microsoft Word Viewer from the Microsoft Office Download Center.

# Replmon Remarks

Updated: April 18, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ReplMon Remarks**
The Replmon graphical user interface tool was removed from Windows Server 2008 and later. Repadmin is still available for troubleshooting replication. For more information on using Repadmin, see Monitoring and Troubleshooting Active Directory Replication Using Repadmin and Getting Over Replmon.

Installing ReplMon

If you choose to install Support Tools in a directory other than the default (\Program Files\Support Tools), and if you install Support Tools in a directory that contains extended characters, the required Visual Basic controls might fail to register. If this occurs, the work-around is to remove Support Tools, and then to install them in the \Program Files\Support Tools folder.

Context-Sensitive Menus

ReplMon is designed for use with context-sensitive menus. Replmon UI and Replmon Examples specify the menu options as the method for accessing commands. For a shortcut, right-click objects in the ReplMon window to display the context-sensitive menus.

Creating a List of Monitored Servers

The list of monitored servers in ReplMon can be created by adding each server individually. If a number of servers must be monitored on a regular basis, however, the task of building the list can be automated by creating a file that lists the servers to be monitored. The file is created either by using a text editor, or in ReplMon by saving a list of servers already being monitored. The file is then opened in ReplMon.

**To create a list of monitored servers and save it as a text file**

1. Open a text editor.

2. Type a list of host names for the servers. Each server must be on its own line.

3. If alternative credentials are needed, add a comma after *ServerName*, followed by *Domain**User*. If *ServerName* is Server1, *Domain* is Reskit, and *User* is Admin, the command looks like the following:

   ```
   server1,reskit\admin
   ```

   For security reasons, the password is not included. When the text file is read by ReplMon, a dialog box prompts the user for the password.

4. Save the file with an .ini extension in the \Program Files\Active Directory Replication Monitor folder.

Another way to create a text file of servers is by using ReplMon. If ReplMon is open and monitoring servers, the current list of monitored servers can be saved for future use.

**To create a list of monitored servers from ReplMon**

1. While monitoring a list of servers in ReplMon, on the **File** menu, click **Save Monitored List As**.

2. Save the file with an .ini extension in the \Program Files\Active Directory Replication Monitor folder.

Populating the Monitored Servers List in ReplMon

**To load an .ini file to create a list of monitored servers for ReplMon**

1. With ReplMon open, on the **File** menu, click **Open Script**.

A list of .ini files from \Program Files\Active Directory Replication Monitor is displayed.

2. Select the .ini file that contains the list of servers to be monitored.

ReplMon and RepAdmin Similarities

Many of the tasks that can be performed with ReplMon can be performed from the command line by using Repadmin Overview.

# Replmon Examples

Updated: April 18, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ReplMon Examples**
The Replmon graphical user interface tool was removed from Windows Server 2008 and later. Repadmin is still available for troubleshooting replication. For more information on using Repadmin, see Monitoring and Troubleshooting Active Directory Replication Using Repadmin and Getting Over Replmon.

Example 1: Generate a status report for a server

In this example, you use ReplMon to create a log file that records replication events for an individual server. This data is used to troubleshoot possible replication errors in the forest or domain.

**To create the log file**

1. In ReplMon, select the server in the **Monitored Servers** section of the window.
2. On the **Action** menu, select **Server**, and then click **Generate Status Report**. The **Save As** dialog box appears.
3. In the **Save As** dialog box, type a name for the log file to generate, (optionally) select a new path for the file, and then click **Save**.

   The **Report Options** dialog box appears.
4. In the **Report Options** dialog box, select the type of information to be logged.
5. To save the log file and return to ReplMon, click **OK**.

**Notes**

- If a log file is given the same name as an existing log file, ReplMon replaces the existing log file without a warning. To avoid this, incorporate the current date in your naming scheme.
- To set the default path, on the **View** menu, select **Options**, and then use the **General** tab of the **Options** dialog box.

Example 2: Display the replication topology for a server

In this example, you use ReplMon to display replication partners of a server, which graphically represents the replication topology.

**To display replication partners**

1. In ReplMon, select the server in the **Monitored Servers** section of the window.
2. On the **Action** menu, select **Server**, and then click **Show Replication Topologies**.

   The **View Replication Topology** window appears.
3. In the **View Replication Topology** window, on the **View** menu, click **Replication Topologies**.
4. In ReplMon on the **Options** menu, click **Report**.

Example 3: Display pending replication changes

Each domain controller keeps a record of the last changes received from other domain controllers by using the Update Sequence Number (USN) of the replication partner. In this example changes have occurred on the replication partner and the

Active Directory replication process has not propagated those changes to the monitored server. You can use ReplMon to show what objects have changed and therefore need to be replicated to the monitored server. This is done on a per-directory partition basis.

**To show what objects have changed**

1. In ReplMon, expand a server to display the list of directory partitions.

2. Expand and select the replication partner within the directory partition for which you want to view unreplicated changes. Only objects that have changed within the directory partition are displayed.

3. On the **Action** menu, click **Replication Partner**, and then select **Check Current USN and Unreplicated Objects**.

   A separate window opens. Detected changes are displayed and can be saved to a text file. If no changes are detected, a message box informs you of the current USN on the replication partner and that all changes have replicated to the monitored server.

Example 4: Synchronize directory partitions

In this example, you use ReplMon to force a replication event between two directory partitions. By default, directory partitions on servers periodically synchronize with each other. Manual synchronization is necessary only if the network or a server is down for an extended period of time.

**To manually synchronize two directory partitions**

1. In the **Monitored Servers** pane of ReplMon, select the server that needs to be brought up to date.

2. Expand a directory partition.

   A list of replication partners for that directory partition appears.

3. Select the directory partition that needs to be synchronized.

4. On the **Action** menu, click **Synchronize with this Replication Partner**.

5. In the dialog box that appears, select any additional parameters for synchronization, then click **OK** to continue with the synchronization.

**Notes**

- This method works only with direct replication partners.

- This method synchronizes only one directory partition at a time. To synchronize all directory partitions at once, on the **Action** menu, click **Server**, and then click **Synchronize Each Directory Partition with All Servers**.

# Replmon UI

Updated: April 18, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Replmon graphical user interface tool was removed from Windows Server 2008 and later. Repadmin is still available for troubleshooting replication. For more information on using Repadmin, see Monitoring and Troubleshooting Active Directory Replication Using Repadmin and Getting Over Replmon.

**Replmon UI**

ReplMon has the following menus:

File Menu

**File** menu options:

| Option | Description |
|---|---|
| **Open Script** | Opens a dialog box that populates the Active Directory Replication Monitor with monitored servers. These files have an .ini extension and can be created by using a text editor or by using the **Save Monitored List As** command in the **File** menu. |
| **Save Monitored List As** | Opens a dialog box that saves a list of monitored servers in an .ini file. This list can be opened later by using the **Open Script** command on the **File** menu. If the current user does not have permission to monitor a server listed, then a user name must be supplied after *ServerName*, using the *Domain**User* format. Do not supply the password in the .ini file. The password is requested as each server is added to the monitored list when the .ini file is read. |
| **Open Log** | Opens a previously created .log file. Log files are created by default for every monitored server, and statistics are tracked on a per-replication partner and per-directory partition basis. |
| **Exit** | Closes ReplMon and discontinues monitoring servers. |

Edit Menu

**Edit** menu options:

| Option | Description |
|---|---|
| **Add Monitored Server** | Opens a dialog box that adds a single server to the list of servers monitored by ReplMon. By default, ReplMon does not monitor any servers. If you know the name of the server, click **Add the server explicitly by name**, and then type the name of the server. If you need to browse for the server, click **Search the directory for the server to add**, and then click **Next**. The entire forest can be searched if necessary. Enter a user name and password by selecting the **Use Alternate Credentials** checkbox. |

Action Menu

The **Action** menu includes the **Domain**, **Server**, **Site**, **Naming Context**, and **Replication Partner** submenus.

**Domain** submenu option:

| Option | Description |
|---|---|
| **Domain** | Opens the **Search Domain Controllers for Replication Errors** submenu option. |

**Server** submenu options:

| Option | Description |
|---|---|
| **Update Status (only for this server)** | Triggers an immediate status check for the selected server. The time of the updated status is logged and displayed. |

| | |
|---|---|
| **Check Replication Topology** | Triggers the Knowledge Consistency Checker (KCC) to recalculate the replication topology for the selected server. |
| **Synchronize Each Directory Partition with All Servers** | Triggers replication for the selected server's directory partitions with each partition's replication partners. |
| **Generate Status Report** | Creates and saves a status report for the selected server. When you select this option, the **Save As** dialog box appears. In the **Save As** dialog box, you can name the status report. To select the information that should be on the status report, select **Report Options**. |
| **Show Domain Controllers in Domain** | Opens a dialog box that lists all of the domain controllers that belong to the selected server's domain. To close this dialog box, click **OK**. |
| **Show Replication Topologies** | Creates a graphical view of all replication partners for all directory partitions. |
| **Show Group Policy Object Status** | Lists Group Policy objects for a specified domain controller and the object's current version number. Also lists version numbers of the Group Policy object in SysVol. |
| **Show Current Performance Data** | Displays real-time performance monitor counters that are specific to Active Directory replication. |
| **Show Global Catalog Servers in Enterprise** | Opens a dialog box that lists a list of Global Catalog servers in the selected server's forest. To close this dialog box, click **OK**. |
| **Show Bridgehead Servers** | Displays a list of Bridgehead servers for the selected server's site or enterprise. To close this dialog box, click **OK**. |
| **Show Trust Relationships** | Displays a list of trust relationships for the selected server's enterprise. To close this dialog box, click **OK**. |
| **Show Attribute Meta-Data for Active Directory Object** | Displays the attribute metadata for a specified object. Enter the Distinguished Name (DN) of the object in the **Object** dialog box and then click **OK**. |
| **Clear Log** | Clears the contents of the log file generated by ReplMon. |
| **Delete** | Removes the selected server from the list of monitored servers in ReplMon. |
| **Properties** | Displays properties of the selected server. |

**Site** submenu option:

| Option | Description |
|---|---|
| **Site** | Starts the Add Monitored Server wizard. |

**Naming Context** submenu options:

| Option | Description |
|---|---|
| **Synchronize This Directory Partition with All Servers** | Synchronizes a selected directory partition with all domain controllers on the site. |
| **Show Change Notifications To Replication Partners** | Lists the replication messages sent to direct replication partners. |

**Replication Partner** submenu options:

| Option | Description |
|---|---|

| | |
|---|---|
| **Check Current USN and Unreplicated objects** | Displays information on a selected server's replication partner. Displays unreplicated changes on selected replication partners. |
| **Synchronize Each Directory Partition with All Servers** | Manually synchronizes all of the directory partitions on a server with its replication partners. To synchronize an individual replication partner instead, right-click that replication partner and select **Synchronize with this Replication Partner**. |

View Menu

**View** menu options:

| Option | Description |
|---|---|
| **Details View** | Opens a window that shows a log of server status updates. |
| **Refresh** | Updates all listed servers. Refreshes every five minutes. To change the refresh interval, click the **Update Automatically** button and enter a value between 1 and 60. |

**Options** dialog box **General** tab:

| Option | Description |
|---|---|
| **Show Retired Replication Partners** | Shows servers that are no longer replication partners in the graphical replication topology display. |
| **Show Transitive Replication and Extended Data** | When checked, logs replication events from transitive partners. (By default, only replication events from direct replication partners are entered in the log.) |
| **Notify when replication fails after this number of attempts:** | Enter a number of attempts after which ReplMon notes that replication is failing. Specify whether to enter this event in the Application log or to send an e-mail message. |
| **Auto Generate File Names for Log Files** | By default, ReplMon automatically creates a name for log files. |
| **Default Path For Replication Status Logs** | Specify a path to which ReplMon automatically saves log files. |
| **Enable Debug Logging** | Creates a separate log that can be used to troubleshoot errors in ReplMon. |

**Options** dialog box **Status Logging** tab:

| Option | Description |
|---|---|
| **Group Policy Objects** | Enables Group Policy object logging. |
| **Performance Statistics** | Enables the addition of performance objects and counters to the ReplMon log. |
| **Display Changed Attributes When Replication Occurs** | Records in the ReplMon log each attribute changed, and the Update Sequence Number (USN) associated with the change. |

**Options** dialog box **Cache** tab:

| Option | Description |
|---|---|
| **Reset Button** | Flushes the ReplMon cache. |

# Sdcheck Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Sdcheck command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Sdcheck.exe: Security Descriptor Check Utility**
This command-line tool displays the security descriptor for any object stored in Active Directory. The security descriptor contains the access control lists (ACLs) defining the permissions that users have on objects stored in Active Directory.

### Notes

- You must run SDCheck from a command window.
- To enable administrators to determine the effective access controls on an object, SDCheck also displays the object hierarchy and any ACLs that are inherited by the object from its parent.
- As changes are made to the ACLs of an object or its parent, these changes are propagated automatically by Active Directory. SDCheck displays the security descriptor propagation metadata, so that administrators can monitor these changes with respect to propagation of inherited ACLs, as well as replication of ACLs from other domain controllers.
- As a complement to the replication monitoring tools (Repadmin.exe and Replmon.exe), SDCheck can be used to ensure that domain controllers are up-to-date with one another.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Every container and object on the network or in Active Directory has a set of access control information attached to it, known as a security descriptor. A security descriptor contains the security information associated with a securable object. In Windows Server 2003 operating systems, the security descriptor is automatically created when an object is created.

**System Requirements**
The following are the system requirements for SDCheck:

- Windows Server 2003 or Windows XP Professional

**File Required**

- Sdcheck.exe

# Sdcheck Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SDCheck Remarks**
**Security Descriptors**
The security descriptor is the structure of the list of permissions for an object.

The descriptor contains a header that includes a revision number and control flags. It also contains the Owner's SID (Security Identifier), and the SID of the object's primary group. A security descriptor can also contain two other lists: A discretionary access control list (DACL) and a system access control list (SACL).

The DACL is used to determine what access to an object is allowed. It contains Access Control Entries (ACEs) that define which SIDs have what privileges. An ACE has three parts: header, SID, and mask. The header describes whether it allows or denies access. The SID is the security identifier of the group or user that the ACE pertains to. The mask tells what access type the ACE is referring to.

When an access request is received, the system scans the DACL to see if any of the SIDs match any of the SIDs of the requester. If no matches are found or a Deny is found, then access is denied. All the SIDs are scanned, because a Deny Access always has a higher priority than any Allow. The only exception to this rule is that the owner of an object always has full control of the object.

An SACL is similar to a DACL, except that it is used for auditing purposes. If the user's SID is listed in the SACL's ACE, the audit event will be recorded in the event log.

# Sdcheck Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SDCheck Examples**

**Example 1: Display the Summary Security Information for an Object**

In this example, no changes have been applied to the user object (Someone), or the parent organization unit (Sales), since their initial creation. Note the metadata version number.

Type the following at the command line:

```
sdcheck sprocket someone@example.com
```

The following output appears:

```
Microsoft(R) Windows (R) 2000 Operating System
Security Descriptor Check Utility - build(2015)

Input:  someone@example.com
Object: CN=Someone,OU=Sales,DC=example,DC=com
Domain: example.com
Domain: DC=example,DC=com
Server: sprocket

*** Warning: No values returned for dSCorePropagationData on
CN=Someone,OU=Sales,DC=example,DC=com
*** Warning: No values returned for dSCorePropagationData on OU=Sales,DC=example,DC=com
*** Warning: No values returned for dSCorePropagationData on DC=example,DC=com

Object:   CN=Someone,OU=Sales,DC=example,DC=com
Classes:  top person organizationalPerson user
SD:       1012 bytes
Metadata: 04/15/1999 14:53:04 @ SPROCKET.example.com ver: 1

  Object:   OU=Sales,DC=example,DC=com
  Classes:  top organizationalUnit
  SD:       424 bytes
  Metadata: 04/15/1999 14:54:13 @ SPROCKET.example.com ver: 1

    Object:   DC=example,DC=com
    Classes:  top domain domainDNS
    SD:       496 bytes
    Metadata: 04/15/1999 14:51:32 @ SPROCKET.example.com ver: 4

Checking ACL inheritance ...
Parent: 2 - DC=example,DC=com
Child:  1 - OU=Sales,DC=example,DC=com

Checking ACL inheritance ...
Parent: 1 - OU=Sales,DC=example,DC=com
Child:  0 - CN=Someone,OU=Sales,DC=example,DC=com
```

**Example 2: Display the Security Descriptor for an Object**

In this example, two additional access control lists (ACLs) have been added. This can be identified by the version number increase for the security metadata. One ACL denies Read/Write access to members of the Accounts Payable group, and the other ACL audits Read/Write attempts by the Administrator.

Type the following at the command line:

```
sdcheck sprocket someone@example.com -dumpSD
```

Expand to see SDCheck output

```
Microsoft(R) Windows (R) 2000 Operating System

**Example 3: Determine Whether the Security Descriptor is Being Inherited Correctly**

In this example, an inheritable ACL was added to the domain object dc=microsoft,dc=com, denying Read and Write access to the members of the Finance group. Note that the metadata version number for the domain object dc=microsoft,dc=com has been incremented; however, the ACL has yet to propagate to the Sales object.

Type the following at the command line:

```
sdcheck sprocket someone@example.com
```

The following output appears:

```
Microsoft(R) Windows (R) 2000 Operating System
Security Descriptor Check Utility - build(2015)

Input:  someone@example.com
Object: CN=Someone,OU=Sales,DC=example,DC=com
Domain: example.com
Domain: DC=example,DC=com
Server: sprocket

*** Warning: No values returned for dSCorePropagationData on DC=example,DC=com

Object:   CN=Someone,OU=Sales,DC=example,DC=com
Classes:  top person organizationalPerson user
SD:       1108 bytes
Metadata: 04/15/1999 14:59:08 @ SPROCKET.example.com ver: 3

# Sdcheck Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SDCheck Syntax**

SDCheck uses the following syntax:

**sdcheck** *Server Object* [**/dumpsd**] [**/dumpall**] [**/debug**] [[**/domain:***DomainName*] **/user:** *UserName* **/password:** *Password*]

**Parameters**

***Server***

Specifies the name of the domain controller on which to perform the query. The name may be either the DNS name or the NetBIOS name of the domain controller.

***Object***

Specifies the name of the object on which you want to determine the access control list (ACL) entries. The name can be either the logon name (for example, EXAMPLE\someone), the fully distinguished name (for example, cn=Someone, ou=Sales,dc=example,dc=com), or the user principal name (for example, someone@example.com).

**/dumpsd**

Displays only the security descriptor for the selected object.

**/dumpall**

Displays the security descriptor for the selected object along with all security descriptors inherited from parent containers. Administrators can use this parameter to determine the inheritance of security descriptors from parent objects through the object hierarchy.

**/debug**

Displays internal debugging information for the Security Descriptor Check Utility.

**/domain: *DomainName***

Specifies the domain name of *UserName* in either DNS or NetBIOS format. Used to specify credentials other than the current user's.

**/user: *UserName***

Specifies the name of a user other than the current user, in the form of either the logon name or user principal name. If a user principal name is specified, then a domain name is not required.

**/password: *Password***

Specifies the password of *UserName*. Used to specify credentials other than the current user's.

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Search command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Search.vbs: Active Directory Search Tool**
This command-line tool performs searches against a Lightweight Directory Access Protocol (LDAP) server. It can be used by an Administrator or any user who wants to get information from Active Directory.

All search criteria are taken from the command line. However, certain properties of the search, such as the page size, can only be changed by modifying variable values in the script.

**Corresponding UI**
To search Active Directory, open Active Directory Users and Computers.

**Concepts**
For a conceptual overview of LDAP, see the Understanding LDAP white paper on the MSDN web site.

For more information about Security Descriptors, see the Security Descriptor Definition Language topic on the MSDN Web site.

For more information about Active Directory, see Deploying Active Directory.

**System Requirements**
The following are the system requirements for this script:

- A connection to an LDAP server.

**File Required**

- Search.vbs

# Search Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Search Remarks**
**Script Requirements**
Search.vbs works only with a Lightweight Directory Access Protocol (LDAP) provider, and requires Windows Script Host (WSH).

### Note

- WSH is already present on Windows 2000 Server and Windows Server 2003 operating systems. For WSH downloads, updates, and information, visit the Microsoft Windows Script Technologies Web site.

**Finding Required and Optional Values for an Attribute**
The schema defines objects as well as the attributes and permissible values for each. You can view schema classes that contain attribute information about objects. To view this information, search cn=Schema,cn=Configuration,dc=ForestRootDomain for classSchema objects.

# Search Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Search Syntax**

**search.vbs** *adspath* [**/C:***criteria*] [**/P:***properties*] [**/S:***scope*] [**/O**: *outputfile*] [**/U:***username*] [**/W:***password*] [**/Q**]

**Parameters**

***adspath***
Specifies the AdsPath of the root of the search (mandatory).

**/C: *criteria***
Specifies the criteria for the search (Default = "ObjectCategory=*").

**/P: *properties***
Specifies the properties to be retrieved (default = AdsPath).

**/S: *scope***
Specifies the scope of the search (default = OneLevel).

**/U: *username*and /W:*password***
Specifies the user name and password of the current user.

**/Q**
Suppresses all output messages.

**/O: *outputfile***
Specifies the search result output file name.

## Notes

Only the *adspath* parameter is mandatory. The default criteria is ObjectCategory =* (all classes), the default property to be retrieved is AdsPath, and the default scope is OneLevel. The default of *username* and *password* are those of the current user.

# Setspn Overview

Updated: April 23, 2012

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

This content has been moved to Setspn. Be sure to use a version of Setspn.exe that is included with Windows Server 2008 or later because it includes the –S parameter for adding an SPN. Although you can use Setspn –A to add an SPN, you should use Setspn -S instead because -S will verify that there are no duplicate SPNs.

If you are using Windows Server 2003 or earlier, you will not be able to use the -S switch because it is not available for that platform. You can apply Microsoft Knowledge Base 970536 (http://support.microsoft.com/kb/970536) to Windows Server 2003 to get an updated version of SetSPN that does support the –S switch. In the case where you cannot use -S, you should manually verify that there are no duplicate SPNs by first running Setspn -L.

For more information about service principal names (SPNs) and using Setspn.exe to troubleshoot problems with SPNs, see Service Principal Names (SPNs) SetSPN Syntax (Setspn.exe).

# Disk and Data Management Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Disk and File System Management Tools**
Tools in this category are used to manage the following Windows features:

- Disk Defrag
- Disk Quotas
- Distribute File System (DFS)
- Encrypting File System (EFS)
- FAT
- Formatting disks
- NTFS
- Recovering disks
- Remote Storage
- Removable Storage

**Notes**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Connstat Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connstat.cmd: FRS Connection Status Report**
This command-line tool processes the output generated when the NtfrsUtl tool is run with the **sets** parameter. Using the NtfrsUtl **sets** output as its data source, ConnStat creates a report that summarizes the status of the FRS replication connections to and from a specified computer.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
The File Replication Service (FRS), first introduced in Windows 2000, is an essential element of the Microsoft Active Directory technologies. The Active Directory service uses FRS for SYSVOL replication. FRS can also be used with the Microsoft Distributed File System (DFS) technologies for automatic replication of content between alternating targets. For more information on FRS and Active Directory replication please see the Windows Server 2003 Technical Reference.

A replica set consists of two or more computers configured to replicate the contents of a file folder. The individual computers are referred to as replica members.

FRS maintains logs of "change orders" that are either received from replication partners (the inbound log), or are to be sent to outbound replication partners (the outbound log).

The inbound log stores pending change orders to be processed. As entries are processed, FRS sends acknowledgment to the inbound partners. Data stored in the inbound log includes the globally unique identifier (GUID) of the change order, the file name, the object ID, the parent object ID, the version number, and the event time.

The outbound log stores pending change orders to be sent to outbound partners. Change orders remain in the outbound log until all outbound partners receive and acknowledge the change. Data stored in the outbound log is the same as that stored in the inbound log. Also in the outbound log is the leading (next change) and trailing (last acknowledged) index for each partner.

The outbound logs can become quite large, particularly when replica members are unavailable, links between replicas are slow, replication hours are restricted, or a large number of changes occur. For example, even when a member for a given replica set is unavailable, outbound log entries are maintained until the member becomes available. When the changes are then sent, the inbound partner sends all changes in log file order.

**System Requirements**

- Windows 2000 Server or Windows Server 2003
- Perl 5.005 521e or 522e

**Files Required**

- Connstat.cmd
- Ntfrsutl.exe

# Connstat Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ConnStat Syntax**

ConnStat uses the following syntax:

**connstat** [**-sort=***Option* [**-sort=***Option*]...] *DataFile*

**Parameters**

**-sort= *Option***

Specifies how the NtfrsUtl **sets** output is sorted. The following values are valid for the **-sort** parameter:

| Option | Description |
|---|---|
| **send** | Sorts outbound connections in ascending order by the Send Delta column of the ConnStat report. |
| **name** | Sorts outbound connections in ascending order by the Server Name column of the ConnStat report. |
| **clean** | Sorts outbound connections in ascending order by the Cleanup Delta column of the ConnStat report. |
| **lmt** | Sorts outbound connections in ascending order by the LMT (Leading minus Trailing) column of the ConnStat report. |
| **lastjointime** | Sorts outbound connections in ascending order by the LastJoinTime column of the ConnStat report. |
| **lastvvjoin** | Sorts outbound connections in ascending order by the Last VVJoin column of the ConnStat report. |

***DataFile***

Specifies the file that was generated by running NtfrsUtl with the **sets** parameter.

**Sample Usage**

```
connstat ntfrs_sets.txt

connstat sort=lastvvjoin ntfrs_sets.txt
```

# Connstat Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ConnStat Remarks**
**Before Using ConnStat**
If Perl is not installed on your system, if you are connected to the Internet, you can download a free version from the ActiveState Web site.

**Using the ConnStat Report**
The Connstat report consists of three main sections, the Report Header section, the Inbound Connections section, and the Outbound Connections section. Familiarity with FRS concepts and terminology is required in order to interpret these reports.

**The Report Header Section**
The first line of the Report Header lists the file specified in the ConnStat **datafile** parameter as well as the date that the file was last modified. The remainder of the Report Header gives information about the FRS service on the host where the input file was generated. The following table describes this information:

| Report Element | Description | Comment |
|---|---|---|
| **Replica** | Displays the replica set name and GUID. | SYSVOL replica sets are always called "DOMAIN SYSTEM VOLUME (SYSVOL SHARE)." Replica sets are uniquely identified by the GUID. |
| **Member** | Displays the member name. Individual computers in a replica set are referred to as replica members. | Note that for DFS replica sets this name is often a GUID. |
| **ServiceState** | Shows the state of the FRS service. Valid return values are between 0 and 7.<br>• **0** - Allocated: indicates an initializing state<br>• **1** - Initializing: indicates an initializing state<br>• **2** - Starting: indicates an initializing state<br>• **3** - Active: the replica set is functioning<br>• **4** - Stopped: the replica set is stopped with an error<br>• **5** - Error: the replica set is stopped with an error<br>• **6** - Jrnl_Wrap_Error: the replica set is stopped with an error<br>• **7** - Replica_Deleted: indicates the replica set is marked for deletion | The friendly name is displayed in parentheses next to the return value, for example 3 (ACTIVE). |

| | | |
|---|---|---|
| **OutLogSecNum** | Displays the current outbound log sequence number. | |
| **OutLogCleanup** | Displays the outbound log sequence number where the next clean-up will begin. | |
| **Delta** | Represents the difference between OutLogSecNum and OutLogCleanup. This is a good estimation of the number of change orders currently present in the outbound log. | |
| **Config Flags** | Displays state information about the replica set. Possible values are: **Multimaster**, **Primary**, or **Seeding**. | In multi-master replica sets, any domain controller accepts and replicates directory changes to any other domain controller. A primary flag means the host was a primary member when the replica set was created. The seeding flag, used for SYSVOL only, indicates the replica set is in the initial, seeding state. |
| **Root Path** | The root path used by the replica member. | |
| **Staging Path** | The staging path used by the replica member. | |
| **File Filter** | Lists file extensions that were excluded during replication, if any. | |
| **Directory Filter** | Lists directories that were excluded during replication, if any. | |

**The Inbound Connections Section**

This section gives state information for all inbound connections for the given member machine. The following table lists columns and descriptions for this section:

| Column Heading | Description | Comments |
|---|---|---|
| **Partner** | Displays the name of the immediate inbound partner for this replica member (member machine). | To participate in a valid FRS replica set, each member must have at least one inbound partner. |
| **I/O** | Specifies whether the connection is inbound (In) or outbound (Out). | This column appears in both the Inbound and Outbound report sections. |
| **State** | Specifies the current inbound connection state. | See the **Connection State** table in the **Connection State Definitions** remark for a list of valid Inbound connection states and their meanings. |

| | | |
|---|---|---|
| **Rev** | Represents operating system version information for the communication protocol of the inbound partner. Valid values include the following:<br>• **0** - The connection is not currently joined.<br>• **3** - The partner is running either Windows 2000 v. 2195, Windows 2000 v. 2195 SP1, or Windows 2000 v. 2195 SP2 with compression disabled.<br>• **4** - The partner is running Windows 2000 v. 2195 SP2 with compression enabled.<br>• **7** - The partner is running Windows 2000 v. 2195 SP3.<br>• **8** - The partner is running a member of the Windows Server 2003. | |
| LastJoinTime | Displays a timestamp showing when the replica member last successfully joined with this partner. | This data is available only for partners running Windows 2000 SP2 or later. |

**The Outbound Connections Section**

This section gives state information for all outbound connections for the given member machine. The following table lists columns and descriptions for this section.

Note

- The first several columns are identical to the Inbound connection report, with some additional information in the State column (see the **Connection State** table in the **Connection State Definitions** remark for more information). The columns starting with **OLog State** contains outbound log-related state information for the connection.

| **Column Heading** | **Description** | **Comments** |
|---|---|---|
| **Partner** | Displays the name of the immediate outbound partner for this replica member. | |
| **I/O** | Specifies whether the connection is inbound (In) or outbound (Out). | |
| **State** | Specifies the current outbound connection state.<br><br>See the **Connection State** table in the **Connection State Definitions** remark for a list of valid Outbound connection states and their meaning. | In the outbound connections report, the appearance of the tag "-vv" means that this connection is performing a Version Vector-based join operation. Typically this is done when the outbound partner is first added to the replica set or if it is in the process of doing a non-authoritative restore (a D2). Once this initial sync is complete, the connection leaves the VVJoin state. |

| | | |
|---|---|---|
| **Rev** | Represents operating system version information for the outbound partner's communication protocol.<br><br>See the **Inbound Connection** table in the **Inbound Connections Section** remark for definitions of the operating system versions. | |
| **LastJoinTime** | Displays a timestamp showing when the replica member last successfully joined with this partner. | This data is available only for partners running Windows 2000 SP2 or later. |
| **OLog State** | Specifies the state of outbound log processing for this connection.<br><br>• **OLP_UNJOINED** - The partner is not joined.<br><br>• **OLP_ELIGIBLE** - The partner can accept further change orders (Connection joined, and "change orders out" is less than the max limit).<br><br>• **OLP_STANDBY** - The partner is ready to join the eligible list.<br><br>• **OLP_AT_QUOTA** - The partner is at max quota for outstanding change orders.<br><br>• **OLP_INACTIVE** - The partner is not accepting change orders.<br><br>Note<br><br>• OLP_AT_QUOTA is a normal condition when FRS is actively replicating because the service always tries to keep eight change orders outstanding on each joined outbound connection. | |
| **Leadx** | Specifies the index into the outbound log for the next change order to be processed for this connection. | |

| | | |
|---|---|---|
| **Send Delta** | Specifies the difference between **OutLogSeqNum** (index of the most recent change order in the outlog) and the **Leadx** value for this connection. In other words, **Send Delta** specifies the number of change orders that remain to be processed by this connection.<br><br>A **Send Delta** of zero means that this connection is fully synchronized at this time. Unless there is very little activity in the replica set or the connection schedule is *always on*, you are unlikely to find connections with a **Send Delta** of zero. | |
| **Trailx** | Specifies the index into the outbound log of the oldest unacknowledged outbound change order. Each change order sent to the partner for this connection must eventually be acknowledged. | |
| **Cleanup Delta** | Specifies the difference between the **Trailx** value for this connection and **OutLogCleanup** index, the latter being the minimum **Trailx** value for all outbound connections. | Partners having connections with small cleanup deltas should be examined carefully to verify their operational status, since they are often the ones who are furthest behind in replicating content from this member. |
| **LMT** | Specifies the difference between the values in the **Leadx** and **Trailx** columns. This maximum value is limited by the size of the **AckVector**, typically 128.<br><br>A value of 127 in this column indicates that the connection may require investigation. | If the value of **LMT** isnbsp;127, wait for a while to see if the condition changes. If it does not, first try to delete and recreate the related connection object in the directory service. If the condition persists, then you may need to run a non-authoritative restore on the outbound partner. |
| **COs Out** | Specifies the number of active unacknowledged change orders pending at the partner. By default, FRS allows up to 8 change orders to be outstanding at a time on each outbound connection. | This limit is controlled by a registry parameter, which you may want to increase in an environment with high latency communication links. Note that FRS on the partner will try to initiate fetch requests for staging files for all eight change orders concurrently, so increasing this registry parameter will increase the load on the upstream member. See the Microsoft Windows Server 2003 Technical Reference for more details. |
| **Last VVJoin** | Specifies the last date and time that a Version Vector-based join was done on the connection. | |

**Connection State Definitions**

The following table lists Connection State values and their meaning:

| Connection State | Description |
|---|---|
| **Init** | Specifies that the connection is newly allocated. |
| **Unjoined** | Specifies that the connection is not yet joined to a partner. |
| **Start** | Specifies that the inbound partner has requested a join (StartJoin). |
| **Starting** | Specifies that the join has started. |
| **Scanning** | Specifies that FRS is scanning the inbound log for the replica set. |

| | |
|---|---|
| **SendJoin** | Specifies that the scan was completed, and the join request has been forwarded to the partner. |
| **WaitJoin** | Specifies that FRS is waiting for a reply from the partner. |
| **Joined** | Specifies that the join request succeeded. |
| **Unjoining** | Specifies that the join request failed after a series of retries. |
| **Deleted** | Specifies that the connection has been deleted. |

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ConnStat Examples**

**Example 1: Generating the NTFRS SETS Output**

ConnStat organizes the output of the NtfrsUtl tool, specifically the output generated when NtfrsUtl is run with the **sets** parameter. This example creates output that will be used by ConnStat. Type the following at the command line:

**ntfrsutl sets >ntfrs_sets.txt**

This command generates an output file called Ntfrs_sets.txt in the current directory. The command must be run on a computer that is a replica set member.

**Example 2: Using ConnStat to Parse an NtfrsUtl sets Datafile**

This example parses the data file generated in Example 1: Generating the NTFRS SETS Output and then displays the results to the screen. Type the following at the command line to save the ConnStat report to a file in the current directory:

**connstat.cmd ntfrs_sets.txt >connstat_out.txt**

This command runs the ConnStat script against the Ntfrs_sets.txt file, which was generated by the NtfrsUtl **sets** command and saves the resulting output in a file named Connstat_out.txt in the current directory.

# Devcon Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Devcon.exe: Device Console Utility**
This command-line tool brings many of the functions of Device Manager to the command window. Devcon enables, disables, installs, configures, and removes devices on the local computer and displays detailed information about devices on local and remote computers.

- **Display.** Display the following properties of devices on local and remote computers:
  - Hardware IDs, compatible IDs, and instance IDs of devices
  - Device setup classes
  - The devices in a device setup class
  - Driver files
  - Driver nodes
  - Hardware resources
  - Status
  - Expected driver stack
- **Search.** Search for installed and uninstalled devices on a local or remote computer by hardware ID, instance ID, or device setup class.
- **Change.** Changes the status or configuration of Plug and Play devices on the local computer.
  - Enable
  - Disable
  - Update
  - Install
  - Remove
  - Rescan for Plug and Play devices
  - Change the upper and lower filter drivers for a device setup class
- **Restart.** Restart a local device, restart (reboot) the local system on demand, or restart the local system, when required, for another Devcon operation.

**Notes**

- To display help information for this tool, type the following at the command line:

  **devcon /?**

- To display detailed help information for an operation, type the following at the command line:

  **devcon /?operation**

**Corresponding UI**
You can also use Device Manager, a Microsoft Management Console snap-in, to view and manage devices. Devcon and Device Manager perform many of the same functions and the tools can be used together and interchangeably.

To open Device Manager

- Click **Start**, point to **Programs**, point to **Administrative Tools**, and then click **Computer Management**.
- Expand the **System Tools** node and then click **Device Manager**.

or

- Click **Start** and then click **Run**.
- In the **Run** dialog box, type **devmgmt.msc**.

Open Device Manager now.

**Concepts**
A *device* is a piece of equipment that is connected to the computer and controlled by its microprocessors. This category includes equipment built into the computer by the manufacturer and equipment added later. The operating system interacts with devices through customized software, such as device drivers and filters. The device environment also includes supporting resources, such as memory, DMA channels, and port addresses.

Most devices manufactured since 1995 are Plug and Play devices. Plug and Play devices are automatically installed and configured for use by plugging them in and are automatically uninstalled by unplugging them. The operating system can control almost all aspects of a Plug and Play device.

With the advent of Plug and Play technology, the tasks of installing, configuring and uninstalling devices are simplified and most user configuration is eliminated. However, developers, testers and support engineers often need to view and manipulate devices and their supporting software and resources.

Developers typically use Device Manager, the Windows Management Interface (WMI) procedures, or functions in the standard Windows APIs to view and configure devices. Devcon provides a relatively complete set of basic device handling functions available from the command line.

For more information on device drivers and device configuration, see the Windows Driver Development Kit.

**System Requirements**
The following are the system requirements for this tool:

- Windows 2000 Professional, Windows 2000 Server, Windows XP Professional, or Windows Server 2003
- To change the properties of device drivers, users must have the following permissions set. Administrators have these permissions.
  - Load\Unload Drivers (set in System Policy Editor, Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment).
  - Permission to copy files to the System32\Drivers directory (set in the file system directory).
  - Permission to write settings to the registry (set in Regedit.exe).
- To install drivers, users must be logged on to an account in the Administrators group.

### Note

- When users do not have the required permissions, Devcon displays a generic "devcon failed" message with no further explanation.

### File Required

- Devcon.exe

# Devcon Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Devcon Remarks**

**Identifiers**
Devcon uses hardware IDs, compatible IDs, and instance IDs to identify devices.

- A *hardware ID* is a vendor-defined string that the Plug and Play Manager uses to find the INF file for a device. A device can have one or more hardware IDs.

- A *compatible ID* is a vendor-defined string that is more generic than the hardware ID. Devices that use the same INF file can have the same compatible ID. The Plug and Play Manager uses the compatible ID to find an INF file for a device only when it cannot find the hardware ID. However, because the compatible ID is not as reliable as a hardware ID, the system prompts the user for confirmation before installing a device based on a compatible ID match.

- An *instance ID* is a string that uniquely distinguishes a device from other devices on the computer. The instance ID of a device is unique only on a computer and can vary between computers and operating systems. The instance ID of most devices is also its registry path in the Enum registry subkey (HKLM\System\CurrentControlSet\Enum).

  In Devcon commands, instance IDs must be prefixed with the at character (@) to distinguish them from hardware IDs and compatible IDs. For example, **devcon status root*** searches for hardware IDs or compatible IDs that begin with "root\". However, **devcon hwids @root*** searches for instance IDs (device registry paths) that begin with "root\."

**Devcon Search Logic**
Devcon identifies devices by their computer name, hardware ID, compatible ID, instance ID, and device setup class.

When an ID or ID pattern (an ID with wildcard characters (*)) is preceded by the at character (@), Devcon searches only the instance IDs of devices for a match. Otherwise, it searches both the hardware IDs and compatible IDs of devices for a match.

When a command includes more than one ID or ID pattern, Devcon returns devices whose IDs match any of the IDs or ID patterns. That is, it assumes an OR between the ID arguments.

For example, **devcon hwids *pnp* *mou*** returns devices that include either "pnp" or "mou" in their hardware ID or compatible ID.

When a command includes a device setup class, Devcon first limits the search to the setup class and then applies the ID criteria. Devcon returns devices in the class that match any of the ID patterns. That is, it assumes an AND between the class and the IDs and an OR between each of the ID arguments.

For example, **devcon hwids =media *pnp* *microsoft*** returns devices in the media device setup class that include either "pnp" or "microsoft" in their hardware ID or compatible ID.

**Operational Details**

- **Classes**. Classes are listed in the order that they appear in the registry (alphanumeric order by GUID).

- **Stack**. The stack operation displays the expected driver stack for a device. Although the actual driver stack typically matches the expected stack, variations are possible.

- **Classfilter**. Devcon will not add a class filter to a class unless the driver is installed as a service, that is, there must be a subkey for the driver in the Services subkey (HKLM\System\CurrentControlSet\Services). This safeguard prevents you from accidentally adding a filter driver that does not exist and, thereby, rendering the system unbootable.

- **Findall**. The Findall operation differs from the Find operation, and from other Devcon device enumerations, in that it omits the DIGCF_PRESENT flag when calling SetupDiGetClassDevsEx function. As a result, the Findall display includes *phantom devices* that are not currently attached to the computer. For more information, see SetupDiGetClassDevsEx in

the Windows DDK.

- **Rescan**. Rescanning can cause the Plug and Play Manager to install device drivers without warning when it detects new devices. Rescanning can also detect some non-Plug and Play devices, particularly those that cannot notify the system when they are installed, such as parallel-port devices and serial-port devices. As a result, Administrator privileges are required to run rescan commands.

**Restart, Reboot, and /r**

Devcon provides a method to restart devices, and two methods to restart the operating system.

- The **/r** parameter is a conditional restart that restarts the operating system only when a restart is required to make the accompanying operation effective. This parameter is valid only in commands that include a Devcon operation. It can restart the system on a local or remote computer.

  If a system restart is required, Devcon displays a message explaining that you must restart the system to complete the operation. In response, you can use the **reboot** operation command.

- The **reboot** operation forces the operating system to restart. It is valid only on a local computer and it cannot be combined with other operations.

- The **restart** operation restarts the specified devices. It is valid only on a local computer and it cannot be combined with other operations. Some devices cannot be started without a reboot. The **/r** parameter can be used to reboot the operating system if the devices cannot be started without one.

**Devcon Return Codes**

Devcon returns a numeric (integer) code that can be used in programs and scripts to determine the success of a Devcon command. (For example, **return = devcon hwids ***). The following table lists and describes the return codes.

| Return code | Meaning |
|---|---|
| 0 | Success |
| 1 | Requires reboot |
| 2 | Failure |
| 3 | Syntax error |

# Devcon Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Devcon Examples**

**Display operations**

hwids

classes

listclass

driverfiles

drivernodes

resources

stack

status

**hwids**

The hwids operation displays the hardware IDs, compatible IDs, and instance IDs of devices on the system.

**Example 1: Find all hardware IDs**

Because Devcon operations use IDs and ID patterns to identify devices, a common first step in using Devcon is to create a hardware ID reference file for devices on the computer.

The following command uses the hwids operation, which returns the IDs and the device description. It uses the wildcard character (*) to represent all devices on the local computer.

**devcon hwids ***

Because the output is lengthy and used repeatedly, save the output in a text file for reference.

The following command uses the wildcard character (*) in the hwids operation command to represent all devices on the computer. It uses the redirection character (>) to save the command output in the hwids.txt file.

**devcon hwids * > hwids.txt**

The following command finds the hardware IDs of devices on a remote computer, Server01. It uses the **/m** parameter to specify the name of the remote computer. The command redirects the output to the server01_hwids.txt file for later reference.

**Note**

- This command fails unless the user has the required permissions on the remote computer.

**devcon /m:\\server01 hwids * > server01_hwids.txt**

**Example 2: Find hardware IDs by using a pattern**

To find the hardware IDs of a particular device, you must enter the hardware ID or pattern, the compatible ID or pattern, the instance ID or pattern, or the name of the device setup class.

The following command uses a pattern to find the actual hardware ID of the floppy disk drive on the computer. (The user assumes that the pattern appears in the one of the device identifiers.) The command uses the wildcard character (*) to represent all characters that might precede or follow the word, "floppy," in any of the IDs.

**devcon hwids *floppy***

In response, Devcon displays the instance ID, hardware ID and compatible ID of the floppy disk drive on the computer. These IDs can be used in subsequent Devcon commands.

```
FDC\GENERIC_FLOPPY_DRIVE\5&39194F6D&0&0
    Name: Floppy disk drive
    Hardware ID's:
        FDC\GENERIC_FLOPPY_DRIVE
    Compatible ID's:
        GenFloppyDisk
1 matching device(s) found.
```

In this case, the phrase "floppy" occurs in the hardware ID or compatible ID of only one device on the computer. If it occurs in the ID of more than one device, all devices with "floppy" in their IDs appear in the output.

**Example 3: Find hardware IDs by using a class**
The following command uses a device setup class to find the hardware IDs of all devices in the Ports device setup class. The equal sign (=) preceding the class name indicates that it is a class, not an ID.

**devcon hwids =ports**

In response, Devcon displays the hardware ID and compatible ID of all three devices in the Ports setup class.

```
ACPI\PNP0401\4&B4063F4&0
    Name: ECP Printer Port (LPT1)
    Hardware ID's:
        ACPI\PNP0401
        *PNP0401
ACPI\PNP0501\1
    Name: Communications Port (COM1)
    Hardware ID's:
        ACPI\PNP0501
        *PNP0501
ACPI\PNP0501\2
    Name: Communications Port (COM2)
    Hardware ID's:
        ACPI\PNP0501
        *PNP0501
3 matching device(s) found.
```

**classes**
The classes operation lists the device setup class of devices in the system.

**Example 4: List classes on the local computer**
Because Devcon operations can use the device setup class to identify devices, it is useful to create a reference file of the device setup classes of devices on the computer.

The following command uses classes operation, which returns a list and description of all classes on the computer. The classes operation does not take parameter arguments that specify a device. It only lists all classes on the computer.

**devcon classes**

Because the output is lengthy and used repeatedly, save the output in a text file for reference.

The following command displays all device classes on the computer. It uses the redirection character (>) to save the command output in the classes.txt file.

**devcon classes > classes.txt**

**Example 5: List classes on the remote computer**
The following command lists the device setup classes on a remote computer, Server01

**devcon /m:\\server01 classes**

Because the output is lengthy and used repeatedly, save the output in a text file for reference.

The following command uses the redirection character (>) to save the command output in the server01_classes.txt file.

**devcon /m:\\server01 classes > server01_classes.txt**

**listclass**
The listclasses operation lists the devices in a device setup class.

**Example 6: List the devices in a device setup class**

The following command lists the devices in Net, the device setup class for network adapters. This command is usually preceded by a command to list all of the classes on the computer (**devcon classes**), to get the correct name of the setup class.

**devcon listclass net**

In response, Devcon displays the instance ID and description of each device in the Net setup class.

```
Listing 6 device(s) for setup class "Net" (Network adapters).
PCI\VEN_10B7&DEV_9200&SUBSYS_00BE1028&REV_78\4&BB7B4AE&0&60F0: 3Com 3C920 Integrated
Fast Ethernet Controller (3C905C-TX Compatible)
ROOT\MS_L2TPMINIPORT\0000                                    : WAN Miniport (L2TP)
ROOT\MS_NDISWANIP\0000                                       : WAN Miniport (IP)
ROOT\MS_PPPOEMINIPORT\0000                                   : WAN Miniport (PPPOE)
ROOT\MS_PPTPMINIPORT\0000                                    : WAN Miniport (PPTP)
ROOT\MS_PTIMINIPORT\0000                                     : Direct Parallel
```

This display, while interesting, does not provide the hardware IDs of the devices in the Net setup class. The following command uses the Devcon Syntax operation to list the devices in the Net setup class. In the hwids operation, the class name is preceded by an equal sign (=) to indicate that it is a class, not an ID.

**devcon hwids =net**

The resulting display lists the devices in the Net class and includes the instance ID, hardware IDs and compatible IDs of devices in the class.

```
PCI\VEN_10B7&DEV_9200&SUBSYS_00BE1028&REV_78\4&BB7B4AE&0&60F0
    Name: 3Com 3C920 Integrated Fast Ethernet Controller (3C905C-TX Compatible)
    Hardware ID's:
        PCI\VEN_10B7&DEV_9200&SUBSYS_00BE1028&REV_78
        PCI\VEN_10B7&DEV_9200&SUBSYS_00BE1028
        PCI\VEN_10B7&DEV_9200&CC_020000
        PCI\VEN_10B7&DEV_9200&CC_0200
    Compatible ID's:
        PCI\VEN_10B7&DEV_9200&REV_78
        PCI\VEN_10B7&DEV_9200
        PCI\VEN_10B7&CC_020000
        PCI\VEN_10B7&CC_0200
        PCI\VEN_10B7
        PCI\CC_020000
        PCI\CC_0200
ROOT\MS_L2TPMINIPORT\0000
    Name: WAN Miniport (L2TP)
    Hardware ID's:
        ms_l2tpminiport
ROOT\MS_NDISWANIP\0000
    Name: WAN Miniport (IP)
    Hardware ID's:
        ms_ndiswanip
ROOT\MS_PPPOEMINIPORT\0000
    Name: WAN Miniport (PPPOE)
    Hardware ID's:
        ms_pppoeminiport
ROOT\MS_PPTPMINIPORT\0000
    Name: WAN Miniport (PPTP)
    Hardware ID's:
        ms_pptpminiport
ROOT\MS_PTIMINIPORT\0000
    Name: Direct Parallel
    Hardware ID's:
        ms_ptiminiport
6 matching device(s) found.
```

**Example 7: List the devices in a multiples classes on a remote computer**

The following command lists the devices in the DiskDrive, CDROM, and TapeDrive classes on Server01, a remote computer.

**devcon /m:\\server01 listclass diskdrive cdrom tapedrive**

In response, Devcon displays the devices in those classes on the remote computer.

```
Listing 1 device(s) for setup class "DiskDrive" (Disk drives) on \\server01.
IDE\DISKWDC_WD204BA_____________________________16.13M16\4457572D414D373032313633393820
3120202020: WDC WD204BA
Listing 1 device(s) for setup class "CDROM" (DVD/CD-ROM drives) on \\server01.
IDE\CDROMSAMSUNG_DVD-ROM_SD-608__________________2.2_____\4&13B4AFD&0&0.0.0: SAMSUNG
DVD-ROM SD-608
No devices for setup class "TapeDrive" (Tape drives) on \\server01.
```

**driverfiles**

The driverfiles operation lists the file names of device drivers used by devices on the system.

**Example 8: List all driver files**

The following command lists the file names of drivers used by devices on the system. The command uses the wildcard character (*) to indicate all devices on the system. Because the output is extensive, the command uses the redirection character (>) to redirect the output to a reference file, driverfiles.txt.

### devcon driverfiles * > driverfiles.txt

**Example 9: List the driver files of a particular device.**

The following command searches for the device driver used by the mouse device on the local computer. It identifies the device by one of its hardware IDs, HID\Vid_045e&Pid_0039&Rev_0121. (To find the hardware ID of a device, use the Devcon Syntax operation.) The hardware ID is enclosed in quotation marks because it includes the ampersand character (&).

### devcon driverfiles "HID\Vid_045e&Pid_0039&Rev_0121"

In response, Devcon displays the two device drivers that support the mouse device.

```
HID\VID_045E&PID_0039\6&DC36FDE&0&0000
    Name: Microsoft USB IntelliMouse Optical
    Driver installed from c:\windows\inf\msmouse.inf [HID_Mouse_Inst]. 2 file(s)
 used by driver:
        C:\WINDOWS\System32\DRIVERS\mouhid.sys
        C:\WINDOWS\System32\DRIVERS\mouclass.sys
1 matching device(s) found.
```

**drivernodes**

The drivernodes operation lists all driver packages that are compatible with the device, along with their version and ranking. Valid only on the local computer.

**Example 10: List driver packages by hardware ID pattern**

The following command lists the driver nodes of all devices whose hardware ID begins with "sw" (software devices). Patterns are useful for finding information about similar devices that might not be in the same setup class.

The drivernodes operation is particularly useful for troubleshooting setup problems. For example, you can use the drivernodes operation to find out whether an INF file included in Windows was used for a device instead of a customized third-party INF file.

### devcon drivernodes sw*

In response, Devcon displays the driver nodes of devices whose hardware IDs or compatible IDs begin with "sw."

```
SW\{A7C7A5B0-5AF3-11D1-9CED-00A024BF0407}\{9B365890-165F-11D0-A195-0020AFD156E4}

```

**Example 11: List driver packages by instance ID pattern**

The following command lists the driver nodes of all devices whose instance IDs begin with ROOT\MEDIA, that is, devices in the Enum\Root\Media registry subkey. The command uses the at character (@) to indicate that the phrase is in the instance ID.

**devcon drivernodes @ROOT\MEDIA***

In response, Devcon displays the driver nodes of devices whose instance ID begins with "ROOT\MEDIA"

```

**resources**

The resources operation lists the resources allocated to each device in the system.

**Example 12: List resources of a class of devices**

The following command displays the resources allocated to devices in the hdc class. This class includes IDE controllers. The equal sign (=) is prepended to "hdc" to indicate that it is a class and not an ID.

### devcon resources =hdc

In response, Devcon lists the resources allocated to IDE controllers on the local computer.

```
PCI\VEN_8086&DEV_244B&SUBSYS_00000000&REV_02\3&29E81982&0&F9
    Name: Intel(r) 82801BA Bus Master IDE Controller
    Device is currently using the following resources:
        IO  : ffa0-ffaf
PCIIDE\IDECHANNEL\4&37E53584&0&0
    Name: Primary IDE Channel
    Device is currently using the following resources:
        IO  : 01f0-01f7
        IO  : 03f6-03f6
        IRQ : 14
PCIIDE\IDECHANNEL\4&37E53584&0&1
    Name: Secondary IDE Channel
    Device is currently using the following resources:
        IO  : 0170-0177
        IO  : 0376-0376
        IRQ : 15
3 matching device(s) found.
```

**Example 13: List resources of device on a remote computer by ID**

The following command lists the resources allocated to the system timer on Server01, a remote computer. The command uses the hardware ID of the system timer, ACPI\PNP0100, to specify the device.

**devcon /m:\\Server01 resources *PNP0100**

In response, Devcon displays the resources of the Server01 system timer.

```
ROOT\*PNP0100\PNPBIOS_8
    Name: System timer
    Device has the following resources reserved:
        IO  : 0040-005f
        IRQ : 0
1 matching device(s) found on \\server01.
```

The following command uses the instance ID of the remote system timer in the Devcon resources command. The at character (@) indicates that the string is an instance ID, not a hardware ID or compatible ID.

**devcon /m:\\Server01 resources @ACPI\PNP0100\4&b4063f4&0**

**stack**

The stack operation displays the expected driver stack for devices on the computer.

**Example 14: Display the driver stack for storage devices**

The following command searches for devices in the volume setup class and displays the expected driver stack for those devices. The equal sign (=) indicates that the string is a class name.

**devcon stack =Volume**

In response, Devcon displays the expected stack for the devices. The data returned includes the instance ID and description of each device, the GUID and name of the device setup class, the names of upper and lower filter drivers, and controlling services, if any.

```
STORAGE\VOLUME\1&30A96598&0&SIGNATURE32323533OFFSET271167600LENGTH6E00D0C00
    Name: Generic volume
    Setup Class: {71A27CDD-812A-11D0-BEC7-08002BE2092F} Volume
    Class upper filters:
        VolSnap
    Controlling service:
        (none)
STORAGE\VOLUME\1&30A96598&0&SIGNATURE32323533OFFSET7E00LENGTH27115F800
    Name: Generic volume
    Setup Class: {71A27CDD-812A-11D0-BEC7-08002BE2092F} Volume
    Class upper filters:
        VolSnap
    Controlling service:
        (none)
2 matching device(s) found.
```

**Example 15: Find the setup class of a device**

The stack operation returns the setup class of a device in addition to the upper and lower filter drivers. The following commands find the setup class of the printer port interface by finding its instance ID, and then using the instance ID to find its setup class.

The following command finds the instance ID of the printer port interface by using the Devcon Syntax operation and "LPT," a phrase in the printer port hardware ID.

**devcon hwids *lpt***

In response, Devcon returns the instance ID (displayed in bold text), as well as the hardware ID of the printer port interface.

```
            LPTENUM\MICROSOFTRAWPORT\5&CA97D7E&0&LPT1
    Name: Printer Port Logical Interface
    Hardware ID's:
        LPTENUM\MicrosoftRawPort958A
        MicrosoftRawPort958A
1 matching device(s) found.
```

The next command uses the stack operation to find the class of the device represented by the instance ID. An at character (@)

identifies the ID as an instance ID. The ID is enclosed in quotation marks because it includes ampersand characters.

**devcon stack "@LPTENUM\MICROSOFTRAWPORT\5&CA97D7E&0&LPT1"**

In response, Devcon displays the driver stack for the printer port interface, including the class. The display reveals that the printer port is in the System class.

```
LPTENUM\MICROSOFTRAWPORT\5&CA97D7E&0&LPT1
    Name: Printer Port Logical Interface
    Setup Class: {4D36E97D-E325-11CE-BFC1-08002BE10318} System
    Controlling service:
        (none)
1 matching device(s) found.
```

**Example 16: Display the stack for related devices on a remote computer**
The following command displays the expected stack for miniport devices on Server01, a remote computer. It searches for devices in the Net setup class that have "miniport" in their hardware ID or compatible ID. Note that this command first limits the search to the Net setup class and then find the "miniport" string. It does not find devices other than those in the Net setup class.

**devcon /m:\\server01 stack =net *miniport***

In response, Devcon displays the expected stack for miniports on Server01.

```
ROOT\MS_L2TPMINIPORT\0000
    Name: WAN Miniport (L2TP)
    Setup Class: {4D36E972-E325-11CE-BFC1-08002BE10318} Net
    Controlling service:
        Rasl2tp
ROOT\MS_PPPOEMINIPORT\0000
    Name: WAN Miniport (PPPOE)
    Setup Class: {4D36E972-E325-11CE-BFC1-08002BE10318} Net
    Controlling service:
        RasPppoe
    Lower filters:
        NdisTapi
ROOT\MS_PPTPMINIPORT\0000
    Name: WAN Miniport (PPTP)
    Setup Class: {4D36E972-E325-11CE-BFC1-08002BE10318} Net
    Controlling service:
        PptpMiniport
    Lower filters:
        NdisTapi
ROOT\MS_PTIMINIPORT\0000
    Name: Direct Parallel
    Setup Class: {4D36E972-E325-11CE-BFC1-08002BE10318} Net
    Controlling service:
        Raspti
    Lower filters:
        PtiLink
4 matching device(s) found on \\Server01.
```

**status**
The classes operation lists the operational status of devices on the computer.

**Example 17: Display the status of all devices on the local computer.**
The following command finds the status of all devices on the local computer and saves the status in the status.txt file for logging or later review. The command uses the wildcard character (*) to represent all devices and the redirection character (>) to redirect the output to the status.txt file.

**devcon status * > status.txt**

**Example 18: Display the status of a particular device by instance ID**
The most reliable way to find the status of a particular device is to use the instance ID of the device.

The following command uses the instance ID to find the status of the I/O controller on the local computer. The command includes the instance ID of the device, PCI\VEN_8086&DEV_1130&SUBSYS_00000000&REV_02\3&29E81982&0&00. The at

character (@) prefixed to the ID identifies the string is an instance ID. The ID must be enclosed in quotation marks because it includes ampersand characters.

**devcon status "@PCI\VEN_8086&DEV_1130&SUBSYS_00000000&REV_02\3&29E81982&0&00"**

In response, Devcon displays the status of the I/O controller.

```
PCI\VEN_8086&DEV_1130&SUBSYS_00000000&REV_02\3&29E81982&0&00
    Name: Intel(R) 82815 Processor to I/O Controller - 1130
    Driver is running.
1 matching device(s) found.
```

**Example 19: Display the status of related devices on a remote computer.**
The following command displays the status of particular storage-related devices on Server01, a remote computer. It searches for the following devices:

- Disk drive, GenDisk
- CD-ROM drive, GenCdRom
- Floppy disk drive, FDC\GENERIC_FLOPPY_DRIVE
- Volumes, STORAGE\Volume
- Logical disk manager, ROOT\DMIO
- Volume manager, ROOT\FTDISK
- Floppy disk controller, ACPI\PNP0700

In the command, each ID is separated from the others by spaces. Note that GenDisk and GenCdRom are compatible IDs, while the other IDs are hardware IDs.

**devcon /m:\\server01 status GenDisk GenCdRom FDC\GENERIC_FLOPPY_DRIVE STORAGE\Volume ROOT\DMIO ROOT\FTDISK ACPI\PNP0700**

In response, Devcon displays the status of each device.

```
FDC\GENERIC_FLOPPY_DRIVE\1&3A2146F1&0&0
    Name: Floppy disk drive
    Driver is running.

11 matching device(s) found on \\Server01.
```

**Search Operations**

find

findall

**find**

The find operation displays the instance ID and device description of devices installed on the computer that match the specified criteria.

**Example 20: Find devices by hardware ID pattern.**

The following command searches for mouse devices on Server01, a remote computer. Specifically, the command searches the Server01 computer for devices whose hardware ID or compatible ID includes "mou."

**devcon /m:\\Server01 find *mou***

In this case, Devcon found both two mouse devices.

```
ROOT\*PNP0F03\1_0_21_0_31_0                                    : Microsoft PS/2 Mouse
ROOT\RDP_MOU\0000                                              : Terminal Server Mouse
Driver
```

Because all of the Devcon display operations also find hardware IDs, you can use any display operation to search for hardware IDs. Select the operation based on the content that you need in the output. For example, to find the device drivers that mouse-related devices on a local computer use, submit the following command.

**devcon driverfiles *mou***

In response, Devcon finds the devices and lists their drivers.

```
HID\VID_045E&PID_0039\6&DC36FDE&0&0000
    Name: Microsoft USB IntelliMouse Optical
    Driver installed from c:\windows\inf\msmouse.inf [HID_Mouse_Inst]. 2 file(s) used
by d
river:
        C:\WINDOWS\System32\DRIVERS\mouhid.sys
        C:\WINDOWS\System32\DRIVERS\mouclass.sys
ROOT\RDP_MOU\0000
    Name: Terminal Server Mouse Driver
    Driver installed from c:\windows\inf\machine.inf [RDP_MOU]. 2 file(s) used by
driver:
        C:\WINDOWS\System32\DRIVERS\termdd.sys
        C:\WINDOWS\System32\DRIVERS\mouclass.sys
2 matching device(s) found.
```

**Example 21: Find devices by instance ID or class.**

The following commands display all legacy drivers on the local computer. Because legacy drivers do not have a hardware ID, you must search for them by their instance ID (registry path), ROOT\LEGACY, or their setup class, LegacyDriver.

The first command finds legacy drivers by an instance ID pattern. The ID pattern is prefaced by the at (@) symbol to indicate an instance ID and followed by the wildcard character (*) to find all devices in the ROOT\Legacy subkey.

**devcon find @root\legacy***

The second command finds legacy devices by searching for all devices in the legacydriver class.

**devcon find =legacydriver**

Both commands produce the same output, in this case, finding the same 27 legacy devices.

```
ROOT\LEGACY_AFD\0000                                        : AFD Networking Support

```

**findall**

The findall operation finds all devices, including those that are represented in the registry, but are not present on the computer, because they have been moved or removed.

**Example 22: Find (and find all) devices in a setup class**

The following command finds all devices on the computer in the Net setup class. The equal sign (=) indicates that Net is a setup class and not an ID.

### devcon findall =net

In response, Devcon lists the following seven devices in the Net setup class. The first six are standard miniport devices. The seventh device, the RAS async adapter, is a software-enumerated device (SW*) that is not installed until it is needed.

```
PCI\VEN_10B7&DEV_9200&SUBSYS_00BE1028&REV_78\4&BB7B4AE&0&60F0: 3Com 3C920 Integrated
Fast
Ethernet Controller (3C905C-TX Compatible)
ROOT\MS_L2TPMINIPORT\0000                                   : WAN Miniport (L2TP)
ROOT\MS_NDISWANIP\0000                                      : WAN Miniport (IP)
ROOT\MS_PPPOEMINIPORT\0000                                  : WAN Miniport (PPPOE)
ROOT\MS_PPTPMINIPORT\0000                                   : WAN Miniport (PPTP)
ROOT\MS_PTIMINIPORT\0000                                    : Direct Parallel
SW\{EEAB7790-C514-11D1-B42B-00805FC1270E}\ASYNCMAC          : RAS Async Adapter
7 matching device(s) found.
```

The following command compares the find and findall commands by running a find command with the same parameters as the previous findall command.

### devcon find =net

In response, Devcon lists the following six devices in the Net setup class.

```
PCI\VEN_10B7&DEV_9200&SUBSYS_00BE1028&REV_78\4&BB7B4AE&0&60F0: 3Com 3C920 Integrated
Fast
Ethernet Controller (3C905C-TX Compatible)
```

```
ROOT\MS_L2TPMINIPORT\0000                                    : WAN Miniport (L2TP)
ROOT\MS_NDISWANIP\0000                                       : WAN Miniport (IP)
ROOT\MS_PPPOEMINIPORT\0000                                   : WAN Miniport (PPPOE)
ROOT\MS_PPTPMINIPORT\0000                                    : WAN Miniport (PPTP)
ROOT\MS_PTIMINIPORT\0000                                     : Direct Parallel
6 matching device(s) found.
```

The find command, which returns only currently present devices, does not list the software-enumerated device because it is not actually being used and software-enumerated devices are considered not-present if they are not being used.

**Change Operations**

classfilter

enable

disable

install

remove

restart

reboot

**classfilter**

Adds, deletes, displays, and changes the order of upper and lower filter drivers for a device setup class.

**Example 23: Display the filter drivers for a setup class.**

The following command displays the upper filter drivers for the DiskDrive setup class. Because this command does not include any classfilter operators, Devcon displays, but does not change, the filter drivers for the class.

**devcon classfilter DiskDrive upper**

In response, Devcon displays the new upper filter drivers for the DiskDrive class and confirms that it did not change them. In this case, the display shows that devices in the DiskDrive setup class use the PartMgr.sys (C:\Windows\System32\PartMgr.sys) upper filter driver.

```
Class filters unchanged.
    PartMgr
```

**Example 24: Add a filter driver to a setup class.**

The following command adds a fictitious filter, Disklog.sys, to the list of upper filter drivers for the DiskDrive setup class.

This command uses the add-after (**+**) classfilter operator to load the Disklog driver after the PartMgr driver so that it receives data that has already been processed by PartMgr.sys.

When the command starts, the virtual cursor is positioned before the first filter driver. Because it is not positioned on a particular driver, Devcon adds the Disklog driver to end of the filter driver list.

The command also uses the **/r** parameter, which reboots the system if it is necessary to make the class filter change effective.

**devcon /r classfilter DiskDrive upper +Disklog**

In response, Devcon displays the current upper filter drivers for the DiskDrive class.

```
Class filters changed. Class devices must be restarted for changes to take effect.
    PartMgr
    Disklog
```

If you misspell the driver name, or try to add a driver that is not installed on the system, the command fails. Devcon will not add a driver unless the driver is registered as a service, that is, unless the driver has an subkey in the Services registry subkey (HKLM\System\CurrentControlSet\Services).

The following command tests this safeguard feature. It adds "Disklgg," instead of Disklog, to the list of upper filters for the

DiskDrive class. The output demonstrates that the command fails.

**devcon /r classfilter DiskDrive upper +Disklgg**

```
devcon failed.
```

**Example 25: Insert a filter driver in the class list.**
The following command adds a fictitious filter driver, MyFilter.sys, to the list of upper filter drivers for the DiskDrive setup class. The command places MyFilter.sys between PartMgr.sys and Disklog.sys in the load order.

The following list shows the filter drivers for the DiskDrive class before the command is submitted.

```
    PartMgr
    Disklog
```

The first subcommand, **@Disklog**, uses the positioning operator (**@**) to put the virtual cursor on the Disklog filter driver. The second subcommand, **-MyFilter**, uses the add-before operator (**-**) to add MyFilter.sys before Disklog.sys.

The command also uses the **/r** parameter, which reboots the system if it is necessary to make the class filter change effective.

The positioning operator is essential in this example. Before Devcon processes any classfilter subcommands, the virtual cursor is at the beginning of the list and is not positioned on any filter drivers. If you use the add-before operator when the cursor is not on positioned on a driver, Devcon adds the driver to the beginning of the list. If you use the add-after operator when the cursor is not positioned on a driver, it adds the driver to the end of the list.

**devcon /r classfilter DiskDrive upper @Disklog -MyFilter**

In response, Devcon displays the current upper filter drivers for the DiskDrive class. ??

```
Class filters changed. Class devices must be restarted for changes to take effect.
    PartMgr
    MyFilter
    Disklog
```

You can also use the following command to add the MyFilter driver between PartMgr and Disklog. In this example, the first subcommand, **@PartMgr**, positions the virtual cursor on the PartMgr filter driver. The second subcommand, **+MyFilter**, uses the add after operator (+) to add MyFilter.sys after PartMgr.

**devcon /r classfilter DiskDrive upper @PartMgr +MyFilter**

**Example 26: Replace a filter driver**
The following command replaces the original copy of MyFilter.sys with a new and improved version, MyNewFilter.sys, in the list of filter drivers for the DiskDrive setup class.

The following list shows the filter drivers for the DiskDrive class before the command is submitted.

```
    PartMgr
    MyFilter
    Disklog
```

The first subcommand uses the delete operator (**!**) to delete MyFilter.sys from the list. This command deletes MyFilter from the list of upper filter drivers for the DiskDrive class. It does not affect the MyFilter.sys file in the C:\Windows\System32\Drivers directory.

The second subcommand uses the add-after operator (**+**) to place the new filter driver in the position that the deleted driver occupied. (The delete operator leaves the cursor on the position that the deleted filter occupied. Therefore, add-before (**-**) and add-after (**+**) have the same effect.)

The command also uses the **/r** parameter, which reboots the system if it is necessary to make the class filter change effective.

**devcon /r classfilter DiskDrive upper !MyFilter +MyNewFilter**

In response, Devcon shows the new class filter configuration for the DiskDrive class.

```
Class filters changed. Class devices must be restarted for changes to take effect.
    PartMgr
    MyNewFilter
    Disklog
```

**Example 27: Change the order of filter drivers**
The following command changes the order of filter drivers for the DiskDrive setup class. Specifically, it reverses the order of the second and third filter drivers.

The following list shows the filter drivers for the DiskDrive class before the command is submitted and the intended result of the command.

| Before | After |
|---|---|
| PartMgr | PartMgr |
| MyNewFilter | Disklog |
| Disklog | MyNewFilter |

The first subcommand uses the delete operator (**!**) to delete Disklog from the list. The second subcommand uses the start operator (**=**) to move the virtual cursor back to the starting position, and then uses the positioning operator (**@**) to put the cursor on the PartMgr driver. The start operator is necessary because the virtual cursor only moves forward through the list. The final subcommand uses the add-after operator (**+**) to add Disklog after PartMgr.

**devcon /r classfilter DiskDrive upper !Disklog =@PartMgr +Disklog**

In response, Devcon shows the new class filter configuration for the DiskDrive class.

```
Class filters changed. Class devices must be restarted for changes to take effect.
    PartMgr
    Disklog
    MyNewFilter
```

**enable**
The enable operation enables disabled devices on the system.

**Example 28: Enable a particular device.**
The following command enables a programmable interrupt controller that had been disabled to correct a system problem. Because the controller hardware ID, *PNP0000, includes an asterisk, the command uses the single quote character (') to direct Devcon to find the hardware ID precisely as specified in the command. Otherwise, the asterisk would be interpreted as a wildcard character.

**devcon enable '*PNP0000**

In response, Devcon displays the instance ID of the device, and explains that you must restart the system to enable the device.

```
ACPI\PNP0000\4&B4063F4&0                                    : Enabled on reboot
Not all of 1 device(s) enabled, at least one requires reboot to complete the operation.
```

You can respond by restarting the system, either manually, or by using the Devcon Syntax operation.

The following command adds the **/r** parameter to the previous command. The **/r** parameter reboots the system only when rebooting is required to complete an operation.

**devcon /r enable '*PNP0000**

In response, Devcon enables the device and then restarts the system to make the enabling effective.

When the system restarts, use a Devcon status command to confirm that the device is enabled.

**devcon status '*PNP0000**

```
ACPI\PNP0000\4&B4063F4&0
    Name: Programmable interrupt controller
    Driver is running.
```

**Example 29: Enable devices by class.**
The following command enables all printer devices on the computer by specifying the Printer setup class in the Devcon command. The command includes the **/r** parameter, which reboots the system if it is necessary to make the enabling effective.

**devcon /r enable =Printer**

In response, Devcon displays the instance ID of the printer that it found in the Printer class and reports that it is enabled. Although the command included the **/r** parameter, the system did not reboot because a reboot was not required to enable the printer.

```
LPTENUM\HEWLETT-PACKARDDESKJET_1120C\1&7530F08&0&LPT1.4        : Enabled
1 device(s) enabled.
```

**disable**
The disable operation disables the specified devices.

**Caution**

- If you have a USB keyboard or mouse installed on your computer, this test will disable or remove the device. To recover, you will need to use a PS/2 keyboard.

**Example 30: Disable devices by an ID pattern.**
The following command disables the USB devices on the local computer. It identifies the device by a hardware ID pattern, USB*. This pattern will match an device whose hardware ID or compatible ID begins with "USB." The command includes the **/r** parameter, which reboots the system if it is necessary to make the disabling effective.

**Caution**

- Before using an ID pattern to disable a device, determine which devices will be affected. To do so, use the pattern in a display command, such as **devcon status USB*** or **devcon hwids USB***.

**devcon /r disable USB***

In response, Devcon displays the instance IDs of the USB devices and reports that they are disabled. Although the command included the **/r** parameter, the system did not reboot because a reboot was not required to disable the devices.

```
USB\ROOT_HUB\4&2A40B465&0
: Disabled
USB\ROOT_HUB\4&7EFA360&0
: Disabled
USB\VID_045E&PID_0039\5&29F428A4&0&2
: Disabled
3 device(s) disabled.
```

**Example 31: Disable devices by instance ID.**
The following command disables the USB devices on the local computer. This command identifies the devices by their instance IDs (as indicated by the at character (@) that precedes each ID). Each instance ID is separated from the others by a space. Also, because the instance IDs include the ampersand character (&), they are enclosed in quotation marks. The command includes the **/r** parameter, which reboots the system if it is necessary to make the disabling effective.

**devcon /r disable "@USB\ROOT_HUB\4&2A40B465&0" "@USB\ROOT_HUB\4&7EFA360&0" "@USB\VID_045E&PID_0039\5&29F428A4&0&2"**

In response, Devcon displays the instance IDs of the USB devices and reports that they are disabled. Although the command included the **/r** parameter, the system did not reboot because a reboot was not required to disable the devices.

```
USB\ROOT_HUB\4&2A40B465&0
: Disabled
USB\ROOT_HUB\4&7EFA360&0
: Disabled
USB\VID_045E&PID_0039\5&29F428A4&0&2
: Disabled
3 device(s) disabled.
```

update

The update operation replaces the current device driver with the driver in the specified INF file.

**Example 32: Update the driver for communication ports**
The following command replaces the current device driver for communication ports on the system with the most suitable driver in the test.inf file. The command affects only only devices whose entire hardware ID is *PNP0501 (including the asterisk).

You can use this command to replace signed drivers on the system with alternate drivers for testing or troubleshooting, or to associate the devices with the newest version of the same drivers.

**Caution**

- Before replacing the driver for any device, determine which devices will be affected. To do so, use the pattern in a display command, such as **devcon hwids '*PNP0501** or **devcon driverfiles '*PNP0501**. This is especially important in an update operation, because Devcon does not list the devices affected by an update command.

**Note**

- Commands using the update operation only affect devices that have a hardware ID that is identical to the hardware ID specified in the command, not a pattern or partial match.

**devcon update test.inf *PNP0501**

In response, Devcon displays the following success message.

```
Updating drivers for *PNP0501 from test.inf.
```

To verify that the update was successful, use the Devcon Syntax operation, which lists the INF file and device driver files associated with the device.

The following command lists the driver files used by devices with a hardware ID of *PNP0501. In this command, which can use ID pattern matches, the string must be preceded by a single quote character (') to specify a literal match. Otherwise, the asterisk in the hardware ID is interpreted as a wildcard character.

**devcon driverfiles '*PNP0501**

In response, Devcon displays the driver files for the communication ports. The display shows that the devices are now associated with the devices specified in the test.inf file.

```
ROOT\*PNP0501\PNPBIOS_1
    Name: Communications Port (COM1)
    Driver installed from d:\test.inf [ComPort]. 2 file(s) used b
y driver:
        C:\WINDOWS\system32\DRIVERS\test.sys
        C:\WINDOWS\system32\DRIVERS\serenum.sys
ROOT\*PNP0501\PNPBIOS_2
    Name: Communications Port (COM2)
    Driver installed from d:\test.inf [ComPort]. 2 file(s) used b
y driver:
        C:\WINDOWS\system32\DRIVERS\test.sys
        C:\WINDOWS\system32\DRIVERS\serenum.sys
2 matching device(s) found.
```

**install**

The install operation installs the supporting software for a device.

**Example 33: Install a device**
The following command uses Devcon to install a Loopback device on the local computer. The command includes the full path to the INF file for the device (netloop.inf) and a hardware ID for the device, which typically is provided by the manufacturer (*MSLOOP).

### devcon /r c:\windows\inf\keyboard.inf *PNP030b

In response, Devcon reports that it installed the device by updating the driver files.

### Updating drivers for *PNPO30b from c:\windows\inf\keyboard.inf

**Example 34: Install a device using unattended setup**
The following example demonstrates how to install the MS Loopback Adapter during an unattended installation of Windows XP.

1. Add the following files to a floppy disk: Devcon.exe, Netset.exe, a tool in the Windows Server 2003 Resource Kit, and Netloop.inf (C:\Windows\inf\netloop.inf).

2. To the [GUIRunOnce] section of the unattended setup file, add the following Devcon command:

   **a:\devcon install a:\Netloop.inf *MSLOOP**

   This command installs the loopback adapter by using Netloop.inf and the hardware ID, *MSLOOP. The single quote character preceding "*MSLOOP" tells Devcon to interpret the asterisk as part of the hardware ID, not as a wildcard character.

3. Also, to the [GUIRunOnce] section of the unattended setup file, add a Netset command that specifies the desired network configuration settings.

4. Run the unattended installation.

**remove**
The remove operation uninstalls devices from the computer by deleting the device entry from the registry.

### Caution

- If you have a USB keyboard or mouse installed on your computer, this test will disable or remove the device. To recover, you will need to use a PS/2 keyboard.

**Example 35: Remove devices by instance ID pattern**
The following command removes all USB devices from the computer. It identifies the devices by an instance ID pattern that matches any instance ID (registry path) that begins with "USB\." The at character (@) distinguishes the instance ID from a hardware ID or compatible ID. The command also includes the **/r** parameter which reboots the system if it is required to make the remove procedure effective.

### Caution

- Before removing any devices by using a pattern, determine which devices are affected. To do so, use the pattern in a display command, such as **devcon status @usb*** or **devcon hwids @usb***.

### devcon /r remove @usb*

In response, Devcon displays the instance ID of the devices that it removed

```
USB\ROOT_HUB\4&2A40B465&0                                : Removed
USB\ROOT_HUB\4&7EFA360&0                                 : Removed
USB\VID_045E&PID_0039\5&29F428A4&0&2                     : Removed
3 device(s) removed.
```

**Example 36: Remove a particular network device**
The following command removes (uninstalls) the NDISWAN miniport from the local computer. The command specifies the Net class, and then refines the search by specifying devices in the class whose hardware ID or compatible ID include "ndiswan." The command also includes the **/r** parameter, which reboots the system if rebooting is required to make the remove procedure effective.

### Caution

- Before removing any devices by using a pattern, determine which devices will be affected. To do so, use the pattern in a display command, such as **devcon status =net *ndiswan*** or **devcon hwids =net *ndiswan***.

### devcon /r remove =net *ndiswan*

In response, Devcon displays the instance ID of the device that it removed.

ROOT\MS_NDISWANIP\0000 : Removed 1 device(s) removed.

rescan

The rescan operation scans the computer for new Plug and Play devices.

**Example 37: Scan the computer for new devices**
The following command scans the local computer for new devices.

### devcon rescan

In response, Devcon reports that it is scanning, but does not report finding any new devices.

```
Scanning for new hardware.
```

You can also use rescan on a remote computer. The following command runs the rescan operation on Server01, a remote computer, by adding the **/m** parameter to the command.

### devcon /m:\\server01 rescan

**restart**
The restart operation stops and then restarts devices on the local computer.

**Example 38: Restart a particular device**
The following command restarts the loopback adapter on the local computer. The command limits the search to the Net setup class and, within that class, specifies the instance ID of the loopback adapter, ROOT*MSLOOP\0000. The at character (@) identifies the string as an instance ID. The single quote character ('), which requests a literal search, prevents Devcon from interpreting the asterisk in the ID as a wildcard character.

### devcon restart =net @'ROOT*MSLOOP\0000

In response, Devcon displays the instance ID of the device and reports the result.

```
ROOT\*MSLOOP\0000                                                    : Restarted
1 device(s) restarted.
```

**reboot**
The reboot operation restarts the system on the local computer.

**Example 39: Restart the local computer**
The following command restarts the operating system on the local computer and associates the action to a hardware installation. Unlike the **/r** parameter, the **reboot** operation does not depend on the return code from another operation.

You can include the command in scripts and batch files that require the system to reboot.

### devcon reboot

In response, Devcon displays a message indicating that it is restarting the computer (**Rebooting local machine**.)

Devcon uses the standard ExitWindowsEx function to restart. If the user has open files on the computer or a program will not close, the system does not restart until the user has responded to system prompts to close the files or end the process.

# Devcon Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Devcon Syntax**

Devcon uses the following syntax:

**devcon** [**/m:***computer*] [**/r**] *operation* [*arguments*] | **devcon** {**/?** [*operation*] | **help** [*operation*]}

**Important**

- The parameters in a Devcon command must appear in the order shown in the syntax line. Otherwise, they are ignored without warning.

**Parameters**

**/m:\\ *computer***

Runs the command on the specified remote computer. The backslashes are required.

**/r**

Conditional restart. This parameter restarts the system after completing an operation only when a restart is required to make a change effective.

This parameter differs from the reboot operation, which forces the system to restart. Instead, the **/r** parameter determines whether a restart is required based on the return code from the accompanying operation.

**[ *operation*] /?**

Displays help. If you specify an operation, Devcon displays detailed help for the operation.

The parameters must appear in the specified order. For example, to display help for the status operation, type **devcon /? status** (or **devcon help status**), not **devcon status /?**.

**Operations**

There are three types of Devcon operations, those that display information, those that search for data, and those that manipulate the device or change its configuration.

The following operations *list and display* information about devices on the computer.

hwids

classes

listclass

driverfiles

drivernodes

resources

stack

status

find

findall

classfilter

enable

disable

update

install

remove

rescan

restart

reboot

**hwids**
Displays the hardware IDs, compatible IDs, and instance IDs of devices on the system. Valid on local and remote computers.

**Syntax**
**devcon** [**/m:***computer*] **hwids** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**
***/m:\\ computer***
Runs the command on the specified remote computer. The backslashes are required.

***
Represents all devices on the computer.

***ID***
Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

***= class***
Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The **/m** parameter must precede the operation name (hwids). Otherwise, Devcon ignores the **/m** parameter and displays the hardware IDs of devices on the local computer without returning a syntax error.

- Because many Devcon operations require a hardware ID of a device, run a **devcon hwids *** command first to get the list of hardware IDs for subsequent operations.

**Sample Usage**
```
devcon hwids *

devcon /m:\\server01 hwids acpi*

devcon hwids acpi* *port*

devcon hwids =usb
```

**classes**
Lists all device setup classes, including classes that are not used by devices on the system. Valid on local and remote computers.

**Syntax**
**devcon** [**/m:***computer*]**classes**

**Parameters**

**/m:\\ *computer***
Runs the command on the specified remote computer. The backslashes are required.

**Remarks**

- The **/m** parameter must precede the operation name (classes). Otherwise, Devcon ignores the **/m** parameter and displays the classes on the local computer without returning a syntax error.
- To find the devices in a setup class, use the listclass operation. To find the setup class of a particular device, use the stack operation.

**Sample Usage**

```
devcon classes
```

```
devcon classes > setupclasses.txt
```

```
devcon /m:\\Server01 classes
```

**listclass**
Lists all of the devices in the specified device setup classes. Valid on local and remote computers.

**Syntax**
▸ **devcon**[**/m:***computer*]**listclass***class* [*class*...]

**Parameters**
**/m:\\ *computer***
Runs the command on the specified remote computer. The backslashes are required.

***class***
Specifies a device setup class. To find the device setup classes on the system, use the classes operation.

**Remarks**

- The **/m** parameter must precede the operation name (listclass). Otherwise, Devcon ignores the **/m** parameter and displays the devices on the local computer without returning a syntax error.
- The class name is not preceded by an equal sign (=) in the listclass operation syntax.
- Each entry in a setup class list represents one device. The entry consists of the unique instance name and a description of the device in *instance* **:** *description* format.
- To find the setup class of a particular device, use the stack operation.

**Sample Usage**

```
devcon listclass printers ports
```

```
devcon /m:\\Server01 listclass SmartCardReader
```

**driverfiles**
Displays the full path and file name of installed INF files and device drivers files for the specified devices. Valid only on the local computer.

**Syntax**
▸ **devcon driverfiles** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**
*****
Represents all devices on the computer.

***ID***
Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

***= class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The driverfiles operation runs only on the local computer.

**Sample Usage**

```
devcon driverfiles *

devcon driverfiles FDC\GENERIC_FLOPPY_DRIVE pci*

devcon driverfiles =media

devcon driverfiles =media isapnp*
```

**drivernodes**

The drivernodes operation lists all driver packages that are compatible with the device, along with their version and ranking. Valid only on the local computer.

**Syntax**

**devcon drivernodes** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**

***

Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

***= class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The drivernodes operation runs only on the local computer.

**Sample Usage**

```
devcon drivernodes *

devcon drivernodes *miniport*

devcon drivernodes =netclient
```

```
devcon drivernodes =usb pci* usb*
```

**resources**
Lists the resources allocated to the specified devices. Resources are assignable, addressable bus paths, such as DMA channels, I/O ports, IRQ, and memory addresses. Valid on local and remote computers.

**Syntax**
▸ **devcon** [**/m:***computer*]**resources** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID*...]]}

**Parameters**
***/m:\\ computer***
Runs the command on the specified remote computer. The backslashes are required.

***
Represents all devices on the computer.

***ID***
Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

***= class***
Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The **/m** parameter must precede the operation name (resources). Otherwise, Devcon ignores the **/m** parameter and displays the resources allocated to devices on the local computer without returning a syntax error.

**Sample Usage**
```
devcon resources *

devcon /m:\\server01 resources =media

devcon resources acpi* *port*
```

`devcon resources =class port*` (by class and hardware ID)

`devcon resources =class @port*`(by class and instance ID)

**stack**
Displays the expected driver stack for the specified devices. The stack operation also returns the GUID and the name of the device setup class of a device. Valid on local and remote computers.

A *driver stack* consists of the layered chain of drivers that support a device, such as upper and lower filters and controlling services. The display also includes the setup class of the device.

**Syntax**
▸ **devcon**[**/m:***computer*]**stack** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID*...]]}

**Parameters**
***/m:\\ computer***
Runs the command on the specified remote computer. The backslashes are required.

***
Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

**= *class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The **/m** parameter must precede the operation name (stack). Otherwise, Devcon ignores the **/m** parameter and displays the stack of device drivers on the local computer without returning a syntax error.
- To investigate a device problem, compare the expected driver stack from the stack operation with the drivers installed for the device as displayed by the driverfiles operation, and the actual drivers used by the device available through the kernel debugger.

**Sample Usage**

```
devcon /m:\\Server01 stack * > Server01Stack.txt

devcon stack ISAPNP\ReadDataPort

devcon /m:\\Server01 stack pci*

devcon stack =multifunction
```

**status**

Displays the status (running, stopped, disabled) of the driver for devices on the computer. Valid on local and remote computers.

**Syntax**

**devcon**[**/m:***computer*]**status** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**

***/m:\\ computer***

Runs the command on the specified remote computer. The backslashes are required.

***

Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

***= class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The **/m** parameter must precede the operation name (status). Otherwise, Devcon ignores the **/m** parameter and displays the status of device drivers on the local computer without returning a syntax error.

**Sample Usage**

```
devcon /m:\\Server01 status *

devcon status pci*

devcon status "PCI\VEN_115D&DEV_0003&SUBSYS_0181115D"

devcon status =printer
```

The following operations *search* for information about devices on the computer.

**find**

Finds all devices that are currently attached to the computer. Displays the instance ID and device description. Valid on local and remote computers.

**Syntax**

**devcon**[**/m:***computer*]**find** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**

***/m:\\ computer***

Runs the command on the specified remote computer. The backslashes are required.

*******

Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

***= class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The **/m** parameter must precede the operation name (find). Otherwise, Devcon ignores the **/m** parameter and searches the local computer without returning a syntax error.

- The find operation with a single class argument is the same as a listclass operation.

**Sample Usage**

```
devcon find *

devcon find =media *pnp*
```

```
devcon /m:\\Server01 find *mou*

devcon find @*hub*
```

**findall**
Finds all devices on the computer, including devices that were once attached to the computer, but have been detached or moved (known as nonpresent or phantom devices). Findall also find devices that are enumerated differently as a result of a BIOS change. Valid on local and remote computers.

**Syntax**
**devcon** [**/m:***computer*]**findall** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**
***/m:\\ computer***
Runs the command on the specified remote computer. The backslashes are required.

***
Represents all devices on the computer.

***ID***
Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

***= class***
Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- The **/m** parameter must precede the operation name (findall). Otherwise, Devcon ignores the **/m** parameter and searches the local computer without returning a syntax error.

- To find devices that could be installed, but are not installed compare the output of find and findall operations.

**Sample Usage**
```
devcon resources STORAGE\Volume

devcon resources =ports lpt*

devcon resources @pci*
```

The following operations manipulate the device or change its configuration.

**classfilter**
Adds, deletes, displays, and changes the order of filter drivers for a device setup class. Valid only on the local computer.

**Syntax**
**devcon classfilter** *class*{**upper** | **lower**}[{**=** | **@** | **-** | **+** | **!**}*driver*[{**=** | **@** | **-** | **+** | **!**}*driver* ...]]

## Notes

- A classfilter command includes one or more subcommands consisting of an operator (=, @, -, +, !) and a filter driver name. Devcon executes the subcommands in the order that they appear in the command.

- The classfilter operation uses a virtual cursor to move through the list of drivers in the filter. The cursor starts at the

beginning of the list, before the first driver in the list. Unless returned to the starting position, the cursor always moves forward through the driver list as Devcon executes the subcommands.

- Without operators, "Devcon classfilter *class* {**upper | lower**}" displays the upper or lower filter drivers in the specified class.

**Parameters**

***class***
Specifies the device setup class.

**upper| lower**
Determines whether upper or lower filter drivers are displayed.

**Operators**

**=**
Moves the cursor to the beginning of the filter list (before the first driver).

**@ *driver***
Positions the cursor on the next instance of the specified driver.

**- *driver***
Add before. Inserts the specified driver before the driver on which the cursor is positioned.

If the cursor is not positioned on a driver, Devcon inserts the specified driver at the beginning of the list. When the subcommand completes, the cursor is positioned on the newly added driver.

**+ *driver***
Add after. Inserts the specified driver after the driver on which the cursor is positioned.

If the cursor is not positioned on a driver, Devcon inserts the specified driver at the end of the list. When the subcommand completes, the cursor is positioned on the newly added driver.

**! *driver***
Deletes the next occurrence of specified driver from the filter.

When the subcommand completes, the cursor occupies the position of the deleted driver. Subsequent + or - subcommands will insert a new driver at the cursor position.

**Remarks**

- Because filter driver changes require that the devices be restarted, include the **/r** parameter in the classfilter command.

- To list the device setup classes on the computer, use the classes operation. To list the devices in a device setup class, use the listclass operation. To list the class filters for a device, use the stack operation.

**Sample Usage**

**devcon classfilter mouse upper**

**devcon /r classfilter mouse upper !mouclass +newmou**

**devcon /r classfilter net lower @netfltr -testfltr**

**devcon /r classfilter volume upper !volsnap =!volsnap2**

**enable**
Enables devices on the computer. Valid only on the local computer.

When you enable a device, its driver is loaded into memory and the device is ready for use. Devcon reports a failure when it cannot find or cannot enable a device. It reports a success even when the device is already enabled. Before and after enabling a device, use the **devcon status** operation to verify the device specification and status.

**Syntax**

▸ **devcon enable** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**

***

Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

**= *class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- You might need to restart the device or the system to make the command effective. If so, add the restart parameter **/r** to the command.
- An **enable** command does not fail when the device is already enabled.
- Before and after enabling a device, use the status operation to verify the device status.

**Sample Usage**

`devcon enable *` (not recommended)

```
devcon /r enable *DVD-ROM*
```

```
devcon /r enable =printer
```

**disable**

Disables devices on the computer. Valid only on the local computer.

When you disable a device, the device remains physically connected to the computer, but its driver is unloaded from memory and its resources are freed, so the device cannot be used. Devcon reports a failure when it cannot find or cannot disable a device. It reports a success even when the device is already disabled. Before and after disabling a device, use the **devcon status** operation to verify the device specification and status.

**Syntax**

**devcon disable** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**

***

Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |

| | |
|---|---|
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

**= *class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- You might need to restart the system to make the command effective. If so, add the restart parameter **/r** to the command.
- A **disable** command does not fail when the device is already disabled.
- Before and after disabling a device, use the status operation to verify the device status.

**Sample Usage**

`devcon disable *` (not recommended)

```
devcon /r disable *DVD-ROM*
```

```
devcon /r disable =printer
```

**update**

Replaces the current device driver with the driver specified in the INF file. Valid only on the local computer. If Devcon cannot find the device, or if it cannot update it, it reports a failure. To isolate the problem, use a Devcon **find** command.

**Syntax**

**devcon update** *INFfile HardwareID*

**Parameters**

**INFfile**

Specifies the full path and file name of the INF (information) file for the device.

**HardwareID**

Specifies a hardware identifier for the device.

**Remarks**

- The hardware ID specified must exactly match the hardware ID of the device. Patterns are not valid. Do not type a single quote character (') before hardware IDs that include an asterisk.
- Because you might need to restart the system to make the command effective, add the restart parameter **/r** to the command.

**Sample Usage**

```
devcon update c:\windows\inf\newdvc.inf ISAPNP\CSC4324\0
```

```
devcon /r update c:\windows\inf\newdvc.inf *PNP030b
```

**install**

Installs the supporting software for a device. Valid only on the local computer. **ls/** can only be used to install devices that have no hardware (eg MS Loopback adapter) or non-PnP devices (eg non PnP ISA sound card).

**Syntax**

**devcon install** *INFfile HardwareID*

**Parameters**

**INFfile**

Specifies the full path and file name of the INF (information) file for the device. INF files contain the information that the system needs to install the software for a device.

**HardwareID**

Specifies a hardware identifier for the device.

For the syntax rules for hardward IDs, see "Hardware ID" in the Windows DDK Glossary.

**Remarks**

- You might need to restart the device or the system to make the command effective.
- The success message for the install operation says that Devcon has updated the drivers for the device.

**Sample Usage**

```
devcon install c:\windows\inf\newdvc.inf ISAPNP\CSC4324\0

devcon /r install c:\windows\inf\newdvc.inf ISAPNP\CSC4324\0
```

**remove**

Uninstalls the specified devices. Valid only on the local computer.

**Syntax**

▸ **devcon remove** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**

*****

Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

**= *class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- Because you might need to restart the system to make the command effective, add the restart parameter **/r** to the command.
- The **rescan** operation can also be used to reinstall a device that was removed.

**Sample Usage**

```
devcon /r remove "PCI\VEN_8086&DEV_7110"

devcon /r remove =printer

devcon /r remove =printer *deskj*
```

**rescan**

Directs Windows Plug and Play to search the computer for newly installed Plug and Play devices. Valid on local and remote computers.

**Syntax**

▸ **devcon** [**/m:***computer*]**rescan**

**Parameters**

**/m:\\ *computer***

Runs the command on the specified remote computer. The backslashes are required.

**Remarks**

- The **/m** parameter must precede the operation name (rescan). Otherwise, Devcon ignores the **/m** parameter and scans the local computer without returning a syntax error.

**Sample Usage**

```
devcon rescan

devcon /m:\\Server01 rescan
```

**restart**

Stops and restarts the specified devices. Valid only on the local computer. If Devcon cannot find a device, or if it cannot restart it, it reports a failure. To isolate the problem, use a Devcon **find** command.

**Syntax**

▸ **devcon restart** {***** | *ID* [*ID* ...] | **=***class* [*ID* [*ID* ...]]}

**Parameters**

***

Represents all devices on the computer.

***ID***

Specifies all or part of a hardware ID, compatible ID, or instance ID of a device. When specifying multiple IDs, separate each ID with a space. IDs that include an ampersand character (&) must be enclosed in quotation marks.

The following special characters modify the ID parameter.

| | |
|---|---|
| * | Matches any character or characters. Use the wildcard character (*) to create an ID pattern. For example, *disk*. |
| @ | Indicates an instance ID. For example, @ROOT\FTDISK\0000. |
| ' | Matches the string literally (exactly as it appears). Use it to indicate that an asterisk is part of the ID name, and is not a wildcard character. For example, '*PNP0600, where *PNP0600 (including the asterisk) is the hardware ID. |

**= *class***

Specifies the device setup class of the devices. To find the setup class of a device, use the classes operation.

You can also specify hardware IDs, compatible IDs, or instance IDs or ID patterns following the class name. Separate each ID or pattern with a space. Devcon finds devices in the class that match the specified IDs.

**Remarks**

- Because you might need to restart the system to make the command effective, add the restart parameter **/r** to the command.

**Sample Usage**

```
devcon restart *

devcon restart pci*

devcon restart "PCI\VEN_115D&DEV_0003&SUBSYS_0181115D"

devcon restart =printer

devcon restart =printer *desk*
```

**reboot**

Stops and then starts the operating system. Valid only on the local computer.

**Syntax**

▸ **devcon reboot**

**Remarks**

- Unlike the **/r** parameter, which restarts the system only when required to make a change effective, the reboot operation restarts the system without determining whether a restart is required.

- The reboot operation does not force a restart. If the system cannot close a program or if a user file is not saved, the restart cannot complete.

**Sample Usage**

```
devcon reboot
```

# Dfsutil Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dfsutil.exe: Distributed File System Utility**
This tool enables administrators to query and troubleshoot the Microsoft Distributed File System (DFS) from the command prompt. It can be used to perform maintenance of a DFS root and to clean up metadata left behind when domain-based DFS roots are orphaned or abandoned.

### Note

- You must run DFSUtil from the command window.

**Corresponding UI**
DFSUtil provides command-line functionality that parallels much of the Distributed File System Manager snap-in.

**Concepts**
Microsoft Distributed File System (DFS), a feature of Windows Server 2003, makes it easier to access and manage files that are physically distributed across a network. By using DFS, you can make files that are distributed across multiple servers appear to users as if they reside in one place on the network. Users and applications no longer need to know and specify the actual physical location of files in order to gain access to them: DFS makes the physical storage of data transparent by mapping it to a logical representation.

DFS does for servers and shares what file systems do for hard disks. File systems provide uniform named access to collections of sectors on disks; DFS provides a uniform naming convention and mapping for collections of servers, shares, and files. Thus, by using DFS you can organize file servers and their shares into a logical hierarchy, which makes it considerably easier to manage and use extensive information resources. In addition, DFS is not limited to a single file protocol. It can support the mapping of servers, shares, and files, regardless of the file client being used, provided that the client supports the native server and share.

In the past, with the Universal Naming Convention (UNC), to access file information a user or application was required to specify the physical server and share; that is, the user or application had to specify *Server**Share**Path**FileName*).

**System Requirements**
The following are the system requirements for DFSUtil:

- Windows Server 2003

**File Required**

- Dfsutil.exe

**DfsUtil Remarks**

DFSUtil Parameter Usage (Administration, Debugging/Monitoring, Troubleshooting/Disaster Recovery)

The following is an overview of when an administrator would typically use a specific DfsUtil parameters, as well as the parameters' general area of impact.

| Parameter | Use for Routine Administration | Use for Debugging And Monitoring | Use for Troubleshooting And Disaster Recovery | Impact: View (Passive) | Impact: Server Modification (Active) | Impact: Client Modification (Active) |
|---|---|---|---|---|---|---|
| AddStdRoot | yes | - | - | - | DFS Namespace modification | - |
| CheckBlob | - | yes | - | Verify blob stored in a file | - | - |
| Clean | - | - | yes | - | DFS Namespace modification | - |
| DisplayBlob | - | yes | - | Display blob contents to standard output | - | - |
| Export | yes | yes | yes | Save DFS namespace to a file | - | - |
| ExportBlob | - | yes | - | Export blob to a file | - | - |
| Import | yes | - | yes | - | DFS Namespace modification | - |
| ImportRoot | - | - | yes | - | DFS Namespace modification | - |
| Insite | yes | - | - | - | DFS Operations, Client behavior | - |
| PKTFlush | - | - | yes | - | - | Client behavior |
| PKTInfo | - | yes | - | Display target referrals and active target for a link (Client) | - | - |
| PurgeMupCache | - | - | yes | - | - | Client behavior |

| | | | | | | |
|---|---|---|---|---|---|---|
| PurgeWin2kStaticSiteTable | - | - | yes | - | DFS metadata site information | - |
| RemFtRoot | yes | - | - | - | DFS Namespace modification | - |
| RemoveReparse | - | - | - | - | DFS related directories on the server | - |
| AddFTRoot | - | - | yes | - | DFS related directories on the server | - |
| RemStdRoot | yes | - | - | - | DFS Namespace modification | - |
| RenameFtRoot | yes | - | - | - | DFS Namespace modification | - |
| RootScalability | yes | - | - | - | DFS Sensitivity | - |
| ShowWin2kStaticSiteTable | yes | yes | yes | Display Windows 2000 Server DFS site information when in mixed mode | - | - |
| SiteCosting | yes | - | - | - | DFS Operations, Client behavior | - |
| SiteName | yes | yes | - | View Site name of a computer | - | - |
| SPCFlush | - | - | yes | - | - | Client behavior |
| SPCInfo | - | yes | - | Display trusted domains and its DCs known on client | - | - |
| UnmapFtRoot | - | - | yes | - | DFS Namespace modification | - |
| UpdateWin2kStaticSiteTable | yes | - | yes | - | DFS metadata site information | - |
| View | - | yes | - | View DFS Namespace | - | - |

| | | | | | | |
|---|---|---|---|---|---|---|
| ViewDfsDirs | - | yes | yes | Displays DFS related directories in a volume | Displays DFS related directories in a volume | - |

**Output Description for /PktInfo**

Current Partition Knowledge Table (PKT) information can be displayed by using the /pktinfo parameter. The following describes the type of output produced when /pktinfo is used. The description numbers correspond to the numbers in the sample output.

1. The initial entry specifies how many entries are included in the output.

2. Every entry has both a full (**Entry**) and a short (**ShortEntry**) name.

3. **Expires** or Time To Live (TTL) is the length of time a DFS client stores referral information from the PKT in its local cache. The DFS client requests new information from the PKT if the TTL expires or the client is restarted. The TTL is reset if the shared folder is accessed before it expires.

4. **UseCount** is the number of times it's used since got this referral. **Type** specifies the type of referral being made.

5. Each entry contains a sequentially numbered target list. A referral is a list of targets a DFS client receives from the PKT when a user attempts to access a root or a link in the namespace. Referrals are cached locally on the client for a time specified by time indicated in **Expires**. The referral information can tell you which target is active for your DFS client. The number after each target name indicates the state of the target. Attempts to access an inactive target will be referred to the currently active target.

- State 0x21:inactive or not responding
- State 0x31:responding and an active target

6. An **ACTIVE** target status indicates it is currently being accessed by the client. If access to this target fails, the client will try to access the next target in the list. In this entry, the client would try to access the 12th target, \dom-dc-12.dom.company.com\SysVol.

DfsUtil command completed successfully.
```

**Output Description for /SpcInfo**

SPC table information can be displayed by using the /spcinfo parameter. The following describes the type of output produced when /spcinfo is used. The description numbers correspond to the numbers in the sample output.

1. Entries beginning with [*] are not expanded, and are local to the domain.

2. Entries beginning with [+] are expanded into the DC list due to access.

3. Indented entries are expanded entries of the domain entry of the domain1.companydom.com domain.

4. Unexpanded domains which have not been accessed or required to expand by the client. The local client cache contains no further information about these domains. Only trusted domains are listed.

### dfsutil /spcinfo

# Dfsutil Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DFSUtil Examples**
**Example 1: Control a DFS Client's Ability to Link to Sites**
**Enabling** the insite setting of a DFS server is useful when:

- You don't want the DFS clients to connect outside the site.
- You don't want the DFS client to connect to a site other than the site it is in, and hence avoid using expensive WAN links.

```
dfsutil /insite:\\example.com\dfsroot /enable
```

After using this command statement, clients will not get any referral for a replica outside the dfsroot site. This means that if the Replica sets in the client Site are down, the client will not do a failover to a Replica set in another site.

**Disabling** the insite setting of a DFS server is useful when:

- You want to enable outside site referrals.

**Note**

- If you want your DFS clients to be able to link to outside sites when no local server is available, and the DFS clients never seem to link outside the site, it may be because connectivity has been limited to an internal site using the **/insiteenable** setting. Disabling this setting will restore the ability of clients to link outside the site.

To reset your site preferences, type the following at the command prompt:

```
dfsutil /insite:\\example.com\Sales /disable
```

After using this command statement, clients will also get referrals for servers outside the example.com site. This means that, if all the servers in the client Site are down, the client will do a failover to a server in another site. Be aware that this may require traversing through expensive WAN links.

**Example 2: Configure a DFS Server to be Site Cost Aware**
You want DFS clients to be able to connect outside the internal site, but you want clients to connect to the closest site first, saving the expensive network bandwidth. You want to maintain *high availability* as a priority, but obviously you want DFS clients to connect to closer sites rather than farther sites when the former are reachable and up. To configure the server to be site cost aware, type either of the following statements at the command line:

```
dfsutil /sitecosting:\\example.com\sales /enable
```

```
dfsutil /root:\\example.com\sales /sitecosting /enable
```

Now the server sends the referral list composed of the randomly ranked targets in the same site as the client, followed by the targets in the next closest site from the site in which the client resides, followed by targets in the second closest site, and then the third and so on.

Notes

- If you do not know if a root is site costing aware, you can check its status by substituting the **/display** parameter for the **/sitecosting** parameter.
- If you want to disable site costing, substitute the **/disable** parameter for the **/enable** parameter.
- If you want additional insight into the processing behind this command, append the **/verbose** parameter to the end of either command statement.
- Do not use the **/sitecosting** parameter in conjunction with the **/api** parameter. Site costing cannot be done in the API

mode.

**Example 3: Back up the DFS Namespace**
You want to back up the DFS namespace for a specified root so that you can restore it later in case of system crash and loss of namespace from the system. Backing up namespace information is especially important when you have large namespaces. Using a single command statement per root, you can back up the namespaces into simple files. The files are in an XML format. To back up a namespace, type the following at the command line:

```
dfsutil /root:\\example.com\sales /export:c:\NameSpaceBackups\DateToday\saRoot20.txt
```

Note

- The output of the export file is in XML in Windows Server 2003 DFS. This means that, if your current DFS is a prior version and the output file is coming from a prior version, it should be converted to the XML format used by the **/import** parameter.

**Example 4: Restore the DFS Namespace from a Back Up**
Your system has crashed and you have lost your namespace data. In order to restore the namespace, type the following at the command line:

```
dfsutil /root:\\example.com\sales /import:c:\NameSpaceBackups\DateToday\saRoot20.txt /set
```

Notes

- It is often advisable to use the **/verify** option before doing the restore to assess the changes that will be made by the import using either the **merge** or **set** parameters. To use the **/verify** parameter, substitute it for the **/set** parameter.

- If you backed up the namespaces of the specified root from an earlier version and not Windows Server 2003, then this restore will not work.

**Example 5: Copy a Namespace**
You want to set up a backup server with the same namespace configuration as your main DFS server. This means that even if you have to take your main DFS server offline or if it goes down, the backup server can act as the DFS server. To copy one namespace to another, type the following at the command line:

```
dfsutil /root:\\example.com\sales /importroot:\\example1.com\sales1 /mirror
```

To verify that the namespace configuration has been mirrored on the backup server, type the following at the command line:

```
dfsutil /root:\\example.com\sales /importroot:\\example1.com\sales1 /compare /verbose
```

### Note

- By default, DFSUtil works in direct mode to get or update the DFS metadata. If you want DFSUtil to work in the API mode, use the **/api** parameter.

**Example 6: Force a DFS Client to Get a Target Referral List from the Server**
A client benefits from *high availability* in DFS by getting a list of link target referrals within the same site as well as targets in farther sites. In some cases targets in the closer sites may be inaccessible at the beginning of the client's use, causing the client to successfully failover to a target at a farther site. Once a closer and less expensive target is available, you would like the client to use it. If you do not want to reboot the client to cause a closer site to be selected, type the following at the command line:

```
dfsutil /pktflush
```

This command statement flushes the local partition knowledge table (PKT). This forces the client to get the referral list of the targets from the server again. Some of the entries in the PKT may not get flushed, especially if DFS is in the process of using the referrals. Once the PKT is flushed from the client cache, the client gets a new list of referrals from the server and it surely will try accessing the closer targets.

Notes

- There is no guarantee that the client select a desired target in the same site when there are other equivalent candidates available in the same site.

- Rebooting the client can replace the need of using the **/pktflush** parameter.

**Example 7: Use Windows 2000 DFS with Windows Server 2003 DFS**
You have a domain-based DFS with at least one member server that is a Windows 2000 DFS and at least one that is a Windows Server 2003 DFS. This could happen as a result of using site costing in mixed-mode DFS. It could also result from upgrading from a D-DFS with all member servers as Windows 2000 to one with all member servers as Windows Server 2003. To view what site information is currently kept on the Active Directory (blob), type the following at the command line:

```
dfsutil /root:\\example.com\Sales /showwin2kstaticsitetable
```

Now if you create links or roots on this DFS using one of the Windows Server 2003 tools, it never writes the Site Information to the DFS blob because Windows Server 2003 DFS discovers it dynamically. For Windows 2000 to function correctly, however, it needs to have this information on the blob it reads. To write links and roots to the blob which will allow Windows 2000 DFS to function properly, type the following at the command line:

```
dfsutil /root:\\example.com\Sales /updatewin2kstaticsitetable
```

This command statement updates the site information needed for Windows 2000 DFS to function properly. Repeat this command statement after every addition, deletion, and modification in a link or root on the DFS.

### Notes

- The Windows 2000 DFS uses an Active Directory object to learn about the site information in the DFS blob which in turn is written by the DFS administration tools when the roots and links were created. Windows Server 2003 does not read site information; it determines site information dynamically.

- The information kept on the blob is static in nature; it is not updated automatically on any changes in DFS.

**Example 8: Optimize Active Directory Metadata for Windows Server 2003 DFS**
Once you have completed your upgrade of DFS from Windows to Windows Server 2003 and all your DFS roots become Windows Server 2003 servers, the site information details stored in Active Directory are useless. It is good practice to keep the DFS blob optimal for best results and scalability of DFS. To remove this site information from the blob, type the following at the command line:

```
dfsutil /root:\\example.com\Sales /purgewin2kstaticsitetable
```

This ensures that the DFS blob will not contain any unnecessary site information.

**Example 9: Clean Up a Root-Server Entry in Active Directory**
If, for some reason, you have removed a root server and the metadata in Active Directory has not been updated, you can manually cause the root-server entry to be removed from the blob. This parameter is used as a problem/corruption repair setting. Do not confuse it with parameters like **/remftroot** or **/clean**. Unless absolutely necessary, use of this parameter should be avoided. To eliminate the resultant obsolete root target in the DFS namespace, type the following at the command line:

```
dfsutil /unmapftroot /root:\\ex.com\salesdata /server:\\mainshare1
```

### Caution

- Using this option deletes an entire namespace. This option is used **only** when you already have removed a domain-based root server. When this command statement is executed, the actual server is never contacted before it unmapped (because it is assumed to have been removed and, as such, would not exist). As a result, a functioning root can get removed accidentally.

Notes

- The root-server that has been removed must be domain-based for this method to work.

- DFSUtil works in direct mode to get or update the DFS metadata. This command statement will fail if the root-server is not domain-based or if direct mode cannot be initialized.

- Back up your namespace before using the **/unmapftroot** parameter.

# Dfsutil Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DFSUtil Syntax**

DFSUtil uses the following syntax:

**dfsutil** [**/?**] [*parameters*]

**Parameters**

/api

/verbose

/? | /command /?

/root:

/server:

/share:

/domain:dfsDomainName

/newDomain:dfsDomainName

/oldDomain:dfsDomainName

/comment:

/AddFTRoot:

/AddStdRoot:

/RemFTRoot

/RemStdRoot

/RenameFTRoot

/RootScalability

/SiteName

/InSite

/SiteCosting

/Export

/Import

/UpdateWin2kStaticSiteTable

/ShowWin2kStaticSiteTable

/PurgeWin2kStaticSiteTable

/View

/PktInfo

/SpcInfo

/ExportBlob:filepathname

/CheckBlob

/DisplayBlob:filepathname

/ViewDfsDirs:volume

/ImportRoot:SrcDfsName /{Mirror|Compare}

/UnMapFtRoot

/Clean

/PktFlush

/SpcFlush

/PurgeMupCache

/RemoveReparse:absolute_directory_path

**/api**
Instructs DFSUtil to go through regular server APIs instead of directly connecting to the Active Directory.

DFSUtil normally operates on domain-based roots directly, without communicating with the DFS Service on the server hosting a particular root. This default mode is known as Direct Mode. In Direct Mode, commands execute faster, especially when importing large namespaces. However, for debugging purposes, you may decide to communicate with the DFS server by using its APIs instead.

**Syntax**
- **dfsutil** *option* **/api** [**/verbose**]

**Parameters**
***option***
The option that is to be modified by the **/api** parameter.

**[ /verbose]**
Provides verbose output to the screen. This mode also notifies the user what mode a command executes in.

**Remarks**
Direct mode is essential when using parameters such as **/RenameFtRoot**, **/UnmapFtRoot**, and **/Insite**. These parameters will fail if Direct Mode does not initialize properly. Parameters that do not require a well-initialized Direct Mode (such as **/View**, **/Import**, and **/export**) will attempt to execute in the **/api** mode if the default Direct Mode fails. Specifying **/Verbose** displays the following information:

**Sample Usage**
```
dfsutil /view /root:\\dfsname\dfsshare /api
```

**/verbose**
Displays more detailed information when used with an Dfsutil Remarks.

**Syntax**
- **dfsutil** *option* **/verbose**

**Parameters**
**[ *option*]**
The option to be modified by **/verbose**.

**Sample Usage**
```
dfsutil /view /root:\\dfsname\dfsshare /verbose
```

**/? | /command /?**
Displays command-line help. The ***/command /?*** parameter displays more specific help about that command.

**Syntax**
- **dfsutil** [*option*] {**/?** | **/help**}

**Parameters**
**[ *option*]**
The option that is to be modified by the **/?** or **/help** parameter.

**Remarks**
Some parameters provide additional help text when used with **/?** or **/help**.

**Sample Usage**

```
dfsutil /?

dfsutil /help

dfsutil /export /?
```

**/root:**

Specifies the DFS root context where the specified command is to be performed.

**Syntax**

- **dfsutil** *option* **/root:** *dfs_root_name*

**Parameters**

***option***

The option that is to be modified by the **/root:** parameter.

**/root:** ***dfs_root_name***

The UNC path to the DFS root context.

**Sample Usage**

To display the DFS configuration data of a specific DFS root:

```
dfsutil /view /root:\\dfsname\dfsshare
```

**/server:**

Specifies the DFS namespace server on which the designated command is performed.

**Syntax**

- **dfsutil** *option* **/server:** *dfs_server_name*

**Parameters**

**[** ***option*** **]**

The option that is to be modified by the **/server:** parameter.

**/server:** ***dfs_server_name***

Specifies a DFS name space server.

**Sample Usage**

```
dfsutil /view /server:mycomputer.mydomain.com
```

**/share:**

Specifies the DFS or SMB share on which the designated command is performed.

**Syntax**

- **dfsutil** [*option*] **/share:***dfs_share_name*

**Parameters**

**[** ***option*** **]**

The option that is to be modified by the **/share:** parameter.

**/share:** ***dfs_share_name***

The name of a DFS or SMB share.

**Sample Usage**

```
dfsutil /clean /server:aseanl-test1 /share:dfsroot
```

**/domain:dfsDomainName**

Specifies the DFS domain on which the designated command is performed.

**Syntax**

- **dfsutil** *option* **/domain:** *dfs_domain_name*

**Parameters**

**[** ***option*** **]**

The option that is to be modified by the **/domain:** parameter.

***dfsDomainName***

The netbios name or the fully qualified name of a domain.

**/newDomain:dfsDomainName**

Specifies the DFS domain on which the designated command is performed.

**Syntax**

▸ **dfsutil** *option* **/newdomain:** *dfs_domain_name*

**Parameters**

**[ *option*]**

The option that is to be modified by the **/newdomain:** parameter.

***dfsDomainName***

The netbios name or the full qualified name of a domain.

**/oldDomain:dfsDomainName**

Specifies the DFS domain on which the designated command is performed.

**Syntax**

▸ **dfsutil** *option* **/olddomain:** *dfs_domain_name*

**Parameters**

**[ *option*]**

The option that is to be modified by the **/olddomain:** parameter.

***dfsDomainName***

The netbios name or the fully qualified name of a domain.

**/comment:**

Adds a custom text comment to the blob when creating or deleting a Root, Link, or Target.

**Syntax**

▸ **dfsutil** *option* **/comment:** *text*

**Parameters**

**[ *option*]**

The option that is to be modified by the **/comment** parameter.

***text***

The text to be added.

**Remarks**

Because they consume blob space, keep comments short.

### Important

- Avoid or reduce the usage of comments if you have a fairly high number of links and targets for a given root. Doing so will save blob space and improve overall DFS performance and scalability.

**Sample Usage**

```
dfsutil /AddFtRoot:MyDfs /server:MyServer /share:MyShare /comment:"A root of my dfs."
```

**/AddFTRoot:**

Creates a new DFS root in an existing domain-based DFS namespace. This command can also be used to add a computer as a root target to an existing namespace.

**Syntax**

▸ **dfsutil /addftroot:** *new_dfs_root_name* **/server:** *dfs_server_name* **/share:** *dfs_share_name* [**/comment:** *text*]

**Parameters**

***newDfsRootName***

Name of the DFS to which the root will belong.

**/server: *dfsServerName***

Name of the server on which to create the root.

**/share: *dfsShareName***

Name of the share that will back the root.

**/comment: *text***

Optional custom text added to the blob related to this action.

**Remarks**
Because they consume blob space, keep comments short.

**Sample Usage**
In a domain-based DFS named \\DomainName\MyDfs, add \\MyServer\MyShare as a root of that DFS.

```
dfsutil /AddFtRoot:MyDfs /server:MyServer /share:MyShare /comment:"A root of my dfs."
```

**/AddStdRoot:**
Creates a new DFS root in an existing standalone DFS namespace. This command can also be used to add a computer as a root target to an existing namespace.

**Syntax**
▸ **dfsutil /addstdroot:** *dfsRootName* **/server:** *dfsServerName* **/share:** *dfsShareName* [**/comment:** *text*] [**/api**]

**Parameters**
***dfsRootName***
Name of the root to remove.

**/server: *dfsServerName***
Name of the server on which to delete the root.

**/share: *dfsShareName***
Name of the root backup share.

**/comment: '' *text* ''**
Optional custom text added to the blob related to this action.

**Remarks**
Because they consume blob space, keep comments short.

**Sample Usage**
In a domain-based DFS named \\DomainName\MyDfs, add \\MyServer\MyShare as a root of that DFS.

```
dfsutil /AddStdRoot:MyDfs /server:MyServer /share:MyShare /comment:"A root of my dfs."
```

**/RemFTRoot**
Removes a root target from an existing domain-based DFS root.

**Syntax**
▸ **dfsutil /RemFTRoot:** *dfsRootName* **/server:** *dfsServerName* **/share:** *dfsShareName* [**/api**]

**Parameters**
***dfsRootName***
Name of root to remove.

**/server: *dfsServerName***
Name of the server on which to delete the root.

**/share: *dfsShareName***
Name of the root backup share.

**Remarks**
Prior to using this option, use **/View** to see how many replicas exist for this namespace.

**Caution**

- Removing the last replica of a DFS namespace causes the namespace to be wiped out.

To back up a namespace, use **/export**. To reload a namespace which has been backed up with **/export**, use **/import**.

**Sample Usage**
To remove the root target of MyDfs which currently is backed up by \\MyServer\MyShare:

```
dfsutil /RemFtRoot:MyDfs /server:MyServer /share:MyShare
```

**/RemStdRoot**
Removes a root target from an existing stand-alone DFS root.

**Syntax**

**dfsutil /RemStdRoot:** *dfsRootName* **/server:** dfsServerName **/share:** *dfsShareName* [**/api**]

**Parameters**

***dfsRootName***
Name of the root to remove.

**/server:** ***dfs_server_name***
Name of the server on which to delete the root.

**/share:** ***dfsShareName***
Name of the root backup share.

**Remarks**

Prior to using this option, use **/View** to see how many replicas exist for this namespace.

**Caution**

- Removing the last replica of a DFS namespace causes the namespace to be wiped out.

To back up a namespace, use **/export**. To reload a namespace which has been backed up with **/export**, use **/import**.

**Sample Usage**

To remove a root target of MyDfs that is backed up by \\MyServer\MyShare:

```
dfsutil /RemFtRoot:MyDfs /server:MyServer /share:MyShare
```

**/RenameFTRoot**

Given a DFS namespace, **/RenameFtRoot** renames references to an obsolete domain within that namespace.

This command can also be used to rename any link or target in a namespace.

**Syntax**

**dfsutil /renameftroot root:** *dfs_root_name* **/olddomain:** *domain_name* **/newdomain:** *domain_name* [**/verbose**]

**Parameters**

**/root:** ***dfs_root_name***
The UNC path to the DFS root context.

**/olddomain:** ***domain_name***
The name that you want to change your DFS namespace from. The same name that the **/root:** parameter references. This is a required parameter.

**/newdomain:** ***domain_name***
The name that you want to change your DFS namespace to. This is a required parameter.

**[ /verbose]**
Displays verbose information in the output.

**Remarks**

Prior to changing the root, it is a good practice to discover the existing state. The **/verbose** parameter is useful with this command as it lists all changes which have been made to the namespace.

**Important**

- After running this parameter, you must restart the DFS service on the servers where this command was run. Restarting the service causes the servers to recognize the new domain name in the namespace.

This command is typically run as a part of a domain rename. It is expected that the domain has already been renamed and the affected systems have been rebooted by the time this command is run. DFS servers that are running Windows 2000 Server or earlier are supported as root target servers; **/RenameFtRoot** will in fact change the registry entries of those systems appropriately.

**/RenameFtRoot** does not run in the **/Api** Mode. If Direct Mode initialization fails on the root specified (typically because the root is not Domain-based), then this command will fail.

**Sample Usage**

```
dfsutil /renameftroot /root: machname.OLDDOMAIN.company.com /olddomain: machname.OLDDOMAIN.company.com
```

```
/newdomain: machname.NEWDOMAIN.company.com
```

**/RootScalability**
An advanced command which increases the performance of a large scale deployment of DFS namespaces.

**Syntax**
▸ **dfsutil /rootscalability /root:** *dfs_root_name* {**/Enable**|**/Disable**|**/Display**} [**/verbose**]

**Parameters**
***/root: dfs_root_name***
The UNC path to the DFS root context.

**/rootscalability { /enable| disable| display}**
Select the appropriate root scaleability action.

| Value | Description |
|---|---|
| **enable** | Enables root scalability among DFS root servers. When enabled, network traffic among DFS root servers is kept to a minimum. In addition, there will be less traffic between the primary domain controller and DFS servers. This option is a tradeoff between users needing up-to-date information from DFS servers, and administrators needing minimal bandwidth consumptions by the DFS operations, (inter-DFS-server and DFS-to-domain-controller communication). |
| **disable** | Default behavior. This option results in tighter synchronization between DFS servers and Domain Controllers. |
| **display** | Display the current root scalability mode (enabled or disabled). |

**[ /verbose]**
Displays whether the root-scalability feature is currently enabled.

**Remarks**
Use this option in scenarios where the DFS metadata is comparably less dynamic and the network bandwidth has priority over up-to-date information or accessibility to up-to-date targets. Enabling this option may cause users to see outdated information from DFS servers at times, in terms of the target links and related information.

**Notes**

- This command does not work in **/Api** mode.
- The path specified must be a root, not a link.
- This has no effect on Standalone roots.
- It is a good practice to find out the current state before changing it.
- When **/rootscalability** is enabled, it is not uncommon to see an event log message such as, "DFS could not access its private data from the DS...". While this error may still indicate a problem in DS connectivity, typically this occurs because the nearest domain controller has outdated DFS information (expected behavior when **/rootscalability** is enabled).

**/SiteName**
Displays the site name that a certain computer belongs to.

**Syntax**
▸ **dfsutil /sitename:** *dfsSiteName*

**Parameters**
***dfsSiteName***
The name of the computer on which site(s) reside. Valid formats in which to specify the computer name include:

- computer name (local only)
- UNC name
- IP address

**Sample Usage**

```
dfsutil /sitename:machine4

dfsutil /sitename:mailserver.dom.com

dfsutil /sitename:georgeLaptop.domain.com

dfsutil /sitename:12.230.25.24
```

**/InSite**

Set or reset the insite setting on a root or a link, and view the current insite setting of a link or a root.

The insite setting on a link or root in a DFS defines how the DFS redirects the client access to that link or root, depending on the sites in which the client and the targets reside. The target could be a link target or a root target. This becomes important when the administrator wants to control the client accessing the root targets or link targets outside its own site. By using **/InSite**, the administrator can force the server to provide, in the referral list it returns to the client, only those targets which are in the same site as that of the client, when the client requests access to a certain root or link.

The **/InSite** setting has two modes: enabled and disabled.

**Syntax**

- **dfsutil /root:** *dfs_root_name* **/insite** /{**Enable** | **Disable** | **Display**} [**/verbose**]

**/root:** ***dfs_root_name***

The root name or the entire link name in UNC.

**/insite { /enable| disable| display}**

Select the appropriate insite action.

| Value | Description |
|---|---|
| **enable** | Clients will only access insite targets. This mode saves bandwidth by prohibiting client access to targets outside its site. However, this also reduces the availability of the DFS root on the link. |
| **disable** | Client will also access targets outside its site if necessary. |
| **display** | Displays the current insite mode (enabled or disabled) for the link or root. |

**[ /verbose]**

Displays verbose output to the screen.

**Remarks**

If you do not want to enable **/InSite**, see the **/SiteCosting** parameter. **/SiteCosting** provides more control over the DFS target referrals sent by the DFS server.

**Sample Usage**

```
dfsutil /root:\\dom.com\dfsroot /insite /display
```

Displays the current insite setting of the root dfsroot on domain dom.com.

```
Dfsutil /root:\\dom.com\DfsName\LinkA\B\C /insite /enable /verbose
```

This forces the DFS server to provide only insite target lists in the referrals for the link LinkA\B\C under the root \\dom.com\DfsName. As a result, the client accessing the link \\dom.com\DfsName\LinkA\B\C will not get a referral outside its site and will fail if there are NO targets responding in its site.

```
dfsutil /root:\\dom.com\DfsName\LinkA\B\C /insite /disable /verbose
```

This instructs the DFS server to provide all the link targets under link LinkA\B\C under the root \\dom.com\DfsName. As a result, the client accessing the link \\dom.com\DfsName\LinkA\B\C will get a list of referrals with targets in its site and outside its site as well. In fact, the targets of its site will be listed first (randomly), followed by the targets outside its site (also randomly).

**/SiteCosting**

Enables the DFS to issue referrals to the clients. The order in which the target referrals are listed is based on the following rules:

1. The targets of the same site as that of the client are listed first. The order is randomized to provide load balancing.

2. The targets from the next closest site are listed next (randomized again). This repeats until #3 occurs.

3. The targets without any site information are taken as the farthest site, listed at the end of the referrals and randomized.

**Syntax**

- **dfsutil /root:** *dfs_root_name* /sitecosting {/Enable | /Disable | /Display} [**/verbose**]

**Parameters**

***/root: dfs_root_name***

The UNC path to the DFS root context. This is a required parameter.

**/sitecosting { /enable| disable| display}**

Select the appropriate sitecosting action.

| Value | Description |
|---|---|
| **enable** | Enable sitecosting. |
| **disable** | Disable sitecosting. (Default.) |
| **display** | Display the current sitecosting mode (enabled or disabled). |

**Remarks**

To illustrate how SiteCosting works, the Root \\dom5.com\fsRoot has a link named linkA\B\C, which, in turn, has 10 targets in different sites as follows:

| | Entity | Site | Cost from client site |
|---|---|---|---|
| **Client** | \\myLaptop.dom1.com | NY-MANHATTAN-01 | 0 |
| Targets for link LinkA\B\C | \\nyServ1\Folder | NY-MANHATTAN-01 | 0 |
| | \\Asterix\universal | -- | Infinite |
| | \\laOrange\ShareData | LA-ORANGE-21 | 5 |
| | \\Bromley02\Kohinoor | LONDON-UK-10 | 22 |
| | \\Champs1\Elysee | PARIS-Douxieme-01 | 19 |
| | \\Eiffel4\Distributed | PARIS-Douxieme-01 | 19 |
| | \\LondonBridge01\Data | LONDON-UK-06 | 21 |
| | \\ny43rdFloor\Data | NY-MANHATTAN-01 | 0 |
| | \\Submarine\Air | -- | Infinite |
| | \\laOrange5\Replicated | LA-ORANGE-21 | 5 |

When SiteCosting is disabled, the DFS server issues the referral as follows:

1. Targets \\nyServ1\Folder, \\ny43rdFloor\Data randomly sequenced.

2. Remaining targets randomly sequenced irrespective of their site.

When SiteCosting is enabled, the Referral list looks like this:

1. Targets from the site same as the client randomly sequenced: \\ny43rdFloor\Data, \\nyServ1\Folder

2. Targets from the next least expensive Site randomly sequenced: here site LA-ORANGE-21. Targets:

\\laOrange\ShareData, \\laOrange5\Replicated.

3. Targets from 3rd least expensive site randomly sequenced: here the site PARIS-Douxieme-01. Targets: \\Eiffel4\Distributed, \\Champs1\Elysee.

4. Targets from 4th least expensive Site randomly sequenced: here the site LONDON-UK-06. Targets: \\LondonBridge01\Data.

5. Targets from 5th least expensive Site randomly sequenced: here the site LONDON-UK-10. Targets: \\Bromley02\Kohinoor.

6. Finally, targets without any site information known, believed to be the most expensive, are randomly sequenced. Targets: \\Asterix\universal, \\Submarine\Air.

**Sample Usage**

```
dfsutil /root:\\dom5.com\fsroot /sitecosting /enable /verbose
```

**/Export**

The **/export** parameter converts the configuration data into a reusable script file that describes an entire namespace. You specify the DFS namespace to export, and a file in which to save the exported configuration data. This file typically is the input for the **/import** parameter described later.

**Syntax**

▸ **dfsutil /root:** dfs_root **/export:** *file_name*

**Parameters**

***/root: dfs_root_name***

The UNC path to the DFS root context. This is a required parameter.

***/export: file_name***

The name of the file to export DFS configuration data to.

**Remarks**

The output file of the export is an XML file in DFS on a Windows Server 2003 system. Hence, it is important to note that if your current DFS is of a prior version, or the output files are coming from a prior version, it should be converted to the XML format to be reloaded by using the **/import** command option.

Warning

- If the file you specify to export already exists it will be overwritten without any warning. You will lose any data in the original file.

**Sample Usage**

```
dfsutil /root:\\dfsname\dfsshare /export:dfsoutput.txt
```

**/Import**

The **/import** parameter creates or updates a DFS namespace from a DFS metadata stored in a specified file.

**Syntax**

▸ **dfsutil /Root:** *dfsRootName* **/import:** *filename* **/{ Verify** | **Set** | **Merge**} [**/Verbose**]

**Parameters**

***dfsRootName***

An existing DFS root to which the *filename* file is imported. Only the namespace specified by the root argument is affected.

***filename***

An XML-formatted text file containing the DFS namespace. This file has usually been created by running **/export**.

**/{ Verify| Set| Merge}**

Select the appropriate namespace action. This is a required parameter.

| Value | Description |
|---|---|

| | |
|---|---|
| **Verify** | Displays changes that may happen during the import. |
| **Set** | Replaces the old namespace with the new namespace. All links and targets specified in the import file but not present in the new namespace are deleted. |
| **Merge** | Merge options decide the fate of the namespace that existed before the import command. The Merge option updates not only the links and targets that are common to both namespaces but also the new links and targets scripted in the input file. This is, in effect, a union of the existing namespace with the importing file-based namespace. If there is a conflict between the two, the file-based configuration is considered final. |

**Remarks**

Use **/Verify** prior to the actual import (that is, using **/Set** or **/Merge**), to assess changes that may happen during the import.

The output file of the export is in XML format for Windows Server 2003 DFS. If your current DFS is of a prior version, or the output files are coming from a prior version, it should be converted to the XML format to be reloaded in the import command option with this version 4.0, that is, this version of DFSUtil.exe.

**/UpdateWin2kStaticSiteTable**

This is a mixed mode-only (Windows 2000 *and* Windows Server 2003) option.

In case of a DFS environment with servers running both Windows 2000 and Windows Server 2003, this option runs on the server running Windows Server 2003 to update the site information useful to the server running Windows 2000. When a link target is being added to a link on a domain-based DFS from a server running Windows Server 2003, the site information for that link target is not added to the DFS blob on the Active Directory. (This is different from a Windows 2000 domain-based DFS, where it would be added to the blob. The reason for this difference in behavior is that the server running Windows Server 2003 determines the site information dynamically (on an as-needed basis), so there is no need to add it to the blob in order to save the blob space. In the mixed mode scenario, where there is a domain-based DFS with at least one member server running Windows Server 2003 and at least one member server running Windows 2000, site information of any link target added by the server running Windows Server 2003 will not be added to the blob. So the member server running Windows 2000 will never know its site information.

**Syntax**

- **dfsutil /root:** *dfsRootName* **/UpdateWin2kStaticSiteTable**

**Parameters**

***/root:h dfsRootName***

The DFS root on which this command is performed. Valid names are constructed as: \\dfsname\dfsshare.

**Remarks**

This command updates the Windows 2000 Site table.

The problem of mixed-mode interoperability is solved until more link targets are added from any server running Windows Server 2003. It is a good practice to update this site information table, as it is static, and an up-to-date table keeps the blob size optimal.

Use **/ShowWin2kStaticSiteTable** to display the state of the existing namespace. This can be especially useful in determining if the actual DFS namespace matches your namespace design.

**/ShowWin2kStaticSiteTable**

This is a mixed mode-only (Windows 2000 *and* Windows Server 2003) option.

Displays the current Target-to-Site mapping information stored in the blob of a DFS server running Windows 2000.

In a domain-based DFS with at least one member server running Windows Server 2003, and at least one member server is running Windows 2000, site information of any link target added by the server running Windows Server 2003 will not be added to the blob. So the member server running Windows 2000 will never know its site information.

To verify what the server running Windows 2000 knows about the sites of various targets, this option displays the Target-to-Site mapping.

**Syntax**

- **dfsutil /Root:** *dfsRootName* **/ShowWin2kStaticSiteTable**

**Parameters**

***dfsRootName***

The DFS root on which this command is performed. Valid names are constructed as: \\dfsname\dfsshare.

**Remarks**
This helps the Administrator verify if member server running Windows 2000 has all the necessary site information.

**/PurgeWin2kStaticSiteTable**
This is a mixed mode-only (Windows 2000 *and* Windows Server 2003) option.

This parameter flushes site information from the blob. In a domain-based DFS with at least one member server is running Windows Server 2003, and at least one member server is running Windows 2000, site information of any link target added by the server running Windows Server 2003 will not be added to the blob. So the member server running Windows 2000 will never know its site information.

**Syntax**
**dfsutil /Root:** *dfsRootName* **/PurgeWin2kStaticSiteTable**

**Parameters**
***dfsRootName***
The DFS root on which this command is performed. Valid names are constructed as: \\dfsname\dfsshare.

**/View**
Displays the DFS configuration data of a DFS root. Included in the configuration data is a list of the roots of the DFS, a list of all of the links of the DFS, and site information for the DFS.

**Syntax**
**dfsutil /view** {**/Root:** *dfsRootName*|**/server:** *dfs_root*|**/domain:** *dfs_root*}

**Parameters**
***dfsRootName***
The DFS root on which this command is performed. Valid names are constructed as: \\dfsname\dfsshare.

**/server:** ***dfs_root***
Specifies the DFS namespace server on which this command is performed.

**/domain:** ***dfs_root***
Specifies the domain on which this command is performed.

**Sample Usage**
```
dfsutil /view
```

**/PktInfo**
Displays the following client information currently in the Partition Knowledge Table (PKT):

- Parts of the DFS namespace cached by the client
- Names of the servers participating in the DFS share
- Clients' randomization order of the participating servers
- Current "go to" server

See Dfsutil Remarks for a description of the output produced by this parameter.

**Syntax**
**dfsutil /pktinfo** [**level:**{**0**|**1**}]

**Parameters**
**/level:{ 0|1}**
Optional report detail argument which takes a value of either 0 (low detail) or 1 (high detail).

**Remarks**
This is a DFS client-side operation.

Each entry will report a name, both full and short, the remaining time that the referral and information contained in it will remain in the referral list, followed by the referral list itself. Active alternate DFS client targets are indicated by the number "0X31" after the alternate name entry.

**Note**

- Flushing the Partition Knowledge Table (PKT) clears existing information and force the DFS client to fetch new information for the next series of access attempts. See \PKTFlush.

DFS servers store the DFS namespace and the servers backing up the namespace in a BLOB format in the registry (stand-alone DFS) or Active Directory (domain DFS). The DFS BLOB is formally known as the Partition Knowledge Table (PKT). DFS clients retrieve and cache each piece of the DFS namespace for a period of time determined by the server.

For DFS servers running Windows NT 4.0, the servers send the list of servers backing a piece of the DFS namespace in the same order. Clients randomize the list of servers to provide a degree of load balancing.

For DFS servers running Windows 2000, Windows XP, or Windows Server 2003 that are accessed by Windows 2000 DFS clients, the scrambling and site preference takes place on the server.

**Sample Usage**
```
dfsutil /pktinfo
```

**/SpcInfo**
Displays the content of SPC. The SPC contains the list of trusted domains; under each trusted domain there may be one or more domain controllers.

See Dfsutil Remarks for a description of the output produced by this parameter.

**Syntax**
▸ **dfsutil /spcinfo**

**Remarks**
This is a DFS client-side operation.

This cache can be flushed if you feel the client has inaccurate information or is not aligned with the design of a DFS environment. See the SPCflush option.

**Sample Usage**
```
dfsutil /spcinfo
```

**/ExportBlob:filepathname**
Exports the blob of a DFS namespace which already exists (that is, specific to a root). This option saves the blob of the namespace specified, without any format changes, directly to a file.

**Syntax**
▸ **dfsutil** *dfsRootName* **/exportblob:** *filename*

**Parameters**
***dfsRootName***
The DFS root on which this command is performed. Valid names are constructed as: \\dfsname\dfsshare.

***filename***
An absolute or relative pathname or working directory file.

**Sample Usage**
```
dfsutil /Root:\\dom.com\homedirroot /ExportBlob:e:\Backups\DFSbackups\Homedirroot\today.dfs
```

**/CheckBlob**
Checks the blob of a DFS namespace which already exists (that is, specific to a root). This is a basic consistency check.

**Syntax**
▸ **dfsutil /Root:** *dfsRootName* **/checkblob**

**Parameters**
***dfsRootName***
The DFS root on which this command is performed. Valid names are constructed as: \\dfsname\dfsshare.

**Sample Usage**
```
dfsutil /Root:\\dom.com\homedirroot /checkBlob
```

**/DisplayBlob:filepathname**
Displays the blob stored in a blob file. The blob file is generally exported with /ExportBlob. This option is used to view the blob of a specific root.

**Syntax**

**dfsutil /displayblob:** *filepathname*

**Parameters**

***filepathname***

Displays an existing file containing blob information.

**/ViewDfsDirs:volume**

Scans the specified volume and lists all DFS reparse directories. Reparse directories can also be removed when this option is used with the RemoveReparse option.

**Syntax**

**dfsutil /viewdfsdirs:** *volume* [**/removereparse**: *path*] [**/verbose**]

**Parameters**

***volume***

Name of the volume to scan.

**/removereparse:** ***path***

Removes all DFS reparse directories under a given absolute path directory/ hierarchy.

**/verbose**

Displays more detailed information.

**Remarks**

The **/RemoveReparse** parameter can be used separately over a directory tree to remove all the DFS reparse directories under it.

**Sample Usage**

The following syntax lists all DFS reparse directories existing on volume (drive) e:`dfsutil /viewdfsdirs:e:`

The following syntax views and deletes (removes) all DFS reparse directories on volume (drive) c:. The **/verbose** parameter includes more descriptive details.`dfsutil /ViewDfsDirs:c: /removereparse /verbose`

**/ImportRoot:SrcDfsName /{Mirror|Compare}**

Copies an entire namespace under a DFS root to another DFS root, which, in turn, enables you to perform other operations such as Namespace Backup, DFS Server Maintenance, Create DFS mirror etc.

**Syntax**

dfsutil **/Root:***dfsRootName***/ImportRoot**:*SrcDfsName* {**/Mirror** | **/Compare**} [**/Api**]

**Parameters**

***SrcDfsName***

An existing DFS namespace (root).

**/{Mirror| Compare}**

Select the appropriate namespace action.

| Value | Description |
|---|---|
| **Mirror** | Back up the *SrcDfsName* namespace. |
| **Compare** | Compare the *SrcDfsName* namespace with the new namespace. |

**/ API**

Execute in API mode.

**Remarks**

Back up the existing namespace using the **/export** parameter before performing this operation.

Warning

- When mirroring the DFS namespace, be careful to provide the **/Root** and **/ImportRoot** parameters in the correct order. Specifying these parameters in reverse order could be disastrous and irrecoverable.

**Sample Usage**

The namespace \\dom1\existing is compared to \\dom2\bin, where \\dom\bin can also exist.`dfsutil /Root:\\dom2\bin /ImportRoot:\\dom1\existing /Compare` The namespace \\dom1\existing is to be mirrored to \\dom2\bin, where \\dom\bin

can also exist but this will overwrite the existing namespace.

```
dfsutil /Root:\\dom2\bin /ImportRoot:\\dom1\existing /Mirror
```

**/UnMapFtRoot**
Manually removes references to an obsolete domain-based root target. At times it may not be feasible for the administrator to remove a root target server from the namespace gracefully. This command eliminates the resultant obsolete root target in the DFS namespace. Since the target host server is unlikely to exist at this point, DFSUtil does not attempt to contact it.

**Syntax**
**/unmapftroot /server:** *root_target_server* **/share:** *root_target_share*

**Parameters**
**/server: *root_target_server***
This option specifies the root target server. This is a required parameter.

**/share: *root_target_share***
This option specifies the target share server.

**Remarks**
This advanced command should be used only to delete references to a fault-tolerant root target that does not exist. It works only on domain-based roots.

### Caution

- This command is essentially a problem/corruption repair tool. Do not confuse it with commands such as **/RemFtRoot** or **/Clean**.

The command will fail if Direct Mode was unable to initialize.

**Sample Usage**
```
dfsutil /UnmapFtRoot /root:\\mydomain.com\namespaceroot /server:\\otherservername /share:\\myserver\share
```

**/Clean**
A troubleshooting option which removes a reference to an obsolete root.

**Syntax**
**dfsutil /clean /server:** *hostServer* **/share:** *rootname* [**/verbose**]

**Parameters**
**/server: *hostServer***
The server where the obsolete root existed.

**/share: *rootname***
The root reference to remove.

**Remarks**
If a root was not removed properly (by using the **/RemFtRoot** command), other root target servers may still try to reference the obsolete root. This option fixes the incorrect references.

This command contacts the registry of the specified system to delete obsolete references. It does not affect the Domain Controller or the Active Directory. This option should not be confused with commands such as **/UnmapFtRoot** and **/RemFtRoot**.

**/PktFlush**
Flushes the client's locally cached target referral list provided by the DFS server. When the client tries to access the corresponding link, this forces the client to refresh the referral list of targets from the DFS server. Some of the entries in the PKT may not get flushed, especially if DFS is in the process of using the referrals.

**Syntax**
**dfsutil /pktflush**

**Remarks**
This is a DFS client-side operation.

### Important

- This option should be avoided unless absolutely necessary. Under normal DFS operating conditions, there is no reason to

flush the existing referral list.

DFS clients cache the portions of the DFS namespace (PKT) for the duration of time specified in the Distributed File System Manager and referred to as the Time to Live (TTL). For DFS version 4.1, the PKT was cached for a hard-coded seven (7) days. Servers running Windows 2000 use 1800 seconds (30 minutes) as the default TTL. All Microsoft DFS clients delete the PKT for a given folder in the DFS tree if not accessed by the TTL expiration or when the client is rebooted, whichever occurs first.

Computers running Windows 2000 and Windows XP operating systems support the DFS tab in the Windows Explorer property sheet, which uses the **NetDFSGetClientInfo()** and **NetDFSSetClientInfo()** APIs to show the list of alternative paths residing in the volume, and which allows choosing another alternative (refresh PKT) without having to reboot or wait for TTL to expire.

DFS clients that run an operating system other than Windows 2000 or Windows XP must reboot or wait for the TTL for a cached portion of the DFS tree to expire.

**/SpcFlush**
Forces the client to fetch the latest information on the trusted domains and their domain controllers, when the client programs try to access a corresponding link or root. By using this option, the client flushes out its cached knowledge about the trusted domains and the domain controllers of these domains.

**Syntax**
**dfsutil /spcflush**

**Remarks**
This is a DFS client-side operation.

**/PurgeMupCache**
Resets the client's knowledge about the various sites' information. This is a troubleshooting option which should only be run on the client.

Clears the client MUP cache, preventing confusion about the current provider when such names conflict. Except for a temporary performance hit, this command has no other adverse effects. This command does not affect any DFS metadata. If this command is not run, and the namespace is not accessed, the obsolete cache entry eventually expires.

**Syntax**
**dfsutil /purgemupcache**

**Remarks**
This is a DFS client-side operation.

The MUP cache keeps information about both DFS and other shares on the client system. You create a non-DFS (for example, SMB) share and access it before mapping a DFS namespace by the same name on it. The MUP cache might still think that the share is served by the previous provider (SMB) although DFS is the correct provider now.

**/RemoveReparse:absolute_directory_path**
Removes all DFS reparse directories under a given absolute path directory/hierarchy.

**Syntax**
**dfsutil /removereparse:** *absolute_directory_path* [**/viewdfsdirs**]

**Parameters**
***absolute_directory_path***
The AbsoluteDirectoryPath is the path of the directory tree under which your reparse directories exist, all of which you intend to remove.

**[ /viewdfsdirs]**
See **/viewdfsdirs** for more information

**Remarks**
This option can be used as an additional parameter to **/viewdfsdirs**. In this context, it removes all the DFS reparse directories under a specified volume.

**Sample Usage**
The following syntax removes all DFS reparse directories under the specified directory. `dfsutil /RemoveReparse: c:\dfspath\dfsshares`

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dmdiag.exe: Disk Manager Diagnostics**
This command-line tool displays system state and configuration information describing disk storage.

DmDiag displays the following information for the computer on which it is run:

- Computer name and operating system version
- Physical disk to disk type
- Mount points
- LDM file versions
- Drive letter usage, GetLogicalDrives(), GetDriveType()
- \Device
- Symbolic links
- ldmsize
- Kernel list
- Disk partition information

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
For more information, see Disk Management overview.

**System Requirements**
The following are the system requirements for DmDiag:

- Windows Server 2003 or Windows XP Professional

**File Required**

- Dmdiag.exe

# Dmdiag Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DmDiag Examples**

**Example 1: Write disk configuration to file**

If you want to write disk configuration information to a file named Diskconf.txt, type the following at the command line:

```
dmdiag -f c:\data\diskconf.txt
```

**Example 2: Display disk configuration**

If you want to display disk configuration information in the command window, type the following at the command line:

```
dmdiag
```

**Sample DmDiag output**

```
---------- Computer Name and OS Version ----------

       Computer name: server2
            NT build: 3675

# Dmdiag Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DmDiag Syntax**

DmDiag uses the following syntax:

**dmdiag** [**/v**] [**/f** *FileName*]

**Parameters**

**/v**

Outputs verbose information. Verbose output includes the following fields: Computer Name and OS Version, LDM File Versions, Mount Points, Drive Letter Usage, Drive Type, Dynamic Disk Information, LDM Volume Information, Device Objects, DMIO Kernel List, LDM Disk Header HarddiskX, LDM Disk Config HarddiskX, LDM Disk KLOG HarddiskX, DMAdmin Simple Query, and DMAdmin Verbose Query.

***/f FileName***

Specifies the file name for the output file. If omitted, the file name defaults to Dmdiag.txt.

**Note**

- By default, DmDiag output includes the following:

| Field | Description |
|---|---|
| Dynamic Disk Information | Displays the disk group name and ID as well as the list of dynamic disks belonging to the group. For each disk the disk extents and the volumes to which these extents belong are displayed. |
| LDM Volume Information | Displays the list of dynamic volumes. For each volume the disk extents are displayed. |

# Dskprobe Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dskprobe.exe: DiskProbe**
This GUI tool is a sector editor for drives on computers running Windows XP and Windows Server 2003. A user with local Administrator rights can use DiskProbe to directly edit, save, and copy data on a physical hard drive that is not accessible in any other way.

This tool can help you prepare for disk-based problems by saving critical disk structures before problems arise. Documenting and preserving these disk structures, such as the Master Boot Record (MBR) and boot sector, provides a fallback in case of disk corruption. DiskProbe can also be used to resolve problems that you might encounter. With it, you can edit and repair disk sectors on a byte-by-byte basis if corruption occurs.

You can use DiskProbe to replace the Master Boot Record, repair damaged partition table information, and repair or replace damaged Partition Boot Sectors or other file system data. The tool can also save Master Boot Records and Partition Boot Sectors as files. They can then be replaced if the sectors become damaged at a later time. These on-disk data structures are not accessible through the file system, and so are not saved by any backup programs currently available.

### Caution

- Before you make changes with a low-level tool such as DiskProbe, make sure that a reliable, complete backup of the drive is available. Misuse of DiskProbe might make all data on the drive or volume permanently inaccessible.

  DiskProbe and other sector editors function at a level "below" the file system, so the normal checks for maintaining disk consistency are not enforced. This tool gives the user direct access to every byte on the physical disk without regard to access privilege, which makes it possible to damage or permanently overwrite critical on-disk data structures.

**Concepts**
The Master Boot Record (MBR) is created when the disk is partitioned. The MBR contains a small amount of executable code called the master boot code, the disk signature, and the partition table for the disk. At the end of the MBR is a 2-byte structure called a signature word or end of sector marker, which is always set to 0x55AA. A signature word also marks the end of an extended boot record (EBR) and the boot sector.

When you start a computer from the hard disk, the system BIOS code identifies the startup disk and reads the MBR. The master boot code in the MBR searches for the active, primary partition on the hard disk. Occasionally the MBR can become corrupted. This can be caused by human error, hardware problems, power fluctuations, viruses, and other factors.

### Note

- You can also use the Recovery Console to rewrite the MBR to resolve a corrupted MBR on a startup disk.

**Corresponding UI**
DiskProbe provides its own user interface.

**System Requirements**
The following are the system requirements for DiskProbe:

- Windows Server 2003

**Files Required**

- Dskprobe.exe
- Dskprobe.chm
- LoIOSrv.dll

# Ftonline Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Ftonline.exe: Fault Tolerant Disk Mounter**
This command-line tool enables an administrator to mount and recover files from a fault tolerant disk created in a previous version of Windows. This tool is useful if you failed to upgrade your disks to dynamic disks, or failed to back the up your data before installing Windows Server 2003.

### Notes

- You must run FTOnline from the command window.
- FTOnline only mounts the disks as read-only to allow recovery of data. You can then back up your data, recreate the fault tolerant volumes, and restore your data.
- Disks mounted with FTOnline are not persistent. The disks will not be remounted when the computer is restarted.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Fault tolerant volumes on basic disks are no longer supported in Windows Server 2003.

Fault tolerant volumes are disks that use some type of RAID configuration to increase either performance or reliability. Windows Server 2003 supports disk striping (RAID-0), disk mirroring (RAID-1), and disk striping with parity (RAID-5).

A basic disk is a physical disk with primary and extended partitions. These disks are accessible from earlier versions of Windows.

**System Requirements**
The following are the system requirements for FTOnline:

- Windows Server 2003

**File Required**

- Ftonline.exe

# Ftonline Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**FTOnline Remarks**

**FTOnline Usage**
This is a recovery tool for use in an emergency situation, and should not be used on a regular basis. It is used for emergency recovery of data when the computer running Windows Server 2003 does not have its data backed up.

Because Windows 2000 supports dynamic disks, you should upgrade your fault tolerant volumes to dynamic disks before installing Windows Server 2003. However, because Windows NT 4.0 does not support dynamic disks, you will need to back up your data before upgrading from Windows NT 4.0.

# Ftonline Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**FTOnline Examples**

**Example: Mount an Inaccessible Fault Tolerant Disk**
In this example, you install a product from Windows Server 2003 and discover that a mirrored partition containing company data is assigned a letter, but is inaccessible. You look in Disk Administrator and see that it is labeled **e:**. To recover the data, type the following:

```
ftonline e:
```

This mounts the disk as a read-only volume, enabling you to back up the data. Once you back up the information, delete the volumes and recreate them as dynamic volumes, then restore the data from the backup.

# Health_chk Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Health_chk.cmd: FRS Health Check**
This command-line tool retrieves FRS-related state information from the specified domain controller or server. It collects and provides administrators with in-depth data that can be used to monitor or troubleshoot an FRS system.

Health_Chk calls a series of tools for the output they produce. It can be run against a remote server, however, running the script directly on the server to be analyzed enables the tools to gather additional useful data not available when the script is run remotely.

- For monitoring, Health_Chk should be run regularly against hub servers and a small selection of spoke servers. Building a simple script that invokes these health checks and collects them to a single server for analysis is very valuable - especially when scheduled to run on a daily basis.

- For troubleshooting, Health_Chk should be run against the server that shows the symptoms of replication failures, but also, ideally, against all other related servers. It may not be possible to collect data for all servers in a large enterprise, but including direct replication partners or, if this is still too much, a good sample set of them, will provide more complete information about your topology.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
The File Replication Service (FRS) is a multi-master file replication service for NTFS that allows member machines to be interconnected in an arbitrary topology and uses last-writer-wins conflict resolution. It uses authenticated Remote Procedure Call (RPC) with encryption as the communication protocol between members, and can also support disconnected operation. FRS supports multiple replication sets per computer, each with potentially distinct topology.

**System Requirements**

- Windows 2000 Server or Windows Server 2003

- File Replication Service running on the target server(s)

- Administrator priveleges on the account running Health_Chk.

**Files Required**

- Health_chk.cmd

- Reg (Provided with the system)

- Eventquery.vbs (Provided with the system)

# Health_chk Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Health_Chk Remarks**
**Logs and Output Files**
Health_Chk retrieves FRS-related state information from the specified domain controller or server and stores this information in text files. These text files provide administrators with in-depth data that can be used to monitor or troubleshoot an FRS system.

Health_Chk can take quite a while to run. The script may collect huge amounts of data. This is especially true if you encounter problems with full staging areas, though staging area problems are not common on computers running Windows 2000 SP3 and later.

The text files are written to a specified directory using the name of the target machine.

**Note**

- Organizations typically have well-established tools for collecting event logs from Windows systems, and these should also continue to be used. The event log data collected by Health_Chk contains only a subset of the full event information.

The following lists the specific text files that Health_Chk creates, with a description of the data they contain:

| File | Description |
|---|---|
| ds_showconn.txt | The output from repadmin /**showconn**. |
| ds_showreps.txt | The output from repadmin /**showreps**. |
| evl_application.txt | Application event logs in text format. |
| evl_dns.txt | DNS server event logs in text format. |
| evl_ds.txt | Active Directory event logs in text format. |
| evl_ntfrs.txt | FRS event logs in text format. |
| evl_system.txt | System event logs in text format. |
| ntfrs_config.txt | Output from ntfrsutl **configtable**: Lists all replica sets. |
| ntfrs_ds.txt | The output from ntfrsutl **ds**: Displays the machine (FRS) topology definition in the local Domain Controller, from the perspective of the machine. |
| ntfrs_errscan.txt | A scan of error messages from the FRS debug logs. |
| ntfrs_inlog.txt | The output from ntfrsutl **inlog**: Shows inbound Change Orders (CO's). |
| ntfrs_machine.txt | A listing of free disk space on all drives. |
| ntfrs_outlog.txt | The output from ntfrsutl **outlog**: Shows outbound Change Orders (CO's). |
| Ntfrs_reg.txt | The registry data from HKLM\system\currentcontrolset\services\NtFrs and below. |
| Ntfrs_sets.txt | The output from ntfrsutl **sets**: A list of inbound and outbound connections and their status. |
| Ntfrs_sysvol.txt | The output from 'dir /s *.*' of the SYSVOL share. |
| Ntfrs_version.txt | The output from ntfrsutl **version**: Shows FRS version information. |

**Configuration Settings**
Health_Chk does not modify any configuration settings either on the target computer or in the Active Directory. The script only

reads configuration and status information.

# Health_chk Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Health_Chk Examples**

In this example, the remote computer, DfsRepA, is part of a DFS replica set. It is not a domain controller, so the warnings about no SYSVOL are reasonable.

```
C:\tools>health_chk logdir DfsRepA
```

When given this command, Health_Chk runs a number of tools and scripts, generates text output files in the logdir folder, and then exits.

```
Please WAIT....

 NTFRSUTL checks are running ...

 Dumping FRS inbound and outbound logs ..

 Dumping FRS registry parameters ...

SYSVOL check is running

The network path was not found.

SMB/DFS check is running

repadmin /showreps frsdoga is running

repadmin /showconn frsdoga is running

dcdiag /v /s:frsdoga is running

 Scanning eventlogs ...

 Scanning FRS debug logs for error/warning info ...

 Done ...
```

After Health_Chk completes, twenty text log files are created. The data in these generated text files can be used to monitor and troubleshoot the FRS system. For a description of the contents of the text files, see the Logs and Output Files section on the Health_chk Remarks page.

```
C:\tools>dir logdir\DfsRepA

 Volume in drive C is OS_VOL

 Volume Serial Number is 4D59-4447

 Directory of C:\Program Files\Support Tools\logdir\DfsRepA

# Iologsum Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Iologsum.cmd: FRS Inbound and Outbound Logs Summary Report Tool**
This command-line tool processes the output generated when the NtfrsUtl tool is run with the **inlog**, **outlog**, or **idtable** parameters.

Running NtfrsUtl **inlog** or NtfrsUtl **outlog** creates a summary inbound or outbound NtfrsUtl log report showing the pending change orders for the replica member. Running NtfrsUtl **idtable** creates a report with version information for each file in the replica tree; this version information tracks the last change order accepted for that particular file or directory. Running IOLogSum then sorts and formats this NtfrsUtl output.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
The File Replication Service (FRS), first introduced in Windows 2000, is an essential element of the Microsoft Active Directory technologies. The Active Directory service uses FRS for SYSVOL replication. FRS can also be used with the Microsoft Distributed File System (DFS) technologies for automatic replication of content between alternating targets. For more information on FRS and Active Directory replication please see the Windows Server 2003 Technical Reference.

A replica set consists of two or more computers configured to replicate the contents of a file folder. The individual computers are referred to as replica members.

FRS maintains logs of *change orders* that are either received from replication partners (the inbound log), or are to be sent to outbound replication partners (the outbound log).

The inbound log stores pending change orders to be processed. As entries are processed, FRS sends acknowledgment to the inbound partners. Data stored in the inbound log includes the change order's globally unique identifier (GUID), file name, object ID, parent object ID, version number, and event time.

The outbound log stores pending change orders to be sent to outbound partners. Change orders remain in the outbound log until all outbound partners receive and acknowledge the change. Data stored in the outbound log is the same as that stored in the inbound log. Also in the outbound log is the leading (next change) and trailing (last acknowledged) index for each partner.

The outbound logs can become quite large, particularly when replica members are unavailable, links between replicas are slow, replication hours are restricted, or a large number of changes occur. For example, even when a member for a given replica set is unavailable, outbound log entries are maintained until the member becomes available. When the changes are then sent, the inbound partner sends all changes in log file order.

**System Requirements**

- Windows 2000 Server or Windows Server 2003
- Perl 5.005 521e or 522e

**Files Required**

- Iologsum.cmd
- Ntfrsutl.exe

# Iologsum Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IOLogSum Remarks**
**Before Using IOLogSum**
If Perl is not installed on your system, if you are connected to the Internet, you can download a free version from the ActiveState Web site.

**IOLogSum Report**
When used with NtfrsUtl **inlog** and NtfrsUtl **outlog**, the IOLogSum report can be used to determine which files are involved in FRS replication, and what has caused them to replicate. When used with NtfrsUtl **idtable**, IOLogSum can generate a report describing the state of all files and folders known to an FRS member.

Familiarity with FRS concepts and terminology is required in order to interpret IOLogSum reports.

Each IOLogSum report starts by identifying the name of the file that it processed, and the sort options used to generate the report. Then, for every replica set in which the computer participates, the report lists one row per change order.

The following table lists and describes each column in the report.

| Column Heading | Description |
|---|---|
| **SeqNumber** | Specifies the unique sequence number for the change order. For NtfrsUtl **idtable** reports, this is always reported as 00000000. |
| **EventTime** | Specifies the USN Journal Entry Timestamp; in other words, the time the file was changed on the originating machine. |
| **FileVersNum** | Specifies the file version number, incremented each time the file is closed. |
| **FileUsn** | Specifies the USN that the file must match on the Fetch request. |
| **FileSize** | Specifies the file size (in KB). |
| **FileGuid** | Specifies the object ID of the file or directory. For brevity, only the last 8 digits are printed. |
| **OriginatorGuid** | Specifies the GUID of the originating member. For brevity, only the last 8 digits are printed. The originator GUID can be mapped back to the server name by searching the NtfrsUtl **sets** output. |
| **Cxtion** | Specifies the GUID of the remote connection – for brevity, only the last 8 digits are printed |
| **FileName** | Specifies the Unicode file name. |

| | |
|---|---|
| **Flags** | Specifies a valid Change Order Flag. Valid flags are shown in the following list.<br>• **Abort** - Set when CO is being aborted.<br>• **VVAct** - Set when VV activate request is made.<br>• **Content** - Valid content command.<br>• **Locn** - Valid location command.<br>• **LclCo** - CO is locally generated.<br>• **Retry** - CO needs to retry.<br>• **InstallInc** - Local install not completed.<br>• **Refresh** - CO is an upstream-originated file refresh request.<br>• **OofOrd** - Do not check/update version vector.<br>• **NewFile** - If CO fails, delete IDTable entry.<br>• **DirectedCo** - This CO is directed to a single connection.<br>• **DemandRef** - CO is a downstream demand for refresh.<br>• **VVjoinToOri** - CO is from vvjoin to originator.<br>• **MorphGen** - CO generated as part of name morph resolution.<br>• **MoveinGen** - This CO was generated as part of a sub-dir MOVEIN.<br>• **OidReset** - This CO reset the Object ID (OID) back to the FRS defined value.<br>• **CmpresStage** - The stage file for this CO is compressed.<br>• **MD5** - The MD5 hash of the file is included.<br>• **DELETED** - The file has been deleted. On **idtable** reports, this indicates that the record is a tombstone, ensuring the file remains deleted throughout the replica set. |

| | |
|---|---|
| **LocationCmd** | Specifies the Change Order Location command. Valid Location Commands are shown in the following list.<br>• **CREATE** - Create a new file or directory.<br>• **DELETE** - Delete a file or directory.<br>• **MOVEIN** - Rename a file or directory from a point outside the Replica Tree, into a Replica Tree on the same volume.<br>• **MOVEOUT** - Rename a file or dir from a point inside the Replica Tree to a point outside the Replica Tree on the same volume.<br>• **MOVERS** - Rename a file or directory from one Replica Tree to another Replica Tree on the same volume (currently unsupported).<br>• **MOVEDIR** - Rename a file or directory from one directory to another in the same Replica Tree. |

| | |
|---|---|
| **ContentCmd** | Specifies the Change Order content changes from the USN reason. Flags set in the NTFS change log describing modifications to the file.<br>• **Close** - Change log close record.<br>• **Create** - File or directory was created.<br>• **Delete** - File or directory was deleted.<br>• **RenNew** - File or directory was renamed.<br>• **DatOvrWrt** - Main file data stream was overwritten.<br>• **DatExt** - Main file data stream was extended.<br>• **DatTrunc** - Main file data stream was truncated.<br>• **Info** - Basic info change (attrib, last write time, etc.).<br>• **Oid** - Object ID change.<br>• **StreamNam** - Alternate data stream name change.<br>• **StrmOvrWrt** - Alternate data stream was overwritten.<br>• **StrmExt** - Alternate data stream was extended.<br>• **StrmTrunc** - Alternate data stream was truncated.<br>• **EAChg** - Extended file attribute was changed.<br>• **Security** - File access permissions changed.<br>• **IndexableChg** - File change requires re-indexing.<br>• **HLink** - Hard link change.<br>• **CompressChg** - File compression attribute changed.<br>• **EncryptChg** - File encryption changed.<br>• **Reparse** - Reparse point changed. |

By default, the records are sorted by sequence number, but it is possible to sort by other columns.

- Sorting by File GUID makes it easy to detect repetitive changes to single files and the times at which they occurred (for example, once per hour).
- Sorting by Event Time is useful for identifying older change orders that may indicate a particular partner has been unavailable for a while. The IOLogSum report, coupled with the report that Connstat Overview generates, can tell you what change orders are pending for the delinquent partner.

# Iologsum Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IOLogSum Syntax**

IOLogSum uses the following syntax:

**iologsum** [**-sort=***Option*] *DataFile*

**Parameters**

**-sort= *Option***

Specifies a sort order for the IOLogSum report. The following table lists are valid values for *Option*:

| Option | Description |
|---|---|
| **seqnum** | Sorts output by sequence number. This is the default sort order. |
| **version** | Sorts output by file version number. |
| **filename** | Sorts output by file name. |
| **size** | Sorts output by file size. |
| **fileguid** | Sorts output by file GUID. |
| **origguid** | Sorts output by originator GUID. |
| **cxtion** | Sorts output by cxtion name/GUID. |
| **eventtime** | Sorts output by event time. |

***DataFile***

Specifies a file that was created by running NtfrsUtl with the **inlog**, **outlog** or **idtable** parameters. This is a required parameter.

Note

- The Perl interpreter should be installed and in the path for this command to function. See Iologsum Remarks for details on obtaining Perl.

**Sample Usage**

```
iologsum ntfrs_inlog.txt > in.txtiologsum -sort=fileguid ntfrs_outlog.txt > out.txt
```

# Rsdiag Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Rsdiag.exe: Remote Storage Diagnostic Utility**
This command-line tool examines Remote Storage (HSM) databases and displays diagnostic information in text format about migration jobs, managed volumes of the version of NTFS file system used in Windows Server 2003, and physical media, as well as other Remote Storage information useful for system analysis.

Remote Storage stores its data in a series of databases and collection files in the *Systemroot*\System32\RemoteStorage directory. The data enables the Remote Storage service to associate file placeholders and file data, and to track managed and unmanaged volumes, files on managed volumes, jobs, and physical media. RsDiag lets you display this data in easy-to-read format on the console and in text files.

You can use RsDiag to display the following information:

- The contents of the Remote Storage database (EngDb), the FSA database (FsaDb: premigrated files), the FSA temporary unmanaged database, and the collection files that store the configuration options for each volume (RsFsa.col) and for the installation (RsEng.col).
- Version information for the configuration collection files.
- Volumes that are eligible for Remote Storage management.
- Properties of managed volumes.
- Properties of physical media used for Remote Storage.
- The physical location of the file data for premigrated and truncated files.
- Remote Storage jobs scheduled on the system, including migration, validation, free space, managed, and unmanaged jobs. You can also use RsDiag to stop a job in progress.
- The internal recall queue. You can use RsDiag to delete a job from the recall queue, preventing a file from being recalled.
- Descriptions of error codes generated by Rss.exe and found in the Service and Driver logs in Event Viewer.

RsDiag works with the Rsdir Overview to help diagnose problems in the Remote Storage databases and, if necessary, recover lost data.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Remote Storage extends the disk space on the computer by copying files to remote storage based on criteria that you establish, including the location and size of the files, and the amount of free space on the volume. Files are recalled from remote storage automatically when they are accessed.

Files stored remotely appear unchanged in Microsoft Windows Explorer. Users open them by the same methods, but the files do not consume any local disk space. Instead, Remote Storage uses NTFS Reparse Points as placeholders for the files on the local volumes. The Reparse Points store information about the file, including its actual location in remote storage.

**System Requirements**
The following are the system requirements for RsDiag:

- This version of RsDiag runs only on Windows Server 2003. A version of RsDiag for Windows 2000 is included in the Support Tools directory of the Windows 2000 Server operating system.

- The user must be a member of the Administrators group on the computer.
- RsDiag is a local computer tool. You cannot use it to display information about volumes on a remote computer.

**Files Required**

- Rsdiag.exe
- Rstools.dll

The Rstools.dll library must be registered on the system. The Support Tools installation process registers the DLL. However, if you copy these files to another computer, you must register the DLL manually by typing the following at the command prompt:

```
regsvr32 RsTools.dll
```

### For More Information

For more information about Remote Storage Server, download the "Enterprise Class Storage in the Next Generation of Windows NT" document from the Microsoft Windows 2000 Server Web site.

# Rsdiag Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RsDiag Examples**
**Example 1: Display the engine database**
The following command displays diagnostic information about the Remote Storage Engine database (EngDb).

```
rsdiag /d e
```

The Engine database consists of the following three tables:

- The **Segment Table** associates the placeholder for a file to the location in remote storage where the file data is stored. This is done by mapping the BAG (migration group) identifier and location to the media storage.
- The **Media Table** associates the media identifier to an external media name that is used by the media management subsystem.
- The **BAG Information Table** contains global information about each BAG (migration group). There is one entry for each BAG.

**Segment Table**

| Short Name | Long Name | Description |
|---|---|---|
| **BagId** | BAG ID | A GUID that uniquely identifies the migration group of the file. A BAG is a group of files migrated in the same job and stored in a single data set (MTF/BKF) on the remote media. Remote Storage uses the BAG ID to locate and recall files. |
| **StartLoc** | BAG Segment Start Location | The starting position of this segment within the BAG. |
| **SegLen** | BAG Segment Length | The length of this segment of the BAG. This length can extend to the entire BAG or only a portion of the BAG. |
| **LocType** | Location Type | Indicates whether this location is a media location or a logical redirection to another BAG and location. |
| **PrimPos** | Primary Location Position Specifier | For media locations, this is a media identifier. For logical redirections, this is a BAG identifier. |
| **SecPos** | Secondary Location Position Specifier | For media locations, a starting location on media. For logical redirections, a BAG start location. |
| **IDB SeqNum** | | The database sequence number, indicating the sequence in which this record was originally added to the database |

**Segment Table dump example**

```
00000  BagId = {b010419f-fb1b-11d1-a1ba-00a0c9190447}, StartLoc = 3072, SegLen = 52224,
LocType = 0, PrimPos = {b0104199-fb1b-11d1-a1ba-00a0c9190447}, SecPos = 0  (IDB SeqNum
=      1)
```

**Media Table**

| Short Name | Long Name | Description |
|---|---|---|

| | | |
|---|---|---|
| **Id** | Media ID | |
| **NtmsId** | | The media handle of the media identifier for the Media Service. This is a Removable Storage Management (RSM) Media ID. |
| **StoragePoolId** | Storage Pool ID | A unique storage pool identifier. |
| **IDB SeqNum** | | The database sequence number, indicating the sequence in which this record was originally added to the database. |

**Media Table dump example**

```
00000  id = {b0104199-fb1b-11d1-a1ba-00a0c9190447} ntmsId = {da96022d-fb19-11d1-a1ba-
00a0c9190447} StoragePoolId = {e5390a42-fb19-11d1-a1ba-00a0c9190447} (IDB SeqNum =
1)
```

**BAG Information Table**

| Short Name | Long Name | Description |
|---|---|---|
| **Type** | | The record type. |
| **BagId** | BAG ID | A GUID created when the BAG is initially created. |
| **BirthDate** | BAG Birthdate | The date and time the BAG was created. |
| **Len** | Original BAG Length | The actual length of the BAG at create time. |
| **Type** | BAG Type | Not currently used. |
| **VolId** | Volume ID | The managed volume from which the data in this BAG was originally taken. |
| **DeletedAmount** | Deleted BAG amount | The amount of space within the BAG that has been deleted. Not currently used. |
| **RemoteDataSet** | Remote Data Set Number | The unique ID used on media to identify this session. |
| **IDB SeqNum** | | The database sequence number, indicating the sequence in which this record was originally added to the database. |

**Bag Information dump example**

```
00000 , Type = 2 BagId = {b010419f-fb1b-11d1-a1ba-00a0c9190447}, BirthDate = 06/03/1998
20:42:20, Len = 47051200, Type = 0, VolId = {9db6f302-fb1b-11d1-a1ba-00a0c9190447},
DeletedAmount = 0, RemoteDataSet = 1 (IDB SeqNum =      1)
```

**Example 2: Display the FSA database**

The following command displays the File System Agent (FSA) database. This database contains an entry for each premigrated file.

```
rsdiag /d f
```

The following is a sample display of an FSA database generated by using the **/d f** parameter:

```
Dump of DB: E:\WINDOWS\system32\RemoteStorage\FsaDb\{C0835F1E-01C1-804D-80B9-
FB1600000000}
  version = 1, # record types = 2
RecType =        1, Flags = 00000001, MaxSize =    65760, # keys =    3
  KeyType =        2, Size =       33, Flags = 00000001
  KeyType =        1, Size =       33, Flags = 00000002
  KeyType =        3, Size =       33, Flags = 00000001
RecType =        2, Flags = 00000001, MaxSize =    65708, # keys =    1
  KeyType =        1, Size =      254, Flags = 00000002
```

```
*** Dump of records of Type = 1 ***
00000  AccessTime = 12/17/2001 21:27:33 BagId = {7A4CBCE5-A0DB-4A74-9B0A-7B9AF561850F},
BagOffset = 1061888, FileId = 36028797018964002 Waiting for close = FALSE, Offset = 0,
Path = \test2.bkf, Size = 4002816 RecallTime =   01/01/1601 00:00:00, File USN = 1168
(IDB SeqNum =      2)
00001  AccessTime = 12/20/2001 17:05:56 BagId = {7A4CBCE5-A0DB-4A74-9B0A-7B9AF561850F},
BagOffset = 3072, FileId = 7921831744544702504 Waiting for close = FALSE, Offset = 0,
Path = \blslsslsl.txt, Size = 1057792 RecallTime = 01/01/1601 00:00:00, File USN = 920
(IDB SeqNum =      1)
00002  AccessTime = 12/20/2001 17:05:56 BagId = {7A4CBCE5-A0DB-4A74-9B0A-7B9AF561850F},
BagOffset = 5065728, FileId = 281474976710697 Waiting for close = FALSE, Offset = 0,
Path = \vrdsgsre.txt, Size = 2884608 RecallTime =  01/01/1601 00:00:00, File USN = 1424
(IDB SeqNum =      3)

*** File System Agent Database Dump Complete ***
```

The following table lists and describes the data fields in the record dump.

| Property | Description |
|---|---|
| **AccessTime** | The date and time that the file was last accessed, in Coordinated Universal Time (UTC). Migrating and recalling files does not change this value. |
| **BagID** | A GUID that uniquely identifies the migration group of the file. A BAG is a group of files migrated in the same job and stored in a single data set (MTF/BKF) on the remote media. Remote Storage uses the BAG ID to locate and recall files. |
| **BagOffset** | The offset of the file into the BAG. |
| **FileId** | The remote storage identifier for the file. |
| **Waiting for Close** | This field is not currently used. |
| **Offset** | This field is not currently used. |
| **Path** | The path for this file. This information may be compressed. |
| **Size** | The logical size of the premigrated data. |
| **RecallTime** | The date and time that the system most recently attempted to retrieve this file from remote storage, in Coordinated Universal Time (UTC). Files that have never been recalled have a recall date of 01/01/1601. |
| **File USN** | The Update Sequence Number (USN) for this file. |

**Example 3: Cancel a validation job**

The following series of commands finds a running validation job and then cancels the job before it completes. This procedure can be used on all types of Remote Storage jobs, such as migration jobs and jobs that force truncation to create free space on the volume.

The first command lists the Remote Storage jobs scheduled on the system:

```
rsdiag /j
```

In response, RsDiag displays the job list:

```
Name                                          JobState   IsUsers Done   DoneOk
Manage                                        Idle       False   Ok     Ok
Remote Storage Automatic Validate D           Active     Ok      False  Ok
Remote Storage Remove D                       Idle       Ok      Ok     Ok
Remote Storage Automatic Validate E           Idle       Ok      Ok     Ok
Remote Storage Validate E                     Idle       Ok      Ok     Ok
Remote Storage Copy Files E                   Idle       Ok      Ok     Ok
Remote Storage Free Disk Space E              Idle       Ok      Ok     Ok
```

The display reveals that the "Remote Storage Automatic Validate D" job is running.

The following command displays more detailed information about this particular job:

```
rsdiag /j "Remote Storage Automatic Validate D"

  Name              : Remote Storage Automatic Validate D
  Identifier        : {e65a104f-2753-49e2-bf8d-41573e1bbc27}
  Hsm Identifier    : {4d6e0baf-6d9c-4048-af3f-ca10d94cc8f9}
  Run Identifier    : 1
  Max Sessions      : 2
  Is User Defined   : Ok
  Is Active         : True
  Did Finish        : False
  Did Finish Ok     : False

    Resource Name     : SERVER01\NTFS\D:
    State             : Done
    Starting Path     : \
    Current Path      : \
    Start Time        : 03/15/2001 20:22:00
    Stop Time         : 03/15/2001 20:22:00
    Sub-Run Id        : 0

      Phase Name        : Scan
      State             : Done
      Media State       : Idle
      Priority          : Normal
      Start Time        : 03/15/2001 20:22:00
      Stop Time         : False
      Elapsed Time      : 0 days, 00:00:03
      Items             : 0
      Size              : 0
      Skipped Items     : 0
      Skipped Size      : 0
      Error Items       : 0
      Error Size        : 0
```

The following command stops the job:

```
rsdiag /c "Remote Storage Automatic Validate D"
```

Remember that stopping a job does not remove the job from the schedule. Also, stopping a job does not reverse actions already completed by the job. For example, if you cancel a free-disk-space job in progress, it does not restore data to files that were truncated earlier in the job.

**Example 4: Determine the tape on which a file is stored**

The following series of commands finds the data for a file on a physical tape. The first command uses Rsdir Overview, a tool that enumerates the files in a directory and adds Remote Storage properties to the attributes typically displayed.

```
C:\Inside Win2K>rsdir

Showing information for <\\?\C:\Inside Win2k\*.*>

Status        Attributes    Physical     Logical        Migrate Time File Name
------        ----------    --------     -------        ------------ ---------
non-HSM      --D--------           0           0                  NA .
non-HSM      --D--------           0           0                  NA ..
non-HSM      A-------R--          47          47                  NA Autorun.inf
non-HSM      --D-----R--           0           0                  NA Debuggers
non-HSM      --D-----R--           0           0                  NA Ebook
truncated    A-----OPR-Z           0       10004 08\11\2001 09:07:27 Readme.txt
non-HSM      --D-----R--           0           0                  NA Setup
non-HSM      --D-----R--           0           0                  NA StartCD
truncated    A-----OPR-Z           0       28672 04\27\2001 17:27:12 StartCD.exe

                3 File(s)              47 bytes
                4 Dir(s)            38676 bytes required to recall offline files
```

This display shows that the Readme.txt file is truncated and was migrated on 8/11/2001.

The next command displays the location of the Readme.txt file on a remote physical storage medium. This command uses the **/w** parameter to display the location of the file in secondary storage. It includes the complete path to the file and, because the directory name includes spaces, it encloses the path in quotation marks.

```
rsdiag /w "c:\inside win2k\readme.txt"
```

```
        File <c:\inside win2k\readme.txt> is truncated.
        Located on media <000302> in dataset 28
        Bag ID: <{7eae2dea-6634-4ae5-982a-c987c01ffa38}>
```

The output displays the BAG ID, the internal media name (00302), and the dataset in which data for this file is stored (28).

The final command displays all media used by Remote Storage on this system:

```
rsdiag /s
```

```
Showing:  <RS-SERVER01-4>
        Description     :  RS-SERVER01-4
        Name            :  000302
        Media ID        :  {4464192f-8164-422d-8541-43577071cb24}
        RSM ID          :  {7cb7bd09-888b-4021-bfda-400cfeb2e792}
        Media type      :  4
        Last update     :  12/20/2001 10:04:03
        Last error      :  Ok
        Recall only     :  FALSE
        Capacity        :  19036958720
        Free Bytes      :  3211743232
        Next Data Set   :  81
        Recreate        :  FALSE

Showing:  <RS-SERVER01-3>
        Description     :  RS-SERVER01-3
        Name            :  000301
        Media ID        :  {f926fccb-aa62-4116-8d4e-1d5b7eb8a4f3}
        RSM ID          :  {85e3bc66-d196-49f0-abf0-eb5c15ba2609}
        Media type      :  4
        Last update     :  08/15/2001 09:06:21
        Last error      :  Ok
        Recall only     :  FALSE
        Capacity        :  19036958720
        Free Bytes      :  20130557952
        Next Data Set   :  4
        Recreate        :  FALSE
```

The display reveals that the media known internally by the media name 00302 is a tape (media type 4) commonly known as RS-Server01-4. Optical media are listed as media type 3. Therefore, the data for the Readme.exe file is stored on the RS-SERVER01-4 tape.

**Example 5: Display the version information for a collection file**

The following command displays version information about Remote Storage components:

```
rsdiag /i
```

The following fields are included in the output:

| Name | Description |
|---|---|
| **Title** | Component title |
| **Registry Name** | Component title in registry |
| **Identifier** | Unique identifier of this resource |
| **DB Version** | Component's database version |
| **RS Version** | Remote Storage build number |

| | |
|---|---|
| **Windows Ver** | Windows version |
| **Windows Build** | Windows build number |
| **DB Path** | Path to the component collection file |

The command yields the following output:

```
RsTools
  Build        :  601

FSA
  RegistryName   :  Remote_Storage_Server
  Identifier     :  {4d6e0baf-6d9c-4048-af3f-ca10d94cc8f9}
  Db Version     :  1
  RS Version     :  611
  Windows Ver    :  5.1
  Windows Build  :  3590
  DbPath         :  C:\WINDOWS\system32\RemoteStorage\RsFsa.col

HSM
  RegistryName   :  Remote_Storage_Server
  Identifier     :  {4d6e0baf-6d9c-4048-af3f-ca10d94cc8f9}
  Db Version     :  3
  RS Version     :  611
  Windows Ver    :  5.1
  Windows Build  :  3590

  DbPath         :  C:\WINDOWS\system32\RemoteStorage\RsEng.col
```

# Rsdiag Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RsDiag Syntax**

**rsdiag** [**/d** *DBType OutputFile*] [**/i**] [**/m**] [**/v** [*DriveLetter*]] [**/s**] [**/w** *Path**FileName*] [**/j** [*JobName*]] [**/c** *JobName*] [**/r** [**/f**]] [**/x** *RecallJob*] [**/e** *ErrorCode*] [**/t**] [**/?**]

**Parameters**

**Note**

- Except as noted, you can use only one RsDiag parameter with each command.

**/d *DBType OutputFile***

Writes the specified Remote Storage database to the specified text file. Typically, support engineers use these files to identify or resolve metadata errors.

*DBtype* identifies the database. This variable is required with **/d**. The following table lists valid values for *DBType*.

| DBType | Database type | Description |
|---|---|---|
| **e** | Engine database (EngDb) | The primary remote storage database for the installation. |
| **f** | FSA database (FsaDb) | The FSA database stores a list of premigrated files on each volume.<br><br>In *premigrated files*, the file data has been copied to remote storage, but it also remains on the local volume as long as space is available. Files that were migrated and then recalled are considered to be premigrated. |
| **u** | FSA temporary unmanaged database | A temporary database that stores FSA data for a volume during the unmanaged process. When the process is complete, this database is deleted. |
| **a** | FSA persistent (RsFsa.col) | A collection file that stores the configuration options set for each volume. |
| **n** | Engine persistent (RsEng.col) | A collection file that stores configuration options set for the Remote Storage installation. |

*OutputFile* is the full path and file name of the text file that RsDiag creates to store this display; for example, C:\RSS\myrssdb.txt. The full path is required, even when the file is in the local directory. All directories in the path must exist before you run the command. Use quotation marks to enclose names that contain spaces.

**/i**

Lists and displays version information for the collection (.col) files on this system. The collection files store configuration information for Remote Storage. To display the collection files, use the **/d a** or **/d n** parameter.

**/m**

Lists volumes on this system that are eligible for Remote Storage management.

**/v [*DriveLetter*]**

Lists the managed volumes on this system. With a drive letter, **/v** displays detailed information about the specified managed volume.

**/s**

Lists and describes the physical storage media used on this system.

**/w *Path* \ *FileName***

Finds the specified managed file in remote storage. This parameter displays the physical location of any file on a managed

volume. The display includes the physical storage medium on which the most current version of the specified file resides, and the data set of which the file is a member.

Specify the full path and file name of the file. The full path is required even when the file is in the local directory. Use quotation marks to enclose names that contain spaces.

To see which files are migrated, or to determine the Remote Storage status of a file, use Rsdir Overview.

**/j [*JobName*]**
Lists the Remote Storage jobs scheduled on this system. With a job name, **/j** displays detailed information about the specified job. Use quotation marks to enclose job names that include spaces.

This display lets you predict the duration of a job and compare the run time of different jobs.

**/c *JobName***
Stops a Remote Storage job in progress. This parameter stops the current run of the specified job. It does not affect the job schedule. To display the jobs scheduled for the system, use the **/j** parameter.

**Caution**

- This command stops the job, but does not cancel or reverse actions already completed by the job. Files processed before the job was stopped are not restored to their original state.

**/r [/f]**
Displays the jobs in the Remote Storage server's internal recall queue. The display includes the name and logical size of each recalled file. The **/f** (full) parameter adds the state of the recall, the user who initiated the recall, and the file offset into the media to the display.

**/x *RecallJob***
Deletes the specified recall job from the Remote Storage server's internal recall queue. Only pending recalls can be cancelled. To display the recall queue, use **/r**.

*RecallJob* is the name of the job that recalls the file. It consists of the full path to the file being recalled, including the server name. This value appears in the **Queued Recall** field of the **/r** display.

**/e *ErrorCode***
Explains HRESULT and WIN32 error codes. Type an *ErrorCode* value in decimal or hexadecimal format. The default is decimal. For hexadecimal error codes, prepend **0x** to the error code, for example, **0x81000005**.

**/t**
Reloads the trace files. This setting is for internal use only.

**/?**
Displays help information for the tool.

Rsdir Overview

# Rsdir Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Rsdir.exe: Remote Storage File Analysis Utility**
This command-line tool displays the Remote Storage status of files on local NTFS file system volumes of servers running Windows Server 2003. It is designed to be used on volumes managed by the Remote Storage service. RSDir supplements the enumeration feature of Dir.exe with information about the Remote Storage properties of the objects, such as whether the files reside in local or remote storage, and details of their migration and location.

RSDir displays the following information about files on volumes formatted with NTFS:

- File name and path
- Remote Storage status (Non-Hierarchical Storage Management (HSM), Premigrated, or Truncated)
- File attributes
- Size of files on local and remote media, including the size of the unnamed data stream (file content) and the size of file metadata, such as Reparse Points
- Time stamps: Create, Access, Modify, Migrate, Recall
- IDs: File ID, HSM ID, BAG ID
- Cyclic Redundancy Check (CRC) data: Algorithm type and value for each file and for each migrated data set (Microsoft Tape Format (MTF) or .BKF files)
- Offset of files in remote media

RSDir compiles its display from information stored in Reparse Points on the local volume. You can use this information to monitor the use of Remote Storage and to detect problems with Remote Storage management on the system.

You can use RSDir with the Rsdiag Overview to identify problems in the Remote Storage databases and recover lost data. RSDir and Rsdiag complement Rss.exe, the command-line version of the Remote Storage snap-in.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Remote Storage extends the disk space on the computer by copying files to remote storage based on criteria that you establish, including the location and size of the files and the amount of free space on the volume. Files are recalled from remote storage automatically when they are accessed.

Files stored remotely appear unchanged in Windows Explorer and users use the same methods to open them, but they do not consume any local disk space. Instead, Remote Storage uses NTFS Reparse Points as placeholders for the files on the local volumes. The Reparse Points store information about the file, including its actual location in remote storage.

RSDir displays information stored in the Reparse Points in a formatted display at the command line.

**System Requirements**
The following are the system requirements for RSDir:

- This version of RSDir runs only on Windows Server 2003 operating systems. A version of RSDir for Windows 2000 is included in the Support Tools directory of Windows 2000 Server.
- The user must be a member of the Administrators group on the computer.

- RSDir is a local computer tool. You cannot use it to display information about volumes on a remote computer.

**File Required**

- RSDir.exe

# Rsdir Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RSDir Remarks**
**General Information**

- RSDir displays information about the local computer only. You cannot use it to display information about files or directories on other computers.
- When you run RSDir without a path, or with an invalid or improperly specified path, RSDir displays the Remote Storage status of files in the local directory.
- RSDir displays time stamps in Coordinated Universal Time (UTC), not the time of the local computer.
- RSDir uses the standard set of NTFS file attributes. Truncated (remote) and premigrated files have the Archived (A), Reparse points (P), and Sparse (Z) attributes set. The Sparse attribute, which activates an efficient storage method for zero-filled files, is set for premigrated files even though they are not (yet) zero-filled. Only truncated files are set to Offline (O).

**RSDir Basic Display**
The following table lists and describes the fields in the basic RSDir display.

| Property | Description |
|---|---|
| Status | **Non-HSM**: The file resides only on the local volume, either because the volume is not managed by Remote Storage (Hierarchical Storage Management), or the file has not been migrated.<br><br>**Premigrated**: The file data has been copied to remote storage, but remains on the local volume as long as space is available. Files that were migrated and then recalled are considered to be premigrated.<br><br>**Truncated**: The file data resides in remote storage. A sparse placeholder file remains on the local volume with a Reparse Point that stores the actual location of the file in remote storage. |
| Attributes | **A** Archive<br><br>**C** Compressed<br><br>**E** Encrypted<br><br>**D** Directory<br><br>**H** Hidden<br><br>**O** Offline<br><br>**P** Reparse Points<br><br>**R** Read-only<br><br>**S** System File<br><br>**Z** Sparse |
| Physical | The physical file size, which is the number of bytes that the unnamed data stream (file content) occupies on the local volume. For files migrated to remote storage, this value is 0. |
| Logical | The logical file size, in bytes, which is the actual size of the unnamed data stream (file content), regardless of its physical location. For local files (non-HSM and premigrated), the physical size is equal to the logical size. |

| | |
|---|---|
| Migrate Time | The date and time that the file was most recently copied to remote storage, in Coordinated Universal Time (UTC). Recalling files does not change this value. |
| File Name | The name of the file. |
| Bytes | The combined size of files stored on the local volume, that is, non-HSM and premigrated files. |
| Bytes required to recall offline files | The combined size of files stored remotely, that is, truncated files. |

**RSDir Extended Display (/f)**

The **/f** parameter adds the following fields to the RSDir display.

| Property | Description |
|---|---|
| Create Time | The date and time that the file was created, in Coordinated Universal Time (UTC). |
| Last Access Time | The date and time that the file was last accessed, in Coordinated Universal Time (UTC). Migrating and recalling files does not change this value. |
| Last Modify Time | The date and time that the file was last changed, in Coordinated Universal Time (UTC). Migrating and recalling files does not change this value. |
| RC | (Recall Count) The number of times the file was recalled from remote storage. |
| Last Recall Time | The date and time that the file was most recently retrieved from remote storage, in Coordinated Universal Time (UTC). Files that have never been recalled have a recall date of 01/01/1601. |
| HSM ID | A GUID that uniquely identifies the Remote Storage installation. This ID is used to distinguish installations and resolve conflicts when Remote Storage has been reinstalled as part of a system recovery or reinstallation. |
| Bag ID | A GUID that uniquely identifies the migration group of the file. A *Bag* is a group of files migrated in the same job and stored in a single data set (MTF/BKF) on the remote media. Remote Storage uses the BAG ID to locate and recall files. |
| File ID | This field is not used. Files that are premigrated or truncated have a File ID of 0. |
| File Version ID | A numeric key used to track changes to premigrated and truncated files. |
| Data Stream | A unique identifier for the named data stream. All unnamed data streams (file content) have a Data Stream identifier of 0. |
| CRC Type | The algorithm used to perform the Cyclic Redundancy Check (CRC) on the data stream. Before truncating files, Remote Storage verifies that there are no differences between the local and remote copies of premigrated files. |
| Data Stream CRC | The value that the CRC generated for the data stream. |
| DS Size | The size of the migrated data stream, in bytes. Because Remote Storage migrates only the unnamed data stream (file content), this value is equal to the Data Size. |
| DS Start | The position of the unnamed data stream in remote storage. This value is the offset of the unnamed data stream (file content) from the beginning of the migrated data for this file. Because only the unnamed data stream is migrated, this value is always zero (0). |

| | |
|---|---|
| Data Size | The size that the unnamed data stream (file content) occupies in remote storage. Because Remote Storage always migrates file content as a unit, this value is either **N/A**, meaning zero (for local files), or it is equal to the logical file size (for truncated files). |
| Data Start | The position of the unnamed data stream in remote storage. This value is the offset of the unnamed data stream (file content) from the beginning of the file. Although only the unnamed data stream is migrated, this value is not zero because the data stream is preceded by MTF block headers. |
| File Size | The space that the file and its metadata occupy in remote storage, in bytes, also known as *size on disk*. In addition to the unnamed data stream (file content), this value includes the size of file system metadata, such as Reparse Points, and named streams. |
| File Start | Position of the file in remote storage. This value is the offset of this file, including file metadata, from the beginning of the remote data set for its *Bag* (migration group). |
| Ver Type | The algorithm used to perform a Cyclic Redundancy Check (CRC) on the entire migrated data set (the MTF/BKF, not just a particular data stream). |
| Ver Info | The value that the CRC generated for the entire migrated data set. |

# Rsdir Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RSDir Examples**

**Example 1: Display the status of files in the local directory**

The following command requests a basic display of the Remote Storage status of files in the directory from which the command is issued. Because the command uses the default value for all parameters, no parameters are needed.

```
C:\Inside Win2k\StartCD>RSDir
```

In response, RSDir displays the following information. For descriptions of the fields in the basic display, see Rsdir Remarks.

```
Showing information for <\\?\C:\Inside Win2k\StartCD\*.*>

Status        Attributes    Physical     Logical        Migrate Time File Name
------        ----------    --------     -------        ------------ ---------
non-HSM      --D-----R--           0           0                  NA .
non-HSM      --D-----R--           0           0                  NA ..
premigrated  A------PR-Z      104600      104600 04\27\2001 17:27:12 610215f.bmp
premigrated  A------PR-Z       93656       93656 04\27\2001 17:27:12 banner4.bmp
truncated    A-----OPR-Z           0      204800 04\27\2001 17:27:12 StartCD.exe
truncated    A-----OPR-Z           0        3747 04\27\2001 17:27:12 StartCD.ini

                4 File(s)          198256 bytes
                0 Dir(s)           208547 bytes required to recall offline files
```

This display lists the four files in the local directory and reveals that two are premigrated and two are migrated. The Migrate Time indicates that the files belong to the same BAG (migration group), meaning that they were copied to remote storage at the same time and are stored in the same data set on the remote media.

The two summary lines at the bottom of the display show the size that the file content consumes on the local disk and on remote media. Note that the local size is the sum of the physical size of all local files, including premigrated files. The "required to recall" size is the size of truncated files only.

This display does not reveal whether the premigrated files have ever been truncated, because the premigrated status is also used for files that are truncated and then recalled. That information can be inferred from data in the expanded (**/f**) display.

Finally, the local computer is in Eastern Standard Time, so the file content was actually moved at 12:27:12 local time.

**Example 2: Display the detailed status of a file**

The following command uses the **/f** parameter to request an expanded (full) display of the Remote Storage status of an executable file, Scan.exe. The command uses the redirection character (**>**) to direct the output to a text file, rss-scan.txt, for easier viewing. Also, because the path includes spaces, it is enclosed in quotation marks.

```
RSDir /f "c:\program files\scanco\scan.exe" > rss-scan.txt
```

In response, RSDir writes the following data to the rss-scan.txt file. (The display was edited in Notepad and arranged vertically for readability.)

For descriptions of the fields in the extended display, see Rsdir Remarks.

```
Status:             truncated
Attributes:         A-----OPR-Z
Physical:           0
Logical             2358435
Create Time         04\27\2001 17:08:19
Last Access Time    04\27\2001 17:08:20
Last Modify Time    09\30\1999 10:38:32
Migrate Time        04\27\2001 17:27:23
RC                  0
Last Recall Time    01\01\1601 00:00:00
HSM ID              {4d6e0baf-6d9c-4048-af3f-ca10d94cc8f9}
Bag ID              {21821bd8-dc91-4d13-ba8c-22f9e44b9e2f}
```

```
File ID             {00000000-0000-0000-0000-000000000000}
File Version ID     125831615120000000
Data Stream         0
CRC Type            1
Data Stream CRC     4003735577
DS Size             2358435
DS Start            0
Data Size           2358435
Data Start          322
File Size           2359296
File Start          327766016
Ver Type            1
Ver Info            59026
File Name           C:\Program Files\Scanco\scan.exe

        1 File(s)               0 bytes
        0 Dir(s)          2358435 bytes required to recall offline files
```

**Example 3: Display the status of files in a directory**
The following command displays the Remote Storage status of the Win2K subdirectory:

```
RSDir "c:\inside win2k\symbols\win2k"
```

In response, RSDir displays the Remote Storage status of the subdirectory, not of the files it contains. Because Remote Storage migrates files, not directories, this information is not particularly enlightening.

```
Status         Attributes    Physical     Logical        Migrate Time File Name
------         ----------    --------     -------        ------------ ---------
non-HSM       --D-----R--           0           0                  NA Win2k

                0 File(s)               0 bytes
                1 Dir(s)                0 bytes required to recall offline files
```

The following command adds wildcard characters to request a display of the files in the specified directory.

```
RSDir "c:\inside win2k\symbols\win2k\*.*"
```

In response, RSDir displays the Remote Storage status of files in the Win2k subdirectory, revealing that all files are truncated, even though the subdirectory status is "non-HSM."

```
Showing information for <*.*>

Status         Attributes    Physical     Logical        Migrate Time File Name
------         ----------    --------     -------        ------------ ---------
non-HSM       --D-----R--           0           0                  NA .
non-HSM       --D-----R--           0           0                  NA ..
truncated     A-----OPR-Z           0       99120 04\27\2001 17:27:12 ntkrnlmp.dbg
truncated     A-----OPR-Z           0      738304 04\27\2001 17:27:12 ntkrnlmp.pdb
truncated     A-----OPR-Z           0       98720 04\27\2001 17:27:12 ntkrnlpa.dbg
truncated     A-----OPR-Z           0      738304 04\27\2001 17:27:12 ntkrnlpa.pdb
truncated     A-----OPR-Z           0       99312 04\27\2001 17:27:12 ntkrpamp.dbg
truncated     A-----OPR-Z           0      746496 04\27\2001 17:27:12 ntkrpamp.pdb
truncated     A-----OPR-Z           0     1805372 04\27\2001 17:27:12 ntoskrnl.dbg
truncated     A-----OPR-Z           0      738304 04\27\2001 17:27:12 ntoskrnl.pdb

                8 File(s)               0 bytes
                0 Dir(s)          5063932 bytes required to recall offline files
```

Note that the path is not displayed in the output because RSDir considers the search field to be "*.*". To display the path, use the **/f** parameter, or run RSDir from the local subdirectory, as shown in Example 1: Display the status of files in the local directory.

**Example 4: Display the status of all files on a volume**
The following command lists the Remote Storage status of all files on the E drive of the local computer, and stores the list in a file, RSS-E.txt. The command is run from the root of the E drive and uses the **/s** parameter to request a recursive display. It also uses the redirection character (>) to direct the output to the RSS-E.txt file.

```
E:\>RSDir /s > RSS-E.txt
```

In response, RSDir writes the Remote Storage status of every file on the E drive to the RSS-E.txt file.

The command is run locally, that is, from the root of the E drive, so that correct file paths appear in the basic display output. When you run the command from another directory and specify the files on the E drive, such as `RSDir e:\*.*`, the phrase `*.*` is displayed in the output, instead of path statements. (This is not necessary if you are requesting an extended (full) display.)

Also, RSDir does not display the Remote Storage status of drives. The command `RSDir e:` returns blank or inaccurate output.

**Example 5: List all truncated files on a volume**
The following command creates a list of all truncated files on the C drive of the local computer and stores the list in a text file.

The command uses the **/f** parameter to specify an extended display, which includes the file path, and the **/s** parameter to make the command recursive. Then, the command uses the pipe symbol (`|`) to send the output directly to Find, a tool included in Windows Server 2003. For information about using Find, see "Find" in Help for Windows Server 2003. The Find command finds and displays only lines containing the word "truncated." The redirection character (`>`) directs the output of the Find command to the Trunc-c.txt file.

```
RSDir c:\*.* /f /s | find "truncated" > trunc-c.txt
```

You can use this command format to create logs of the truncated or premigrated files on your volumes. You can also save the command in a batch file and use Scheduled Tasks in Control Panel or use Schtasks to run the command periodically. For information about using Schtasks, see "Schtasks" in Help for Windows Server 2003.

# Rsdir Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**RSDir Syntax**

**RSDir** [*Path*[*****_File_]] [**/s**] [**/f**]

Without parameters, RSDir displays the Remote Storage status of the files in the local directory. The status tells whether the object resides in local or remote storage and provides details of its movement and location.

**Parameters**

***Path* [*File*]**

Displays the Remote Storage status of a specified file or the files on a volume or in a directory. If you omit this parameter, RSDir displays the Remote Storage status of files in the local directory.

To display the status of the files on a specified volume or in a specified directory, use wildcard characters, for example, d:*.* or c:\folder*.log.

**/s**

Recursively displays the Remote Storage status of all files and folders within the specified directory.

**/f**

Displays extended ("full") Remote Storage status information.

**Note**

- To accommodate the extended display, increase the width of the command window buffer to at least 500 characters, or redirect the output to a file.

# Topchk.cmd

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Topchk.cmd: DFS and SYSVOL Replication Topology Analysis Tool**
This command-line tool processes the output generated when the NtfrsUtl tool is run with the **ds** parameter. Using the NtfrsUtl **ds** output as its data source, TopChk creates a report that summarizes the replication topology of one or more replica sets. This report includes the following information:

- Topology
- Server Reference Table
- Server Host Table
- Server Inbound/Outbound partners
- Summary

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
The File Replication Service (FRS), first introduced in Windows 2000, is an essential element of the Microsoft Active Directory technologies. The Active Directory service uses FRS for SYSVOL replication. FRS can also be used with the Microsoft Distributed File System (DFS) technologies for automatic replication of content between alternating targets. For more information on FRS and Active Directory replication, see the Microsoft Windows Server 2003 Resource Kit.

Running NtrfsUtl **ds** produces output listing the raw definition of the FRS replication topology stored in Active Directory. A replica set consists of two or more computers configured to replicate the contents of a file folder. The individual computers are referred to as replica members.

**System Requirements**
The following are the system requirements for TopChk:

- Windows 2000 Server or Windows Server 2003
- PERL 5.005 521e or 522e

**Files Required**

- Topchk.cmd
- Ntfrsutl.exe

# Topchk Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TopChk Remarks**
**Before Using TopChk**
If Perl is not installed on your system, if you are connected to the Internet, you can download a free version from the ActiveState Web site.

**TopChk Report**
The TopChk report is used to verify that configuration information for FRS replica sets has been defined and stored correctly within the Active Directory. It is useful both as a regular health-check tool to confirm that replication is correctly configured, and as a troubleshooting tool for investigating possible causes of FRS replication issues.

Familiarity with FRS concepts and terminology is required in order to interpret TopChk reports.

The report consists of two main sections: The Subscriber List Summary followed by a Topology Analysis for each replica set. There is a section that summarizes the report following these sections.

**Subscriber List Summary**
This part of the report displays one row of information for each replica set that this member participates in. For example:

```
SUBSCRIBER: DOC|SALES      Root: f:\docs\sales                    Stage: e:\frs-stg
SUBSCRIBER: DOC|SUPPORT    Root: f:\docs\support                  Stage: e:\frs-stg
```

Each row shows the replica set name, the location on this computer where the replica set data exists, and the location of the FRS staging directory for this replica set.

**Replica Set Topology Analysis**
This part of the report contains a separate topology section for each replica set that this member participates in. The beginning of each section is indicated by the heading:

SET: <*replica set name*>

There may follow any of several possible sections, depending on the topology of the given replica set. The following sections can be included in the TopChk report:

SERVERS MISSING INBOUND CONNECTIONS

SERVERS MISSING OUTBOUND CONNECTIONS

MISSING NTDS SETTINGS REFERENCES

MEMBERS MISSING COMPUTER REFERENCE

MEMBERS MISSING CONNECTION OBJECTS

MEMBERS WITH SELF-REFERENCE CONNECTION OBJECTS

MEMBERS WITH 168 HOUR CONNECTIONS

**SERVERS MISSING INBOUND CONNECTIONS**
This part of the topology report appears if any FRS member servers have outbound replication partners but no inbound connection objects. There may be several reasons for this condition:

- There are no connection objects under the NTDS Settings object for this server. This is an error.
- The ServerReference Attribute for this server is null. This is an error.
- The FRS member object may be missing. This is an error.
- The server may be in a different domain, therefore no FRS member object can be identified for it. Domain controllers that hold a copy of the Global Catalog and are in a different domain are also listed this way. Such servers very likely do have inbound connections to replicate parts of the local domain naming context, but they are not members of the SYSVOL

replica set. As a result, these servers are listed but they are not in an error state.

**SERVERS MISSING OUTBOUND CONNECTIONS**
This part of the topology report appears if any FRS member servers have inbound replication partners but no outbound connection objects.

**MISSING NTDS SETTINGS REFERENCES**
This part of the topology report appears if any FRS member objects have no Server Reference to an NTDS Settings object. For more information, refer to the Knowledge Base article Q312862: "Recovering Missing FRS Objects and FRS Attributes in AD."

**MEMBERS MISSING COMPUTER REFERENCE**
This part of the topology report appears if any FRS member objects have no computer reference. For more information, refer to the Knowledge Base article Q312862: "Recovering Missing FRS Objects and FRS Attributes in AD."

**MEMBERS MISSING CONNECTION OBJECTS**
This part of the topology report appears if any FRS member objects have no inbound connection objects. This is most commonly caused by an Administrator manually defining a replication topology, and not creating a connection object.

In this situation, an Administrator should check for NTDS connection objects. If none exists, the Administrator can create one by using Active Directory Sites & Services. For more information, refer to Knowledge Base article Q257338, "Troubleshooting Missing SYSVOL and NETLOGON Shares."

**MEMBERS WITH SELF-REFERENCE CONNECTION OBJECTS**
This part of the topology report appears if any FRS member objects have connection objects that refer back to themselves. This is most commonly caused by an Administrator manually defining a replication topology and mistakenly creating this condition. In this situation, the topology must be manually corrected.

**MEMBERS WITH 168 HOUR CONNECTIONS**
This part of the topology report appears if the FRS member object has a connection object with a 168-hour (that is, 24x7) replication schedule. This section intentionally lists connections that are continuously enabled; it does not indicate an error.

**Summary Report Section**
This section provides a statistical overview of the other reports. Each potential entry for this section is described here.

Member objects with no NTDS Settings reference

This entry represents the number of FRS objects that did not replicate their SYSVOL share and need to be further investigated.

Member objects with no connection objects

This entry represents the number of NTDS Settings objects with no connection objects, meaning that the servers shown here are not replicating inbound. Note that each SYSVOL member must have one inbound and one outbound connection object. DFS replica sets are permitted to have inbound connection objects with no outbound connection object when using *hub and spoke* or custom topologies.

Connection objects set to disabled

This entry represents the number of disabled replication connections. The Administrator should investigate these to see which connections have been disabled, and determine if this is intended. The section titled **Connection Summary** printed as part of the Summary Report can be used for this purpose.

Monday Schedule

This section appears if TopChk finds a connection object scheduled to replicate at least daily (Monday in this case is assumed to be representative of the schedule for the business week). This provides some insight into whether the schedules have been staggered across connections, which is a best practice for large configurations.

Number connections with per-week active replication hours

This section displays replication hours for each connection object. It begins with a number of rows showing (a) number of servers, then (b) the number of hours the schedule is enabled for those servers.

### Note

- This is approximate. Any hour in which the schedule byte is non-zero is counted as an active replication hour.

It is possible that objects used for intra-site communication may show high replication hours (in the range of 160 or over); however, in most cases this level of network use is not advised.

Connection Summary

This section lists each connection, along with its Monday schedule, replication hours, and enabled/disabled status in order to facilitate further investigation of schedules.

**Note**

- A connection with a GUID, for example "cxtion: CC9BA0F4-3B12-4ADE-86BA-C405D86D4D59" indicates a connection that has been auto-generated by the Active Directory Knowledge Consistency Checker (KCC) or that has been created by using the DFS MMC snap-in utility. When the connection is associated with a name such as "cxtion: DC22," this indicates the connection was manually generated.

**Server Inbound/Outbound Partner Report**

The Server Inbound/Outbound Partner report (the final part of the Summary) lists the total number of inbound and outbound connections for a given server. Each server shows two entries: one with '<<' signifying an inbound connection list, and one with '>>' signifying an outbound connection list.

This part of the report is beneficial for investigating two aspects of the topology definition:

- It shows whether SYSVOL members have the required minimum of one inbound and one outbound connection object.

- It helps determine if the topology is reasonable with respect to the number of direct partners for each member, the amount of content being replicated (size * change), the link speed, and so forth.

An excessive number of connections to or from any one partner should be evaluated in order to see if the topology is balancing replication load appropriately.

# Topchk Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TopChk Examples**

**Example 1: Generating the NtfrsUtl DS Data File**

TopChk organizes the output of NtfrsUtl ds. Therefore, when running the **topchk** command you must specify a file that contains this output. Type the following at the command line to create the NtfrsUtl output file.

```
ntfrsutl ds >ntfrsout.txt
```

This command statement generates an output file called Ntfrsout.txt in the current directory.

**Example 2: Using Topchk to Parse a Data File**

This example parses the data file generated in Example 1: Generating the NtfrsUtl DS Data File and then displays the results to the screen. Type the following at the command line to save the TopChk report to a file in the current directory:

```
topchk.cmd ntfrsout.txt >topchkout.txt
```

This command runs the TopChk script against the Ntfrsout.txt file, which was generated by the NtfrsUtl ds command and saves the resulting output in a file named Topchkout.txt in the current directory.

# Topchk Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TopChk Syntax**

TopChk uses the following syntax:

**topchk** *DataFile*

**Parameters**

***DataFile***

Specifies a file that was created by running NtfrsUtl with the **ds** parameter. This is a required parameter.

Note

- The Perl interpreter should be installed and in the path for this command to function. See Topchk Remarks for details on obtaining Perl.

**Sample Usage**

```
topchk ntfrs_ds.txt > top.txt
```

# File and Folder Management Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: File and Folder Management Tools**
Tools in this category are used to manage the following Windows features:

- File compression
- File server
- Indexing service
- Offline files
- Shared folders
- Shared folder shadow copy
- Synchronization Manager

**Notes**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Bindiff Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Bindiff.exe: Binary File Difference Finder**
This command-line tool shows the differences between two binaries. BinDiff performs the following types of compares:

- A compare between two binary files that excludes time stamp differences. This is the default comparison.
- A compare between two binary files that excludes both time stamp and version information.
- A straight compare between two binary files that does not exclude time stamp or version information. This can be used to verify a tree copy or a CD burn.
- A compare between the files in one directory and the files in a separate directory.

### Note

- If you want to compare two ASCII text files, see the Windiff Overview Support Tool.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Application code is compiled into files that use binary format, and large applications are made up of a number of binary files. Over the programming life of that application, developers, testers, or writers might want to know what files, if any, have changed between the current and previous builds. While sometimes looking at the size of the file alerts the interested party to a change, it is also possible that an executable file could have had changes made to it, without the overall size of the file reflecting such changes. Being able to find files that have changed helps testers and writers direct their attention efficiently to the affected application areas. Developers can ensure that the proper versions of updated files are included in the installation directory for the product.

**System Requirements**
The following are the system requirements for this tool:

- Windows XP Professional or Windows Server 2003

### Note

- BinDiff can compare either compare 32-bit executables or 64-bit executables.

BinDiff also supports:

- Windows 95, Windows 98 and Windows ME
- Windows NT 4.0

**File Required**

- Bindiff.exe

Bindiff Overview

# Bindiff Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BinDiff Remarks**
**BinDiff Limitations**
BinDiff excludes known time stamp fields and version information that are documented in the Windows module format (known as the PE specification). It also locates date and time string constants (such as __DATE__ and __TIME__) in the source code, and excludes them. This catches the majority of differing regions between two executables, but it is possible to generate files that contain differing regions not excluded by BinDiff. In these cases, BinDiff will report the files as "Different" when the user might have expected the files to be "Near Identical." The following list gives some examples that illustrate this behavior:

- Debug information comes in many formats, each of which has various time stamps scattered among the debug data. BinDiff does not try to parse the debug information. Instead, it excludes all known debug regions in the files. Thus, if debug data is stored outside of the specified debug regions, then BinDiff does not know to exclude it.

- There are many post-processing tools that change modules after they are built. These tools, while optimizing page layout, load order, and resources, might strip out information, such as debug information or user names. Localization tools, for example, also change resource strings. Many of these post-processing tools leave data behind, add data, or neglect to clean up dead space and padding areas. This can lead to unexpected differing regions in the two files, which then causes BinDiff to mark the files as "Different."

- Some modules embed other modules in their resource data. If an embedded module is rebuilt, the time stamps in that module change. Running BinDiff on the embedded module itself should result in a "Near Identical" match. When that module is embedded in another module, however, it becomes part of the resource data of the main module. When BinDiff compares two builds of the main module, it will result in "Different" because the differing regions are now a part of the resource data .

**Understanding FileSpec1 and FileSpec2**
*FileSpec1* and *FileSpec2* can represent either files or directories. If two files are specified, then the files will be compared with each other. If two directories are specified, then all the files within the first directory will be compared with files with the same name in the second directory.

**Regions Excluded By BinDiff**
The following regions are excluded by default if found in a module :

- The IMAGE_FILE_HEADER.TimeDateStamp field

- The IMAGE_OPTIONAL_HEADER.CheckSum field

- The DOS/Win16 stub code

- The IMAGE_EXPORT_DIRECTORY.TimeDateStamp field

- The IMAGE_IMPORT_DESCRIPTOR.TimeDateStamp field

- The entire IMAGE_DEBUG_DIRECTORY array

- All debug sections

- The IMAGE_LOAD_CONFIG_DIRECTORY.TimeDateStamp field

- The IMAGE_BOUND_IMPORT_DESCRIPTOR.TimeDateStamp field

- All IMAGE_BOUND_FORWARDER_REF.TimeDateStamp fields

- The IMAGE_RESOURCE_DIRECTORY.TimeDateStamp field
- All padding between resources
- All ANSI __TIMESTAMP__ string constants used in code
- All ANSI __DATE__ string constants used in code
- All ANSI __TIME__ string constants used in code
- All UNICODE __TIMESTAMP__ string constants used in code
- All UNICODE __DATE__ string constants used in code
- All UNICODE __TIME__ string constants used in code

If the **/v** parameter is specified, the following regions are excluded in addition to the default regions:

- The IMAGE_OPTIONAL_HEADER.MajorLinkerVersion field
- The IMAGE_OPTIONAL_HEADER.MinorLinkerVersion field
- The IMAGE_OPTIONAL_HEADER.MajorOperatingSystemVersion field
- The IMAGE_OPTIONAL_HEADER.MinorOperatingSystemVersion field
- The IMAGE_OPTIONAL_HEADER.MajorImageVersion field
- The IMAGE_OPTIONAL_HEADER.MinorImageVersion field
- The IMAGE_OPTIONAL_HEADER.MajorSubsystemVersion field
- The IMAGE_OPTIONAL_HEADER.MinorSubsystemVersion field
- The IMAGE_OPTIONAL_HEADER.Win32VersionValue field
- All VERSION_INFO resources

**Comparing Executable Files**
By default, BinDiff uses a special compare routine for all 32-bit and 64-bit Windows executable files that masks various build time stamp fields in both files when performing the compare. This allows two executable files to be marked as "Near Identical" when the files are truly identical, except the time they were built. You can override this behavior with the **/b** parameter, which forces BinDiff to perform a straight binary compare of all files.

# Bindiff Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BinDiff Examples**

**Example 1: Compare Two Versions of a File**

You have two versions of the file dcpromo.dll, and you want to see if there are any differences between the two files. Using BinDiff with no parameters other than *FileSpec1* and *FileSpec2* performs a basic compare. To check for different versions of dcpromo.dll, type the following at the command line:

**bindiff \\heapsort\htmdrop\binold\dcpromo.dll \\heapsort\htmdrop\binnew\dcpromo.dll**

Press Enter . The following output is displayed:

```
Different, Right is newer
```

In this case, the two versions are different: the second file (the one specified on the right) (\\heapsort\htmdrop\binnew\dcpromo.dll) is newer than the first file.

**Example 2: Compare Two Versions of a File But Eliminate Version and Time Stamp Differences**

You have two versions of a file that you want to compare, and you want to make sure that versioning and time stamp information are not the only differences between the two files. To compare the two files while ignoring versioning and time stamp information, type the following at the command line:

**bindiff /v \\heapsort\htmdrop\binold\dcpromo.dll \\heapsort\htmdrop\binnew\dcpromo.dll**

Press Enter. The following output is displayed:

```
Different, Right is newer
```

In this case, the two versions are different and the second file (the file on the right) (\\heapsort\htmdrop\binnew\dcpromo.dll) is newer than the first file (the file on the left). Versioning and time stamp information are not the only differences between the two files. If this were the case, the files would be listed as `Near Identical`.

**Example 3: Compare Differing Byte Counts for Two Versions of a File**

You have two versions of a file that you know differ, but you want to see how different they really are. To compare the two files and get a differing byte count, type the following at the command line:

**bindiff /c \\heapsort\htmdrop\binold\dcpromo.dll \\heapsort\htmdrop\binnew\dcpromo.dll**

Press Enter. The following output is displayed:

```
Different, Right is newer  16,294 bytes differ

File Count Summary
   Identical:      0 files
   Near Identical: 0 files
   Different:      1 files
   Left Only:      0 files
   Right Only:     0 files
   Errors:         0 files
   Total:          1 files

Byte Count Summary
   Matched:    16,294 bytes differ
   Left Only:       0 bytes
   Right Only:      0 bytes
   Total:      16,294 bytes
```

Both versions of the file are 29 KB, and 16 KB of code differs between the two files . The 16 KB difference results from deleting code in the original file, then adding code back in.

**Example 4: Compare Files in Two Directories**

You want to compare the files in one build folder to those in another folder. To compare the files in the two directories, discounting any differences due to versioning and time stamp information, type the following at the command line:

**bindiff /s /v \\heapsort\htmdrop\binold \\heapsort\htmdrop\binnew**

Press Enter. The following output is displayed:

```
appsec.dll   Right-only File
appsec.exe   Right-only File
APPSEC.HLP   Right-only File
dcpromo.csv  Identical
dcpromo.dll  Different, Right is newer
dcpromo.exe  Different, Right is newer
```

In this case, three files have been added to the new build directory (in ...\BinNew). One file, (dcpromo.csv), is unchanged between builds, and two files, (dcpromo.dll and dcpromo.exe), have had changes in addition to versioning and timestamp changes made.

# Bindiff Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BinDiff Syntax**

BinDiff uses the following syntax:

**bindiff** [**/b**] [**/c**] [**/d**[*Bytes*]] [**/s**] [**/v**] [*FileSpec1 FileSpec2*]

**Parameters**

**/b**

Performs a straight binary compare. This parameter will not mask any time stamp or version information.

**/c**

Displays differing byte counts and summary information for the files specified in *FileSpec1* and *FileSpec2*.

**/d[ *Bytes*]**

Displays the byte differences between the files specified in *FileSpec1* and *FileSpec2*. Optionally specifies the number of non-differing bytes to show on each side of the differing regions in the files. The default value of *Bytes* is 8 bytes. Set *Bytes* to 0 to show only the differing bytes, or to -1 to dump both entire files.

**/s**

Compares all files in the subdirectory specified in *FileSpec1* to the files in the subdirectory specified in *FileSpec2*.

**/v**

Excludes all version information in the executable files when performing the compare. This allows two executable files to be marked as "Near Identical" when the files are truly identical, differing only in build time or version number information. This parameter is ignored if used in conjunction with **/b.**

***FileSpec1***

Specifies the directory and name of a file, the name of a file, or a subdirectory to be compared to the specification listed in *FileSpec2*. The name can use the Universal Naming Convention (UNC) format ("\\myserver") or reference a local drive. If the file is located in the current directory *FileSpec1* can also be the name of the file.

**Note**

- The type of information listed in *FileSpec1* must be the same type of information listed in *FileSpec2*. For example, if *FileSpec1* is set to c:\myfile.dll, then *FileSpec2* must also contain the name of a file, and not the name of a subdirectory (c:\new\myfile.dll, not c:\new\).

***FileSpec2***

Specifies the directory and name of a file, the name of a file, or a subdirectory to be compared to the specification listed in *FileSpec1*. The name can use the Universal Naming Convention (UNC) format ("\\myserver") or reference a local drive. If the file is located in the current directory *FileSpec2* can also be the name of the file.

**Note**

- The type of information listed in *FileSpec2* must be the same type of information listed in *FileSpec1*. For example, if *FileSpec2* is set to c:\myfile.dll, then *FileSpec1* must also contain the name of a file, and not the name of a subdirectory (c:\new\myfile.dll, not c:\new\).

**/?**

Displays command-line usage.

# Bitsadmin Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Bitsadmin.exe: BITS Administration Utility**
This command-line tool allows administrators to manage the Background Intelligent Transfer Service (BITS), a background file transfer service and queue manager in Windows Server 2003 and Windows XP. Requests to BITS are submitted by an application and the files can be transferred in a throttled manner such that the interactive user is not affected by the bandwidth consumed. Requests are placed in a queue until the files are transferred, at which time the requesting application is invoked and notified of the completion.

**Corresponding UI**
The corresponding user interface for Background Intelligent Transfer Service can be found in the Windows Server 2003 Services snap-in, Services.msc. To open Services, click **Start**, click **Control Panel**, click **Performance and Maintenance**, click **Administrative Tools**, double-click **Services**, and then double-click **Background Intelligent Transfer Services**.

**Concepts**
Background Intelligent Transfer Service (BITS) is a file-transfer technology similar in concept to other standard file-transfer protocols, such as FTP. BITS is used by various applications to manage file transfer using standard Hypertext Transfer Protocol (HTTP).

BITS requires Internet Information Services (IIS) with BITS extensions to be running on the source server if you want to use BITS to upload files to your server.

### Note

- Internet Information Services is not required for downloads, only for uploads.

BITS is used by programs (such as Windows AutoUpdate) to download files by using spare bandwidth. BITS can maintain file transfers through network disconnections and computer restarts.

**System Requirements**
The following are the system requirements for this tool:

- Windows Server 2003, Windows XP Professional, or Windows XP Home Edition
- Internet Information Services (with the BITS Server Extension) is required to receive BITS uploads.
- Administrator rights on the target computer (the computer receiving transfers) is required to modify the jobs of other users.

### Note

- BITS requires a Web server running on the source server for downloading files. For file uploads, BITS requires IIS and a corresponding server component to be running on the destination server.

**File Required**

- Bitsadmin.exe

# Bitsadmin Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BitsAdmin Remarks**

**Windows Updates**

BITS is often erroneously confused with Windows Update service because Windows Update service uses Background Intelligent Transfer Service by default.

**Network Throttling**

BITS regulates the transfer rate to minimize impact on user interactivity, such as a job sent to a network printer or web pages viewed through Internet Explorer.

**Customized APIs**

BITS is exposed to programmers through a set of Application Program Interfaces (APIs). For more information on using BITS programmatic interfaces, see the Microsoft Developer Network.

# Bitsadmin Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BitsAdmin Examples**

**Example 1: Create BITS Job**

You want to create a job. Type the following at the command line:

**bitsadmin /create myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

Created job {2DC7527D-C7A8-444C-84A9-D772E79D4B37}.
```

**Example 2: Get a Job's Type**

You want to get the type of job for **myjob**. Type the following at the command line:

**bitsadmin /gettype myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

DOWNLOAD
```

**Example 3: Get a Job's Size**

You want to know the size of a job. Type the following at the command line:

**bitsadmin /getbytestotal myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

236
```

**Example 4: Get the Number of Bytes Transferred for a Job**

You want to know how much of the job has already been transferred. Type the following at the command line:

**bitsadmin /getbytestransferred myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

106
```

**Example 5: Get the Number of Files in a Job**

You want to know how many files are in a job. Type the following at the command line:

**bitsadmin /getfilestotal myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.
```

```
3
```

**Example 6: Get the Number of Files Transferred for a Job**
You want to know how many files have been transferred from a job. Type the following at the command line:

**bitsadmin /getfilestransferred myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

1
```

**Example 7: Get a Job's Creation Time**
You want to know when a job was created. Type the following at the command line:

**bitsadmin /getcreationtime myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

6/3/2002 10:49:02 AM
```

**Example 8: Get a Job's Last Modification Time**
You want to know when a job was last modified. Type the following at the command line:

**bitsadmin /getmodificationtime myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

6/3/2002 10:49:02 AM
```

**Example 9: Get a Job's Completion Time**
You want to know if and when a job has completed. Type the following at the command line:

**bitsadmin /getcompletiontime myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

WORKING
```

The **myjob** job has not yet completed.

**Example 10: Get a Job's State**
You want to know a job's state. Type the following at the command line:

**bitsadmin /getstate myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

SUSPENDED
```

**Example 11: Get a Job's Owner**
You want to know who owns a job. Type the following at the command line:

**bitsadmin /getowner myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

DOMAINMAIN\smithj
```

**Example 12: Get a Job's Display Name**
You want to know the display name for a job. Type the following at the command line:

**bitsadmin /getdisplayname myjob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3639.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

myjob
```

### Note

- Using DisplayName as the argument for the job will work only if there is one job in the queue with this display name. Otherwise, Bitsadmin will return an error in which case, the GUID must be used.

**Example 13: Add a file to a specified job**
You want to add a file to a specified job. Type the following at the command line:

**bitsadmin /addfile myJob http://myserver/myfile.ext c:\myFile.ext**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3652.0 ]

BITS administration utility.

(C) Copyright 2000-2002 Microsoft Corp.

Added http://myserver/myfile.ext -> c:\myFile.ext to job.
```

### Note

- Instead of using myJob as the parameter the previous example, you could enter the GUID of the job. You can get the GUID of the job when you do the bitsadmin /create. You can also do a bitsadmin /list to get the GUID of the job. The GUIDS are unique, but the display names are not.

**Example 14: Resume a job**
You want to resume a job. Type the following at the command line:

**bitsadmin /resume myJob**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.2.3652.0 ]

BITS administration utility.

(C) Copyright 2000-2002 Microsoft Corp.

Job resumed
```

**Example 15: Delete all jobs in the manager**
You want to delete all jobs in the manager. Type the following at the command line:

**bitsadmin /reset**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

{A305C29C-2247-42A6-918E-C575280CE885} canceled.
{6F2D447C-712E-4674-9FAE-42DBFAD071A8} canceled.
{0B8068F6-2572-4932-AE12-CD58DA78912E} canceled.
3 out of 3 jobs canceled.
```

**Example 16: List transfer jobs**

You want to list the transfer jobs. Type the following at the command line:

**bitsadmin /list**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

{A305C29C-2247-42A6-918E-C575280CE885} job1 SUSPENDED 0 / 0 0 / 0
{6F2D447C-712E-4674-9FAE-42DBFAD071A8} job2 SUSPENDED 0 / 0 0 / 0
{0B8068F6-2572-4932-AE12-CD58DA78912E} job3 SUSPENDED 0 / 0 0 / 0
Listed 3 job(s).
```

**Example 17: Delete a specified job**

You want to delete a specified job. Type the following at the command line:

**bitsadmin /cancel job1**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

Job canceled
```

**Example 18: Perform a series of operations simultaneously**

You want to run a series of operations such as: /create /addfile /resume /list /complete. Type the following at the command line:

**bitsadmin /create /addfile /resume /list /complete**

Press **Enter**. The following output is displayed:

```
BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

Created job {9CFB8267-72BA-4725-A487-8CB1A9390637}.

bitsadmin /addfile job1 http://bitsnet/downloads/50mb.zip c:\temp\50mb.zip

BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

Added http://bitsnet/downloads/50mb.zip -> c:\temp\50mb.zip to job.

bitsadmin /resume job1

BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.
```

```
Job resumed.

bitsadmin /list

BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

{9CFB8267-72BA-4725-A487-8CB1A9390637} job1 TRANSFERRING 0 / 1 2000 / 50189685
Listed 1 job(s).

bitsadmin /list

BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

{9CFB8267-72BA-4725-A487-8CB1A9390637} job1 TRANSFERRED 1 / 1 50189685 / 501896
Listed 1 job(s).

bitsadmin /complete

BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.
(C) Copyright 2000-2002 Microsoft Corp.

Invalid number of arguments.

bitsadmin /complete job1

BITSADMIN version 1.5 [ 5.1.3597.0 ]
BITS administration utility.

# Bitsadmin Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BitsAdmin Syntax**

BitsAdmin uses the following syntax:

**bitsadmin** [**/rawreturn**] [**/wrap**] [**/nowrap** *Job*] [**/help**|**/?**] [**/list** [**/allusers**] [**/verbose**]]
[**/monitor** [**/allusers**] [**/refresh** *Seconds*]] [**/reset**] [**/create** *DisplayName*] [**/info** *Job* [**/verbose**]
[**/addfile** *Job RemoteURL LocalName*] [**/listfiles** *Job*] [**/suspend** *Job*] [**/resume** *Job*] [**/cancel** *Job*] [**/complete** *Job*]
[**/gettype** *Job*] [**/getbytestotal** *Job*] [**/getbytestransferred** *Job*] [**/getfilestotal** *Job*] [**/getfilestransferred** *Job*]
[**/getcreationtime** *Job*] [**/getmodificationtime** *Job*] [**/getcompletiontime** *Job*] [**/getstate** *Job*] [**/geterror** *Job*]
[**/getowner** *Job*] [**/getdisplayname** *Job*] [**/setdisplayname** *Job DisplayName*] [**/getdescription** *Job*]
[**/setdescription** *Job Description*] [**/getpriority** *Job*] [**/setpriority** *Job Priority*] [**/getnotifyflags** *Job*]
[**/setnotifyflags** *Job NotifyFlags*] [**/getnotifyinterface** *Job*] [**/getminretrydelay** *Job*] [**/setminretrydelay** *Job RetryDelay*]
[**/getnoprogresstimeout** *Job*] [**/setnoprogresstimeout** *Job Timeout*] [**/geterrorcount** *Job*] [**/getproxyusage** *Job*]
[**/getproxylist** *Job*] [**/getproxybypasslist** *Job*] [**/setproxysettings** *Job* **use**, *List*, *Bypass*] [**/takeownership** *Job*]
[**/SetNotifycmdline** *Job command-line*] [**/GetNotifycmdline** *Job*]
[**/SetCredentials** *Job Target Scheme Username Password*] [**/RemoveCredentials** *Job Target Scheme*]
[**Getreplyfilename** *Job*] [**Setreplyfilename** *Job Path*] [**/GetReplyProgress** *Job*] [**/GetReplyData** *Job*] [**/GetReplyData** *Job*]

**Parameters**

**/help| /?**
Displays command line usage.

**/list[ /allusers] [ /verbose]**
Lists transfer jobs. The **/allusers** parameter lists jobs for all users on the system. The **/verbose** parameter provides detailed information about jobs.

**/monitor[ /allusers] [ /refresh*Seconds*]**
Monitors the copy manager. The **/allusers** parameter monitors the copy manager for all users on the system. The **/refresh** parameter reacquires copy manager data in the specified time interval in seconds.

**/reset**
Deletes all jobs in the manager. If executed by an administrator, all jobs are deleted. If executed by a normal user, only the jobs owned by the user are deleted.

**/create [type] *DisplayName***
Creates a job and assigns *DisplayName* to it. The **type** can be **/Download**, **/Upload**, or **/Upload-Reply.**

**/info *Job*[ /verbose]**
Displays information about the specified job. The **/verbose** parameter provides detailed information about the job.

**/addfile *Job RemoteURL LocalName***
Adds a file to the specified job. *RemoteURL* specifies the file's source location. *LocalName* specifies the file's name on the local target computer.

**/listfiles *Job***
Lists the files in the specified job.

**/suspend *Job***
Suspends the specified job. The job will not be scheduled to run again until the **/resume** parameter is executed.

**/resume *Job***
Queues the job to the list of jobs enabled for transfer.

**/cancel *Job***
Deletes the specified job.

**/complete *Job***
Completes the job and makes the files available for the destination directory. This is normally executed after the job moves to the transferred state.

**/gettype *Job***
Retrieves the job type of the specified job.

**/getbytestotal *Job***
Retrieves the size of the specified job.

**/getbytestransferred *Job***
Retrieves the number of bytes transferred for the specified job.

**/getfilestotal *Job***
Retrieves the number of files in the specified job.

**/getfilestransferred *Job***
Retrieves the number of files transferred for the specified job.

**/getcreationtime *Job***
Retrieves the job creation time for the specified job.

**/getmodificationtime *Job***
Retrieves the job modification time.

**/getcompletiontime *Job***
Retrieves the job completion time for the specified job.

**/getstate *Job***
Retrieves the job state for the specified job.

**/geterror *Job***
Retrieves detailed error information for the specified job

**/getowner *Job***
Retrieves the job owner for the specified job.

**/getdisplayname *Job***
Retrieves the display name for the specified job.

**/setdisplayname *Job DisplayName***
Sets the *DisplayName* for the specified job.

**/getdescription *Job***
Retrieves the job description of the specified job.

**/setdescription *Job Description***
Sets the description for the specified job.

**/getpriority *Job***
Retrieves the priority of the specified job.

**/setpriority *Job Priority***
Sets the priority for the specified job.

**/getnotifyflags *Job***
Retrieves the notify flags for the specified job.

**/setnotifyflags *Job NotifyFlags***
Sets the notify flags for the specified job.

**/getnotifyinterface *Job***
Determines if notify interface is registered for the specified job.

**/getminretrydelay *Job***
Retrieves the retry delay, in seconds, for the specified job.

**/setminretrydelay *Job RetryDelay***
Sets the *RetryDelay*, in seconds, for the specified job.

**/getnoprogresstimeout *Job***
Retrieves the no progress timeout, in seconds.

**/setnoprogresstimeout *Job Timeout***
Sets the no progress *Timeout*, in seconds, for the specified job.

**/geterrorcount *Job***
Retrieves an error count for the specified job.

**/getproxyusage *Job***
Retrieves the proxy usage setting for the specified job.

**/getproxylist *Job***
Retrieves the proxy list for the specified job.

**/getproxybypasslist *Job***
Retrieves the proxy bypass list for the specified job.

**/setproxysettings *Job* use, *List*, *Bypass***
Sets the proxy Settings for the specified job.

**/takeownership *Job***
Takes ownership of the specified job.

**/SetNotifycmdline *Job command-line***
Sets a command line for job notification.

**/GetNotifycmdline *Job***
Returns the job's notification command line.

**/SetCredentials *Job Target Scheme Username Password***
Adds credentials to a job. The *Target* can be either SERVER or PROXY. The *scheme* can be BASIC, DIGEST, NTLM, NEGOTIATE, or PASSPORT.

**/RemoveCredentials *Job Target Scheme***
Removes credentials from a job. The *Target* can be either SERVER or PROXY. The *scheme* can be BASIC, DIGEST, NTLM, NEGOTIATE, or PASSPORT.

The following options are valid for **Upload-reply** jobs only:

- **Getreplyfilename** *Job*

  **Gets the path of the file containing the server reply.**

- **Setreplyfilename *Job***

  ***Path* Sets the path of the file containing the server reply.**

- **/GetReplyProgress *Job***

  **Returns the size and progress of the server reply.**

- **/GetReplyData *Job***

  **Retrieves the server's reply data in hexadecimal format.**

**The following options can be placed before the command:**

- **/rawreturn**

  **Returns data suitable for parsing. Strips new line characters and formatting from the output. This parameter can be used in conjunction with the /create and /get* parameters.**

- **/wrap**

  **Wraps output to fit in a command window.**

- **/nowrap *Job***

**Does not wrap output to fit in a command window.**

**Note**

- **Commands that take a job parameter will accept either a job name or a job-ID GUID inside braces. BitsAdmin reports an error if the name is ambiguous.**

# Cabarc Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cabarc.exe: Cabinet Tool**
This command-line tool allows users to create, query and extract Windows cabinet (CAB) files.

### Note

- CABArc does not allow you to add files to an existing CAB (.cab) file.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
A CAB file or cabinet file is a single file created to hold a number of compressed files and used for the installation of software products. When a program is installed, the files within the CAB file are decompressed and copied to their appropriate directory locations. Windows CAB files use the extension .cab.

**System Requirements**
The following are the system requirements for this tool:

- Windows Server 2003, or Windows XP Professional

**File Required**

- Cabarc.exe

# Cabarc Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**CABArc Remarks**

**Using CABArc to View the Contents of a CAB File**
To view the contents of a CAB file with CABArc:

1. Open a command window and navigate to the folder containing the .cab file that has the contents you want to view.

2. Type the following at the command prompt:

   **cabarc l FileName.cab**

   *FileName* is the name of the .cab file.

# Cabarc Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**CABArc Examples**

**Example 1: List Files in a Cabinet**

You want to list the files in support.cab. Type the following at the command prompt:

**cabarc l c:\builds\support.cab**

Press **Enter**. You will see the following output:

```
Microsoft (R) Cabinet Tool - Version 5.1.2600.0
Copyright (c) Microsoft Corporation. All rights reserved..

Listing of cabinet file 'c:\builds\support.cab' (size 4091527):
   89 file(s), 4 folder(s), set ID 32099, cabinet #0

File name                       File size     Date      Time   Attrs
-----------------------------  ---------- ---------- -------- -----
   acldiag.exe                      84992 2002/05/24 07:41:56  ----
   adprop.dll                      735232 2002/05/24 07:41:42  ----
   addiag.exe                      216091 2002/05/24 04:28:48  ----
   adsiedit.dll                    330240 2002/05/24 07:41:10  ----
   adsiedit.msc                     42986 2001/10/15 17:40:54  ----
   bitsadmin.exe                    48640 2002/05/24 07:41:16  ----
   bindiff.exe                      17408 2002/05/24 08:28:54  ----
   browstat.exe                     41472 2002/05/24 07:53:38  ----
```

**Example 2: Extract Files from Cabinet**

You want to extract all of the .dll files in the support.cab file. Type the following at the command prompt:

**cabarc x c:\builds\support.cab *.dll**

Press **Enter**. The .dll files will be extracted to the current directory. The following output is displayed:

```
Microsoft (R) Cabinet Tool - Version 5.1.2600.0
Copyright (c) Microsoft Corporation. All rights reserved..

Extracting file(s) from cabinet 'c:\builds\support.cab':
   extracting: adprop.dll
   -- File 'adsiedit.dll' already exists; overwrite? (Yes/No/All/Quit):
```

Type the following to make CABArc overwrite all preexisting files without continuing to prompt:

```
a
```

The following output is displayed:

```
   extracting: adsiedit.dll
   extracting: clonepr.dll
   extracting: depends.dll
   extracting: iadstools.dll
   extracting: movetree.dll
   extracting: rstools.dll
   extracting: sidwkr.dll

Operation successful
```

**Example 3: Create a New Cabinet**

You want to create a new cabinet file. Type the following at the command prompt:

**cabarc n test1.cab *.dll**

Press **Enter**. The following output is displayed:

```
Microsoft (R) Cabinet Tool - Version 5.1.2600.0
Copyright (c) Microsoft Corporation. All rights reserved..

Creating new cabinet 'test1.cab' with compression 'MSZIP':
  -- adding adprop.dll
  -- adding adsiedit.dll
  -- adding apidll.dll
  -- adding clonepr.dll
  -- adding depends.dll
  -- adding gutils.dll
  -- adding iadstools.dll
  -- adding movetree.dll
  -- adding ntfrsapi.dll
  -- adding rstools.dll
  -- adding sidwkr.dll
  -- adding traceprt.dll

Completed successfully
```

The cabinet file test1.cab is created in the current directory with MSZIP compression.

# Cabarc Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**CABArc Syntax**
CABArc uses the following general syntax:

**cabarc** *parameters operation arguments*

**Operations**
**L**
Lists files contained within a CAB file.

**Syntax**
**cabarc l** *CabFileName* **.cab**

**Parameters**
***CabFileName* .cab**
Specifies the name of the CAB file for which the contents are to be listed. The *CabFileName* may include a path (for example, c:\test\mycab.cab).

**N**
Creates a CAB file.

**Syntax**
**cabarc** [**/m {lzx:*Compression*|mszip|none}**] [**/p**] [**/P** *Pathname*] [**/r**] [**/s**] [**/I** *SetID*] **n** *NewCabFileName*[*****]**.cab** *FileNameOrPattern* [*FileNameOrPattern* [...]]

**Parameters**
**/m {lzx: *Compression* |mszip|none}**
Sets compression type. If no compression type is specified, MSZIP format is used.

| Value | Description |
|---|---|
| LZX:*Compression* | Uses LZX compression. Valid *Compression* values are 15 to 21. |
| MSZIP | Uses MSZip format. |
| NONE | Uses no compression. |

**/p**
Preserves path names. Absolute paths are not allowed.

**/P *Pathname***
Strips the specified *Pathname* from files when they are added to the CAB file.

**Note**

- The **/P** option can be used multiple times to strip out multiple paths.

**/r**
Recurses into subdirectories when adding files.

**/s**
Reserves space in the CAB file for signing. For example, `/s 6144` reserves 6K bytes.

**/i *SetID***
Sets the CAB set ID when creating CAB files. The default set ID is 0.

**Note**

- When using the **/d** parameter, the *NewCabFileName* should contain a single "*" character where the cabinet number will be inserted.

***NewCabFileName*[*] .cab**
Specifies the name of the new cab file. The file must have a .cab file type.

**Note**

- When using the **/d** parameter, the *NewCabFileName* should contain a single "*" character where the cabinet number will be inserted.

***FileNameOrPattern***
Specifies the file or pattern of files to include in the CAB file. For example, `myfile.ini mfiles.*` will include the file myfile.ini and all files with a file name of mfiles regardless of type.

**Note**

- When creating a CAB file, the plus sign (+) may be used as a filename to force a folder boundary. For example, `cabarc n test.cab *.c test.h + *.bmp`.

**X**
Extracts files from a CAB file.

**Syntax**
**cabarc** [**/c**] [**/o**] **x** *CabFileNameFileNameOrPattern* [*FileNameOrPattern* [...]] [*Pathname*]

**Parameters**
**/c**
Confirms which files will be extracted.

**/o**
Specifies that existing files with the same name as those being extracted will be overwritten without asking for confirmation.

***CabFileName* .cab**
Specifies the name of the CAB file that contains the files to be extracted. The *CabFileName* may include a path (for example, c:\test\mycab.cab).

***FileNameOrPattern***
Specifies the file or pattern of files to extract from the CAB file. For example, `myfile.ini mfiles.*` will extract the file myfile.ini and all files with a file name of mfiles regardless of type.

***Pathname***
Specifies that path to which the files should be extracted. The path must end with a back slash example, `c:\myfiles\`. If no path is specified, the current path is used.

**Note**

- When run without parameters, operations, or arguments, CABArc displays command line usage.

# Depends Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Depends.exe: Dependency Walker**
This GUI tool scans any Windows module (including .exe, .dll, .ocx, and .sys, among others) and builds a hierarchical tree diagram of all dependent modules. For each module found, it lists all the functions that are exported by that module, and identifies which of those functions are actually being called by other modules. Another view displays the minimum set of required files, along with detailed information about each file, including a full path to the file, base address, version numbers, computer type, debug information, and more.

**Corresponding UI**
Depends provides its own user interface.

Depends is very useful for troubleshooting system errors related to module load problems. During the module scan, this tool detects dozens of common application problems such as missing modules, invalid modules, import/export mismatches, circular dependency errors, and mismatched computer types of modules.

Depends is useful for developers, testers, system administrators, creators of setup scripts, and anyone else who needs to examine what dependencies are required to make a specific module load successfully.

Depends runs on Windows 95, Windows 98, Windows NT 3.51, Windows NT 4.0, Windows 2000, Windows XP, and Windows Server 2003. It can process any Windows modules, including those designed for Windows CE. It can run as a graphical application or as a console application. New features in version 2.0 include C++ function name undecoration, detection of delay-load and dynamic dependencies, application profiling, user-definable search paths, and the ability to save results to several file formats.

Details on running Depends can be found in Dependency Walker 2.0 Help (Depends.hlp), a separate documentation file.

**System Requirements**
The following are the system requirements for Depends:

- Windows 95, Windows 98, Windows NT 3.51, Windows NT 4.0, Windows 2000, Windows XP, or Windows Server 2003

**Files Required**

- Depends.cnt
- Depends.exe
- Depends.hlp
- Depends.dll

# Depends Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Depends Remarks**

**Configuring Depends**

When you first run Depends, it registers itself with your system as a handler for all Win32 binary files. This causes a **View Dependencies** item to be added to the system's context menu. You must configure which file extensions Depends handles by opening the **Options** menu and adding file extensions in the **Handled File Extensions** dialog box. Then, when you right-click a Win32 module file in Windows Explorer, **View Dependencies** is displayed as one of the options.

**Opening a File in Depends**

To open a file in Depends, use one of four methods:

1. Right-click a module file in Windows Explorer and choose **View Dependencies** from the context menu. This requires that you configure Depends to handle certain file extensions. To do this, in Depends on the **View** menu, click **Handled File Extensions**.

2. In Depends on the **File** menu, click **Open**.

3. Drag and drop a file on top of the Depends main window.

4. At the command prompt, type **depends** followed by the name of the file to be viewed.

**Getting Help on Depends**

To get help on Depends while running the tool, open the table of contents by using one of two methods:

- In Depends on the **Help** menu, click **Help Topics**.

- To get help on the view that currently has focus, press F1.

# Diruse Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Diruse.exe: Directory Disk Usage**
This command-line tool displays directory size information, including compression information for NTFS volumes. You can use DirUse to determine the actual usage of space for compressed files and directories.

You can also specify a maximum folder size. DirUse then marks any folders that exceed the specified limit and, if you choose, alerts you to the problem.

If you run DirUse while logged on as a member of the Administrators group, you can check the use of disk space in directories even if you do not have access rights to those directories.

### Note

- DirUse is similar to du used in UNIX.

**Corresponding UI**
You can use Windows Explorer to determine the size of the first level of directories on a drive, but not to determine the overall size of directories and their subdirectories.

There is no other corresponding user interface for DirUse.

**Concepts**
For more information on NTFS, see NTFS.

**System Requirements**
The following are the system requirements for DirUse:

- Windows XP Professional or Windows Server 2003

**File Required**

- Diruse.exe

**See Also**
**Concepts**

# Diruse Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DirUse Remarks**

**Using DirUse to Determine Compressed File Size**
The parameter to use for compressed directories and files is **/c**, which causes DirUse to display the actual size of a compressed file or directory instead of apparent uncompressed size. For example, if your D drive is an NTFS volume, and you want to determine the disk space used (in megabytes) and the number of files in each directory, at the command line, type:

```
diruse /s /m /c d:
```

To see compression information for a file, open Windows Explorer, right-click the file, and then click **Properties**.

# Diruse Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DirUse Examples**

**Example 1: List current file usage for a shared volume**

In your company, users store their files on a shared volume called \\Shared. The \\Shared\Data folder is broken down into folders for each department. Each department folder is broken down into folders for users from that department as well as one or more folders that are shared by all users in that department. The \\Shared\Data folder also has one folder — \\Shared\Data\Common — that is used to share information between departments.

You have been asked to generate a report that shows the current usage for the network volume where users in your company store their data. This report must show the usage by department and list any individual user who has more than 50 MB of data on the volume. To generate the data for the first part of your report, type the following at the command line:

```
diruse /* /m \\shared\data > c:\deptdata.txt
```

This generates a list of usage in megabytes of the top-level folders contained in the \\Shared\Data folder. The output is sent to the Deptdata.txt file on your C drive.

Looking at Deptdata.txt, you see the following output:

```
    Size (mb)  Files  Directory
       248.60   3739  SUB-TOTAL: \\SHARED\DATA\Admin
        31.27     36  SUB-TOTAL: \\SHARED\DATA\Common
      1448.14  23654  SUB-TOTAL: \\SHARED\DATA\ConsultServ
       107.64    750  SUB-TOTAL: \\SHARED\DATA\CorpServ
      1053.28   6145  SUB-TOTAL: \\SHARED\DATA\Design
       147.11    258  SUB-TOTAL: \\SHARED\DATA\Engrg
        70.56    745  SUB-TOTAL: \\SHARED\DATA\Finance
        18.78   1188  SUB-TOTAL: \\SHARED\DATA\Hardware
        12.18     50  SUB-TOTAL: \\SHARED\DATA\HR
         2.22     23  SUB-TOTAL: \\SHARED\DATA\InfoTech
         5.44     46  SUB-TOTAL: \\SHARED\DATA\Legal
        18.53     56  SUB-TOTAL: \\SHARED\DATA\ProdDev
       470.43   2016  SUB-TOTAL: \\SHARED\DATA\ProdMktg
       107.92   1445  SUB-TOTAL: \\SHARED\DATA\Research
        31.10     43  SUB-TOTAL: \\SHARED\DATA\Sales
         9.98     14  SUB-TOTAL: \\SHARED\DATA\TechSupp
       114.82   1269  SUB-TOTAL: \\SHARED\DATA\Training
      3898.00  41477  TOTAL
```

You can see in this output that only the Admin, ConsultServ, CorpServ, Design, Engrg, Finance, ProdMktg, Research, and Training departments have more than 50 MB of data each.

To see what users have more than 50 MB of data stored on \\Shared\Data, type the following at the command line:

```
diruse /* /m /q:50 /d \\shared\data\admin, \\shared\data\consultserv, \\shared\data\corpserv,
\\shared\data\design, \\shared\data\engrg, \\shared\data\finance, \\shared\data\prodmktg,
\\shared\data\research, \\shared\data\training > c:\userdata.txt
```

This generates a list of the all top-level folders contained in any of the listed folders that use more than 50 MB of disk space. The output is sent to the Userdata.txt file on your C drive.

Looking at Userdata.txt, you see the following output:

```
Searching for directories that have exceeded 50 megabytes
    Size (mb)  Files  Directory
!       68.30    697  SUB-TOTAL: \\SHARED\DATA\Finance\Jack
        70.55    744  TOTAL
```

You can see in this output that only one user, Jack, is marked as using more than 50 MB of data.

**Example 2: Determine compressed file and folder sizes**

You want to compare the actual size of folders containing compressed files and the apparent uncompressed size in your Windows folders. To generate a list of top-level folders contained in the Windows folder with their associated compressed

sizes, type the following at the command line:

```
diruse /c /* /m c:\Windows > c:\data\compressed.txt
```

The Compressed.txt file in the C:\Data folder contains the output from the command-line statement. The file contains the following output:

```
    Size (mb)  Files  Directory
         0.00      0  SUB-TOTAL: C:\WINDOWS\addins
         0.19     64  SUB-TOTAL: C:\WINDOWS\Application Compatibility Scripts
         1.56      7  SUB-TOTAL: C:\WINDOWS\AppPatch
         2.52     16  SUB-TOTAL: C:\WINDOWS\Cluster
         0.00      0  SUB-TOTAL: C:\WINDOWS\Config
         0.00      0  SUB-TOTAL: C:\WINDOWS\Connection Wizard
         0.29    184  SUB-TOTAL: C:\WINDOWS\Cursors
         0.03      5  SUB-TOTAL: C:\WINDOWS\Debug
         0.00      3  SUB-TOTAL: C:\WINDOWS\Downloaded Program Files
        86.94      1  SUB-TOTAL: C:\WINDOWS\Driver Cache
        12.04    177  SUB-TOTAL: C:\WINDOWS\Fonts
        40.71   1536  SUB-TOTAL: C:\WINDOWS\Help
         0.00      0  SUB-TOTAL: C:\WINDOWS\IIS Temporary Compressed Files
         0.60      3  SUB-TOTAL: C:\WINDOWS\ime
         0.00      0  SUB-TOTAL: C:\WINDOWS\ime (x86)
        41.86   1323  SUB-TOTAL: C:\WINDOWS\inf
         1.71     29  SUB-TOTAL: C:\WINDOWS\Installer
        10.96     35  SUB-TOTAL: C:\WINDOWS\java
         2.43     40  SUB-TOTAL: C:\WINDOWS\Media
        29.36    137  SUB-TOTAL: C:\WINDOWS\Microsoft
         3.13     30  SUB-TOTAL: C:\WINDOWS\msagent
         0.00      0  SUB-TOTAL: C:\WINDOWS\msapps
         0.00      0  SUB-TOTAL: C:\WINDOWS\mui
         0.00      1  SUB-TOTAL: C:\WINDOWS\Offline Web Pages
        11.75    801  SUB-TOTAL: C:\WINDOWS\PCHEALTH
         1.07      5  SUB-TOTAL: C:\WINDOWS\Registration
        11.62     10  SUB-TOTAL: C:\WINDOWS\repair
         0.00      1  SUB-TOTAL: C:\WINDOWS\Resource Pro Kit
         2.01      4  SUB-TOTAL: C:\WINDOWS\Resources
         9.48     17  SUB-TOTAL: C:\WINDOWS\security
         0.87     25  SUB-TOTAL: C:\WINDOWS\system
       677.42   5524  SUB-TOTAL: C:\WINDOWS\system32
         0.00      1  SUB-TOTAL: C:\WINDOWS\TAPI
         0.00      3  SUB-TOTAL: C:\WINDOWS\Tasks
         0.02      1  SUB-TOTAL: C:\WINDOWS\Temp
         0.00      1  SUB-TOTAL: C:\WINDOWS\twain_32
         2.44     90  SUB-TOTAL: C:\WINDOWS\Web
         5.03     16  SUB-TOTAL: C:\WINDOWS\WinSxS
       956.01  10090  TOTAL
```

To generate a list of top-level folders contained in the Windows folder with their apparent sizes, type the following at the command line:

```
diruse /* /m c:\Windows > c:\data\uncompressed.txt
```

The Uncompressed.txt file in the C:\Data folder contains the output from the command-line statement. The file contains the following output:

```
    Size (mb)  Files  Directory
         0.00      0  SUB-TOTAL: C:\WINDOWS\addins
         0.19     64  SUB-TOTAL: C:\WINDOWS\Application Compatibility Scripts
         1.56      7  SUB-TOTAL: C:\WINDOWS\AppPatch
         2.52     16  SUB-TOTAL: C:\WINDOWS\Cluster

  1090.21  10090  TOTAL
```

When you compare the output, you see that the only folder that contains compressed files is C:\Windows\System32.

**Example 3: Use DirUse in a batch file**
You want to gather directory and subdirectory information on drive X. You use a batch file so that the data generated by DirUse can be manipulated in Microsoft Excel. The sample batch file contains the following lines of code:

```
X:
cd\
diruse /s x:\ > drvdata.txt
c:
"\program files\microsoft office\office\excel.exe" x:\drvdata.txt
```

The **/s** parameter specifies that you want information about all subdirectories on drive X. The redirect symbol (>) redirects the output to a file called Drvdata.txt.

After DirUse writes the directory information to the text file, the batch file switches back to drive C and starts Microsoft Excel. The command-line argument of the file name causes Microsoft Excel to open Drvdata.txt when the application starts. If you plan to use the batch file frequently, you can create a Microsoft Excel macro to sort, delete, or format the data.

To use this batch file, save the sample code in a file called Drvdata.bat and type the following at the command line:

```
drvdata
```

# Diruse Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DirUse Syntax**

DirUse uses the following syntax:

**diruse** [**/s**|**/v**] [**/m**|**/k**|**/b**] [**/c**] [**/,**] [**/q:** *Size*] [**/l**] [**/a**] [**/d**] [**/o**] [**/***] *DirList* [**/?** | **/h** | **/help**]

**Parameters**

**/s**
Includes subdirectories of the specified directories in the output.

**/v**
Writes progress reports while scanning subdirectories. The **/v** parameter is ignored if **/s** is specified.

**/m**
Displays disk usage in megabytes.

**/k**
Displays disk usage in kilobytes.

**/b**
Displays disk usage in bytes (default).

**/c**
Uses compressed file size instead of apparent file size.

See Diruse Examples.

**/,**
Displays the thousands separator (comma or period) in file sizes.

**/q:** ***Size***
Marks, with an exclamation point (!), directories that exceed the specified size. If **/m** (megabytes) or **/k** (kilobytes) are not specified, the size is assumed to be in bytes. If **/q** is specified and any directory is found that exceeds the specified size, the return code is ONE. Otherwise the return code is ZERO.

**/l**
Writes overflows to the log file Diruse.log in the current directory.

**/a**
Specifies that an alert is generated if sizes specified by the **/q:** parameter are exceeded. The Alerter service must be running, and the alert appears only when you are using DirUse.

**/d**
Displays only directories that exceed specified sizes.

**/o**
Specifies that subdirectories are not checked to see if they exceed the specified size.

**/***
Uses the top-level directories residing in the directories specified in *DirList*.

***DirList***
Specifies a list of directories to check. *DirList* is required if you are doing anything other than getting command-line usage. Use semicolons, commas, or spaces to separate multiple directories.

See Diruse Examples for examples where *DirList* is a folder on a network volume and where *DirList* contains a list of folders.

**/?| /h| /help**
Displays command-line usage.

**Note**

- When run without parameters, DirUse displays command-line usage.

# Efsinfo Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Efsinfo.exe: Encrypting File System Information**
This command-line tool displays information about files that are encrypted with Encrypting File System (EFS) on NTFS partitions.

The user can also encrypt or decrypt a file by using the command-line tool Cipher, included with the Windows XP Professional or Windows Server 2003 operating system CD.

Efsinfo.exe info is useful for finding certificate thumbprints.

**Corresponding UI**
The **Encryption Details Dialog Box** lists the user accounts with the associated certificate thumbprint who have access to a particular file. It provides an interface to manage access to an encrypted file and displays a list of Data Recovery Agents.

To access the **Encryption Details Dialog Box** right click an encrypted file and click **Properties**. In the **File Properties Dialog Box**, click **Advanced**. In the **Advanced Attributes Dialog Box** click **Details** to open the **Encryption Details Dialog Box**.

**Concepts**
EFS is a feature of Windows that enables users to encrypt and decrypt files. Using EFS, users can protect files from unauthorized access to their sensitive data, including from a stolen laptop or external disk drive. Folders themselves are not encrypted, but are marked so that files that are created within them will be encrypted.

Accessing an EFS folder is controlled by an ACL, not the certificate key. Only the file access is controlled by certificate keys.

In EFS, users work with encrypted files just as they do with any other files, and the encryption is transparent. If the EFS user is the same person who encrypted the file or folder, then the system decrypts the file or folder when the user accesses it later. However, unauthorized users are prevented from access to encrypted files or folders.

For more information on EFS, see "Encrypting File System overview" in Help for Windows Server 2003. For more information on NTFS, see "NTFS" in Help for Windows Server 2003.

**System Requirements**
The following are the system requirements for EFSInfo:

- Windows XP Professional or Windows Server 2003

**File Required**

- Efsinfo.exe

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**EFSInfo Syntax**

EFSInfo uses the following syntax:

- **efsinfo** [**/u**] [**/r**] [**/c**] [**/i**] [**/y**] [**/k**] [**/s:***Dir*] [*Path*[**,***Path*...]] [**/?**]
- **efsinfo /t:** *dir*

**Parameters**

**Notes**

- When EFSInfo is run without parameters, it displays encryption information about the files and folders in the current folder.
- If no encrypted files or folders have been created on this computer, then EFSInfo returns no information.

**/u**
Displays encryption information about the files and folders in the current folder. This is the default.

**/r**
Displays recovery agent information.

**/c**
Displays certificate thumbnail information.

**/i**
Continues performing the specified operation even after errors have occurred. By default, EFSInfo stops when an error is encountered.

**/y**
Displays the current Encrypting File System (EFS) certificate thumbnail on the local computer. The files specified might not be on this computer. If no items are returned, there are no encrypted files on the system.

**/s: *Dir***
Performs the specified operation on directories in the given directory and all subdirectories.

***Path*[ ,*Path*...]**
Specifies the path of one or more files or directories for which to display encryption information.

**/k**
Displays key and algorithm information used to encrypt the files.

**/t: *dir***
Used to update the EFS key information on the encrypted files in a given directory and all the subdirectories.

**/?**
Displays command-line help.

# Filever Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Filever.exe: File Version**
This command-line tool examines the version resource structure of a file or a directory of files on either a local or a remote computer. It displays information on the versions of executable files such as .exe files and dynamic-link libraries (DLLs).

FileVer is useful in determining the exact binary build of an installed component. Executable files typically have their file dates and times modified to make them easy to identify as part of a major release. Hot fixes and service packs do not always follow this convention.

By identifying the actual version information, it is possible to track where a fix came from. This can be useful for customers who are requested by support personnel to identify hot fixes installed on their computers.

### Note

- FileVer might not work against localized binaries.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
For more information about comparing binary builds, see the Knowledge Base article Comparing Binary Images of Same Project Builds or Using Binary Version Compatibility.

**System Requirements**
The following is the system requirement for FileVer:

- Windows XP Professional or Windows Server 2003

**File Required**

- Filever.exe

# Filever Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**FileVer Examples**

**Example: Determine the version of Internet Explorer**
Some applications are not able to correctly determine the version number of various types of upgraded files. FileVer determines the version numbers of applications by examining the header information in the upgraded file. In this example, to determine the version number of Microsoft Internet Explorer, first append the path environment variable to include the Support Tools directory:

```
path= %PATH%;c:\program files\support tools
```

Change directories to the Internet Explorer directory:

```
cd c:\program files\internet explorer
```

Then, run FileVer by typing the following:

```
filever \v iexplore.exe
```

FileVer displays version information about Microsoft Internet Explorer similar to the following:

```
--a-- W32i   APP ENU      6.0.2484.0 shp     91,136 05-29-2001 iexplore.exe
        Language        0x0409 (English (United States))
        CharSet         0x04b0 Unicode
        OleSelfRegister Disabled
        CompanyName     Microsoft Corporation
        FileDescription Internet Explorer
        InternalName    iexplore
        OriginalFilenam IEXPLORE.EXE
        ProductName     Microsoft« Windows« Operating System
        ProductVersion  6.00.2484.0000
        FileVersion     6.00.2484.0000 (main.010529-2005)
        LegalCopyright  ¬ Microsoft Corporation. All rights reserved.

        VS_FIXEDFILEINFO:
        Signature:      feef04bd
        Struc Ver:      00010000
        FileVer:        00060000:09b40000 (6.0:2484.0)
        ProdVer:        00060000:09b40000 (6.0:2484.0)
        FlagMask:       0000003f
        Flags:          00000000
        OS:             00040004 NT Win32
        FileType:       00000001 App
        SubType:        00000000

# Filever Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**FileVer Syntax**

FileVer uses the following syntax:

**filever** [**/s**] [**/v**] [**/e**] [**/x**] [**/b**] [**/a**] [**/d**] [[[*Drive***:**]*Path*]*FileName*]

**Parameters**

**/s**
Displays files in specified directory and all subdirectories.

**/v**
Lists verbose version information if available.

**/e**
Lists executables only.

**/x**
Displays short names generated for non-8.3 file names.

**/b**
Uses bare format (no dir listing).

**/a**
Specifies not to display file attributes.

**/d**
Specifies not to display file date and time.

**[[ *Drive*:] *Path*] *FileName***
Specifies the file using the name and optionally the drive and path.

# This Topic Is No Longer Available

We're sorry—the topic that you requested is no longer available. Use the search box below to find related information.

# Msicuu Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Msicuu Remarks**

**Msicuu Log File**

Msicuu records the installations that a user deletes in a log file, Msicu.log. It creates a log for each user who runs Msicuu and stores the log in the user profile. The log is cumulative and is updated each time Msicuu runs.

The Msicuu log file, Msicu.log, is located in the *SystemDrive*\Documents and Settings*User*\Local Settings\Temp directory. Because the Local Settings directory is hidden by default, to view the file you must set your Windows Explorer folder options to show hidden files and folders.

The Msicuu log is not updated when you run Msizap.

**Msicuu and Msizap**

Msicuu uses the same programmatic functions as Msizap, and it runs Msizap (with the **T** parameter) to delete registry entries. (You can see the Msizap command window briefly when you click **Remove**.)

Unlike Msizap, Msicuu does not remove rollback data or the InProgress registry subkey, and it does not change permissions to Windows Installer objects. Also, Msicuu removes user-specific installation data only from the profile of the current user. Installation data stored in other user profiles remains in the system.

**Msicuu Products List**

Msicuu displays a list of products that Windows Installer installed on the system. It compiles this list by calling Windows Installer functions that search the registry. Msicuu or Msizap cannot be used on products that do not appear in this list.

Products that are installed on the system, but that do not appear in the list, might have been installed by other technologies, such as those used before the advent of Windows Installer. You must use other methods to clean up these installations.

# Msicuu UI

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Msicuu UI**

**To use Msicuu**

- To run Msicuu, in the **Run** dialog box or at the command prompt, type `msicuu`.
- To quit Msicuu, click **Exit**.
- To delete installation data, select one or more product names from the **Installed Products** box, and then click **Remove**.
- To select all products, click **Select All**, or click **Clear All** to clear selection of all products.
- Msicuu prompts you for confirmation. Its actions are not reversible.

# Msizap Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Msizap.exe: Windows Installer Zapper**
This command-line tool deletes configuration data that Windows Installer maintains for products that it installs, including the directories, files, registry subkeys, and registry entries in which Windows Installer stores configuration data. You can use Msizap to remove remnants of corrupted Windows Installer installations that prevent you from installing a product correctly.

You can also use Msizap to give administrators Full Control permissions to Windows Installer folders, files, and registry subkeys.

**Caution**

- Msizap can delete installation data that is required by the system. Products installed by Windows Installer might not operate properly after using this tool.

  Msizap is designed as a *last resort* tool to be used only when conventional methods of repairing or removing an installation have failed. Before using Msizap, use Add or Remove Programs to remove or repair the installation. If that fails, use the Msicuu Overview (Msicuu.exe), which runs Msizap, but prevents you from causing unnecessary harm to the system.

You can use Msizap to correct the following installation failures.

- A Windows Installer installation, uninstallation, or rollback is interrupted or fails unpredictably. Because the installation did not complete successfully, Windows Installer will not uninstall or reinstall the program, or install any another programs.

- Registry entries for a product have been deleted or changed, damaging the operation of the products and preventing you from uninstalling or reinstalling the product.

- Multiple instances of a setup program are running simultaneously, or an instance of a setup program cannot run.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Windows Installer manages the installation and removal of applications on Windows XP Professional and Windows Server 2003 operating systems. Typically, these installations conclude successfully, or are successfully reversed ("rolled back") or repaired. However, in rare situations, an installation, a rollback, or an uninstallation fails, leaving installation files and registry entries that would otherwise be removed. As long as these objects remain on the system, Windows Installer considers the installation to be active and incomplete.

Because Windows Installer conducts only one installation at a time, it will not start another installation until all indicators of the active installation are removed.

You can use Msizap to remove particular installation remnants, such as the InProgress registry subkey and the rollback registry data. You can also delete all configuration data for a specified installation, or all Windows Installer installations on the system.

**System Requirements**

- This version of Msizap runs on Windows XP Professional and Windows Server 2003 operating systems. (Windows 2000 includes a version of Msizap for that operating system.)

- The user must be a member of the Administrators group on the computer affected.

- Msizap affects only the local computer. You cannot use it to manage a remote computer.

**File Required**

- Msizap.exe

# Msizap Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Msizap Remarks**
**General Information**

- If you type `msizap` without any parameters, or with an incorrect parameter combination, command-line help displays.
- When you run Msizap, it displays a complete transaction log, including a list of the folders, files, and registry subkeys that it deleted or changed.
- Msizap affects only products installed by Windows Installer. It does not affect products that were installed by other technologies, including older Windows applications that were installed before the advent of Windows Installer.
- Msizap does not uninstall programs or delete objects that programs install during their setup procedures. It only deletes configuration data that Windows Installer stores for its own use.
- Programs removed by using Msizap might no longer appear in **Add or Remove Programs** in Control Panel.

**Troubleshooting Windows Installer**
Msizap is designed to be used as a last resort to remove the remnants of a corrupted installation. It is a blunt instrument that can delete installation data that is required by the system.

Before using Msizap, try the following less risky methods for repairing a failed installation:

- Use Add or Remove Programs in Control Panel to remove or repair the installation.
- Use Msiexec (command-line options), the command-line version of Windows Installer, with parameters to repair the installation and recache the local package. For example, use the following syntax to repair the MyPackage installation:

  **msiexec /fvomus package.msi**

**Troubleshooting Msizap**
When Msizap completes successfully, it displays a log of the objects that it searched, deleted, and changed. To determine whether Msizap ran to completion, look for one of the following statements at the end of the log.

| Final Log Statement | Description |
|---|---|
| Searching for files and folders in the %WINDIR%\Installer folder. | Msizap successfully completed a command using the **T** or **A** parameter. If the Installer folder is empty, then Msizap records a final action, in which it deletes the Installer folder. |
| No product data was found. | Msizap searched successfully, but did not find any of the specified objects on the system. Typically, this happens when an **msizap** command is repeated. |
| FAILED to clear all data. | Msizap cannot delete all of the data requested by the command. Output that ends with this statement also includes a failure statement and an error code at the point in the log at which the failure occurred. Failures are typically caused by problems with permissions, or with folders that do not reside on the local computer. |

**Stopping the Windows Installer Service**
The *** ALLPRODUCTS** and **T** parameters stop the Windows Installer service so that Msizap can obtain exclusive access to the files, folders, and registry subkeys that it needs to change or delete. Because the Windows Installer service starts automatically when needed and stops automatically when idle, you do not need to stop or restart this service manually.

**Identifying Package Files**
All Windows Installer Package files end with the file name extension .msi. However, the file names are sometimes obscure and are often numeric, making it hard to determine which program the package file installs. Fortunately, this data is included in the summary information associated with each package file.

To display the summary information for a package file, use one of the following methods:

- In Windows Explorer, place the mouse pointer over the name of an .msi file. (However, do not click.)
- In Windows Explorer, right-click the name of an .msi file, click **Properties**, and then click the **Summary** tab.

**Folders Deleted by Msizap**
Msizap attempts to delete the following directories when it is run with the ***** or **T** parameter. The list of objects actually deleted appears in the command window when you run Msizap.

- *SystemDrive*\Documents and Settings*UserName*\Application Data\Microsoft\Installer*ProductCode*
- *Systemroot*\MSI
- *Systemroot*\Installer*ProductCode* (a hidden system folder)
- *Drive*:\config.msi (for each local drive)

**Active (Incomplete) Installations**
When an installation does not complete or roll back successfully, some remnants of the installation might remain in the system. Windows Installer considers the incomplete installation to be active and will not install new products or reinstall existing products until the installation is resolved.

Because Windows Installer runs only one installation at a time, only one installation is active at any given time and there is only one instance of the indicator objects on any system.

The following objects indicate an active, incomplete installation on the system. When an installation completes successfully, Windows Installer automatically deletes these objects from the system.

- The InProgress registry subkey:

  **HKLM\Software\Microsoft\Windows\CurrentVersion\Installer\InProgress**

- Rollback data, which includes rollback scripts and registry entries for the following Rollback registry subkey:

  **HKLM\Software\Policies\Microsoft\Windows\Installer\Rollback**

To search for the InProgress subkey on a system, use Regedit.exe or Reg.exe, tools included in Windows XP Professional and Windows Server 2003 operating systems. Enter a command that uses the following syntax:

**reg /query** [*****ComputerName*] **HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion\Installer\InProgress**

To search for the Rollback subkey on a system, use Regedit or Reg, tools included in Windows XP Professional and Windows Server 2003 operating systems. Enter a **reg** command that uses the following syntax:

**reg /query** [*****ComputerName*] **HKLM\Software\Policies\Microsoft\Windows\Installer\Rollback**

**Registry Subkeys Deleted by Msizap**
Msizap attempts to delete the following registry subkeys when it is run with the ***** or **T** parameter. The list of objects actually deleted appears in the command window when you run Msizap.

- **HKCU\Software\Classes\Installer\Features***ProductCode*
- **HKCU\Software\Classes\Installer\Products***ProductCode*

# Msizap Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Msizap Examples**

**Example 1: Delete remnants of an active installation**

The following command deletes the InProgress subkey and the indicators of an Msizap Remarks on the computer. Because the command does not specify an installation, Msizap searches all installations until it finds these objects.

In this command, the **P** parameter deletes the InProgress registry subkey and the **S** parameter deletes rollback data:

```
msizap PS
```

In response, Msizap lists the actions it took to comply with the command:

```
MsiZapInfo: Performing operations for user S-1-5-21-2127521184-1604012920-1887927527-
00000

Searching for the Windows Installer InProgress key. . .
   Removed  \Software\Microsoft\Windows\CurrentVersion\Installer\InProgress
Searching for Installer files and folders associated with the product {ALL PRODUCTS}. .
.
  Searching for rollback folders. . .
Searching for the Windows Installer Rollback key. . .
   Removed  \Software\Microsoft\Windows\CurrentVersion\Installer\Rollback
```

The list begins by identifying the user profile from which user-specific data is deleted. Unless the **W** parameter is used, only the SID of the current user appears.

The remaining elements in the list report objects deleted or changed by the command. Note that Msizap searches for all products because the command did not specify a product by name or product code.

**Example 2: Remove installation data for a program**

The following command deletes all Windows Installer configuration data for MyApp.exe, a fictitious program installed by the MyApp.msi package file.

The command identifies the program by using the fully qualified path to the Windows Installer package file for the program. It uses the **T** parameter to delete the folders, files, and registry subkeys that Windows Installer created for the package, and the **P** and **S** parameters to remove rollback data and the InProgress subkey, in case they remain in the system.

Finally, the command redirects the output to a text file (Msizap.log), so that the detailed output is recorded in the file:

```
msizap TPS "C:\Program Files\My Apps\MyApp.msi" > msizap.log
```

The resulting Msizap.log file begins by displaying the SID of the user profile from which Msizap deleted user-specific objects (in this case, the current user profile), followed by a complete log of the objects that it searched, deleted, and changed.

As expected for a command using the **T** parameter, the log ends with a search of the %WINDIR%\Installer folder. If this folder no longer contains any directories, then Msizap deletes the folder. In this case, the folder still contains data for other programs, so Msizap does not delete it.

**Sample output**

```
C:\myapp>msizap tps myapp.msi

```

**Example 3: Change permissions to installation objects**

The following command grants members of the Administrators group on the computer Full Control permission to the folders, files, and registry subkeys for the MyApp.msi installation. The command changes permissions only; it does not delete any installation data.

The command uses the **A** parameter to specify that it is changing permissions, and the **T** and **W** parameters to specify which permissions it is changing. The command changes permissions on objects that the **T** parameter would otherwise delete, that is, the permissions to all files, folders, and registry subkeys that Windows Installer maintains for the installation. The **W** parameter extends the permission changes to objects in all user profiles in the registry.

In this command, the MyApp.msi package is identified by its product code, enclosed in the required braces:

```
msizap ATW {00000001-0001-0000-0000-624474736554}
```

The resulting Msizap.log file is divided into sections for each user profile that Msizap changes. The log lists all the objects for which Msizap searched, and those on which it changed permissions.

As expected for a command using the **A** parameter, each section of the log ends with a search of the %WINDIR%\Installer folder.

**Sample output**

```

```

**Example 4: Delete configuration data for another user**

The following command deletes Windows Installer configuration data for MyApp.msi for all users of the computer. The command is intended to remove installer data from the profile of User21, a user who is not a member of the Administrators group on the computer. To assure that the user's profile is loaded in the registry, the command must run while User21 is logged on to the system. However, because Msizap runs only with Administrator permissions, an administrator must run this command. In this example, the administrator uses the Runas command extension to provide user credentials. For information about using the Runas command, see "Runas" in Help for Windows Server 2003.

The command uses the **T** parameter to specify that all Windows Installer files, folders, and registry subkeys for MyApp.msi are deleted. It also uses the **W** parameter to make certain that the profile of User21 is affected, because Runas can temporarily make the administrator the current user of the computer.

The command is run by the administrator while User21 is logged on to the computer.

```
runas /env /user:Computer21\Administrator msizap TW MyApp.msi
```

In response, Runas prompts the administrator for a password, and then Msizap responds to the command. All MyApp.exe installer configuration data for all users, including User21, is deleted.

**Example 5: Delete all configuration data from the system**

The following command deletes all Windows Installer configuration data for all programs on the system. Because this

command can cause serious and irreparable harm, it is very rarely used.

The command uses the *** ALLPRODUCTS** parameters to extend the command to all products that Windows Installer installed on the system. It uses the **W** parameter to delete data from all user profiles. The only Windows Installer data that might remain in the system when the command completes is data that is stored in user profiles that are not present in the registry when the command runs.

```
msizap *W ALLPRODUCTS
```

# Msizap Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Msizap Syntax**

Msizap uses the following syntax combinations:

To remove remnants of an active (incomplete) installation

**msizap**[**P**][**S**]

To remove data for a specified installation

**msizap**[**T**][**P**][**S**][**W**][**G**] *PackageName* | **{***ProductCode***}**

To remove all installation data

**msizap ***[**W**][**!**]**ALLPRODUCTS**

To give Administrators Full Control permission to installation data

**msizap A**[*****][**T**][**W**][**P**][**S**] [*PackageName* | **{***ProductCode***}** | **ALLPRODUCTS**]

To display help

**msizap /?**

### Notes

- When deleting objects that are unique in the system (such as the InProgress registry subkey or rollback data) or to change permissions, you do not need to specify an installation package.
- The package name, product code, or **ALLPRODUCTS**, if included, must be the last parameter in the command. Other parameters may be listed in any order.
- When using **T**, you must specify an installation by package name or product code. When using *****, you must specify **ALLPRODUCTS**.

**Parameters**

*****

Deletes all Windows Installer configuration data on the computer. **ALLPRODUCTS** is required when using *****.

This parameter deletes the folders, files, registry subkeys, and registry entries in which Windows Installer stores configuration data, including rollback data and the InProgress registry subkeys for each installation. It also stops the Windows Installer service, deletes published icons (icons that offer to install a program), and adjusts shared DLL counts.

**!**

Suppresses all confirmation messages.

**A**

Gives administrators Full Control permission to the folders, files, and registry subkeys specified by other parameters in the command. When combined with **A**, other parameters specify which object DACLs are changed; they do not direct Msizap to delete installation configuration data.

**P**

Deletes the InProgress registry subkey.

This parameter deletes the subkey that indicates to Windows Installer that an installation is in progress:

**HKLM\Software\Microsoft\Windows\CurrentVersion\Installer\InProgress**

While this subkey remains in the registry, Windows Installer will not install another program. Because Windows Installer deletes the InProgress subkey when an installation completes, this subkey is present only for an active installation.

**S**

Deletes rollback data.

This parameter deletes the Rollback registry subkey (below), rollback scripts, and backup copies that enable Windows Installer to restore the computer to its original state when an installation stops before it is complete.

**HKLM\Software\Microsoft\Windows\CurrentVersion\Installer\Rollback**

Because Windows Installer automatically deletes rollback data when an installation completes, rollback data is present only for an active installation.

**T**

Deletes Windows Installer configuration data for a specified installation.

This parameter deletes the folders, files, registry subkeys, and registry entries in which Windows Installer stores configuration data for the installation (except for rollback data and the InProgress registry subkey, which are specified separately). It also stops the Windows Installer service, deletes published icons (icons that offer to install a program), and adjusts shared DLL counts.

**W**

Extends the command to all user profiles. By default, Msizap deletes and changes user-specific data only for the current user.

**G**

Removes orphaned cached Windows Installer data files for all users.

**?**

Displays help.

***PackageName* | {*ProductCode*}**

Specifies an installation as the target of the **msizap** command. Type the product code or the path and file name of the Windows Installer package file, such as:

```
c:\ptree.msi
```

If you do not specify an installation, then **msizap** commands apply to all Windows Installer installations on the computer.

**ALLPRODUCTS**

Indicates all Windows Installer installations on the computer. **ALLPRODUCTS** is required when using *****.

**Sample Usage**

```
msizap *! ALLPRODUCTS
msizap PS
msizap AT ptree.msi
msizap WTP MyPackage.msi
msizap TW {00000001-0001-0000-0000-624474736554}
```

# Showaccs Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Showaccs.exe: Show Access Control Lists**
This command-line tool enables users to examine the access control lists (ACLs) on the registry, file system, and file and print shares, and to look at membership in local groups. ShowAccs command options support looking at specific areas of Windows 2000 and Windows XP (such as specific file-system directories), or examining the entire system.

The output file of ShowAccs is a comma-separated text file, called the access-profile file, that shows all the object-specific access rights on the system. The access-profile file can be reviewed and analyzed by using a text editor, or it can be imported into a spreadsheet or database management program.

ShowAccs also creates a mapping file that lists the security principals (users and groups) that show up somewhere in ACLs. The mapping file can be input to the Security Migration Editor Microsoft Management Console (MMC) snap-in for account mapping.

### Note

- This tool is part of the Sidwalker Security Administration Tools.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Access control is implemented by access control lists (ACLs). Every file in the NTFS file system and every registry key has a unique ACL, granting access rights to file resources to users and groups, and defining what specific access rights each is granted. Each user and group is identified in the ACL by a security identifier (SID).

**System Requirements**
ShowAccs can be run as scheduled batch jobs. It must be run locally on the computer where the access permissions are to be changed. ShowAccs uses Windows NT security APIs (supported on Windows NT 4.0, Windows 2000, and Windows XP) to examine every access control list (ACL) on every object on the system. It is a CPU and I/O intensive program; plan to run it when system use is otherwise very light and expect significant resource use.

In Windows NT 4.0, ShowAccs requires Msvcrt50.dll, which is found in the \System32 directory of any Windows 2000 installation.

**Files Required**

- Showaccs.exe
- Msvcrt50.dll (found in the \System32 directory)

# Showaccs Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ShowAccs Remarks**

**Using ShowAccs**

ShowAccs can examine the registry in approximately five minutes. Walking through the entire registry or file system, however, might require many hours, depending on the size of the file system and the scope of analysis. Examining every ACL on every file and converting security identifiers (SIDs) on a large file system of roughly 50 gigabytes (GB) can take two or more hours with 100 percent CPU utilization.

# Showaccs Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**ShowAccs Syntax**

ShowAccs uses the following syntax:

**showaccs** *AccessProfileFile*[**/f** [*Path*]][**/r**][**/s**][**/p**][**/g**][**/m** [*MapFilePath*]][**/nobuiltins**][**/?**]

**Parameters**

**Note**

- When run without parameters, ShowAccs displays help.

***AccessProfileFile***

Specifies the path of the .csv file to be generated.

**/f[ *Path*]**

Shows access rights for all NTFS files or, optionally, for those in the directory tree of the specified path.

**/r**

Shows access rights for the registry.

**/s**

Shows access rights for file shares.

**/p**

Shows access rights for printer shares.

**/g**

Shows access rights for local groups.

**/m[ *MapFilePath*]**

Generates a map file, optionally in the directory specified by *MapFilePath*.

**/nobuiltins**

Omits access rights for built-in groups.

**/?**

Displays help on Showaccs.

# Spcheck Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Spcheck.exe: Service Pack Checker**
This command-line tool is used by administrators to determine which service pack is installed on a Windows Server 2003, Windows XP Professional, Windows 2000, or Windows NT 4.0 system. SPCheck checks which executable files, dynamic-link libraries, and drivers are installed on the target system. This helps to identify when service packs or hot fixes should be reinstalled, and ensures that all installed services are at the appropriate service pack level.

### Notes

- You must run SPCheck from the command window.
- SPCheck must run under a security context equivalent to the local administrator account.
- To obtain .ini files for SPCheck, search the Microsoft Web site and/or contact Microsoft Product Support Services.

**Concepts**
A *service pack* is a consolidated release of updates for a specific piece of software.

You can find service packs to download at the Windows Update Web site.

**System Requirements**
The following are the system requirements for SPCheck:

- Windows XP Professional or Windows Server 2003, or
- Windows 2000 Professional or Server, or
- Windows NT 4.0

**Files Required**

- Spcheck.exe
- Dbghelp.dll (located in the *Windir*\System32 folder)
- Spcheck.ini

# Spcheck Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SPCheck Remarks**

**Understanding SPCheck**

SPCheck examines target components one file at a time. This means that SPCheck must run under a security context equivalent to the local administrator account. If the tool is not run under this security context, files may be reported as missing even though they are installed on the system. The tool compares the size and date of each file to those listed in Spcheck.ini. SPCheck's search algorithm uses system environment variables in combination with other methods to find and report on target files located on the target system.

**Interpreting the Results**

SPCheck creates a report detailing the results of its scan in the same directory from which SPCheck was run. It has the following format:

```
[WINS]
C:\WINNT\System32\Jet500.dll SP0-3
C:\WINNT\System32\Jet.dll SP0-6a
C:\WINNT\System32\Wins.exe Missing
C:\WINNT\System32\Winsadmin.exe Unknown
C:\WINNT\System32\Winsctrl.dll SP5
```

"Missing" indicates that the file was not found on the target system, and "Unknown" indicates that the file was found on the target system but did not match any of the files recorded in the .ini file.

Not all files are updated for each service pack release. For example, in the report excerpted here, SP0-3 means that Jet500.dll did not change in any of the first three service packs.

# Spcheck Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SPCheck Examples**

**Example: Verify that the RRAS services are at the required service pack level**

Your organization has purchased some new RRAS management software made by another company. After it is installed, the RRAS services no longer function properly. You are concerned that the software might have replaced some of the critical RRAS files with previous versions. After searching on the Microsoft Web site, you find an Rras.ini file for use with SPCheck.

To verify that the RRAS files are current, type the following at the command line:

```
spcheck.exe /i rras.ini /r rras.txt
```

In this example, SPCheck used an .ini file named Rras.ini and created a report named Rras.txt. The following output is an excerpt from Rras.txt:

```
SPCHECK Report File
System Date:Tue May 28 14:38:13 2002

The last Windows service pack to be installed on this system was:
Version 5.0 Service Pack 1 (Build 2195)

Check the system analysis section of this report,
to see if all files are Service Pack 1 files

System Analysis
====================
 [RRAS]
  C:\WINNT\System32\Rascfg.dll SP0-3
  C:\WINNT\System32\Rasfil32.dll SP0-2
  C:\WINNT\System32\Rasadmin.exe SP0-3
  C:\WINNT\System32\Rassapi.dll SP0-1
  C:\WINNT\System32\Rasphone.exe SP0-2
```

You can see by this report that if the target system has Service Pack 1 (SP1) installed on it, each file is within the necessary range for the service pack: The target system contains RRAS-related files that are consistent with SP1. This indicates that the issue is not file-related, but probably a configuration problem. You can find more tips on interpreting the report's format at the end of each report.

# Spcheck Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SPCheck Syntax**

SPCheck uses the following syntax:

**spcheck** [**/i***INIFileName*] [**/r***RepFileName*]

**Parameters**

***/i INIFileName***

Specifies the name of the .ini file to be used. If this parameter is omitted, Spcheck.ini is used.

**Note**

- To obtain .ini files for SPCheck, search the Microsoft Web site and/or contact Microsoft Product Support Services.

***/r RepFileName***

Specifies the name of the report file that is generated when the tool is run. If this parameter is omitted, the default report name Spcheck.rpt is used.

**Examples**

See Spcheck Examples.

# Windiff Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windiff.exe: WinDiff File and Directory Comparison**
This GUI tool shows the differences between specified ASCII text files, or folders containing ASCII text files. This is particularly useful for program source code.

The display shows either a summary of the comparison status of a list of files (outline mode) or a detailed line-by-line comparison of one of the files (expanded mode).

You can run WinDiff as a Windows-based application, using menu commands to choose files to compare and perform other actions. Or you can run WinDiff from the command line by using parameters described in the tool's Help.

**Files Required**

- Windiff.exe
- Windiff.hlp
- Gutils.dll

### For More Information

For more information on WinDiff, click Help on the tool's menu. Alternatively, you can run Windiff.hlp from the command line to see the WinDiff help file.

# Httpcfg Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Httpcfg.exe: HTTP Configuration Utility**
The HTTP Configuration Utility can be used to manage the HTTP application programming interface (API). It may be used to perform many of the tasks associated with web server administration.

**Concepts**
The HTTP API enables applications to communicate over HTTP without using Microsoft Internet Information Services (IIS). Applications can register to receive HTTP requests for particular URLs, receive HTTP requests, and send HTTP responses. The HTTP API includes SSL support so applications can also exchange data over secure HTTP connections without depending on IIS. It is also designed to work with I/O completion ports.

Use this tool to configure a web server in any of the following ways:

- Add, query and delete SSL certificate meta-information. Such meta-information is maintained by the HTTP API in a metastore, and is used to locate certificates for certificate exchange in HTTPS sessions.
- Add, query and delete namespace reservations. The HTTP API allows administrators to reserve URI namespaces and protect them with Access Control Lists (ACLs), so that only specified HTTP API clients can use them.
- Add, query, and delete Internet Protocol (IP) addresses in the IP Listen List. If this list of addresses is specified, the HTTP API listens only to addresses on the list. Otherwise it listens on all IPs on the machine.

**System Requirements**
The following are the system requirements for this tool:

- Windows Server 2003

**Files Required**

- Httpcfg.exe

# Httpcfg Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Httpcfg Remarks**
**The /a Parameter**
**Security Descriptor Definition Language**

The /**a** parameter takes a string in the form of the Security Descriptor Definition Language (SDDL). The SDDL string defines the format that is used by the '**httpcfg** *set urlacl* /**a**' command. The SDDL also defines string elements for describing information in the components of a security descriptor.

For more information, see the Security Descriptor Definition Language topic on the MSDN website (http://msdn.microsoft.com).

**Httpcfg.exe and the HTTP API**
For more information about how Httpcfg corresponds to the HTTP API, see Using the HTTP API Configuration Tool.

**Httpcfg.exe return codes**
The httpcfg.exe commands return a standard WIN32 API error code. A return value of 0 means that the command completed successfully. For more information on WIN32 API error codes, see the Event Logging topic on the MSDN website (http://msdn.microsoft.com).

# Httpcfg Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Httpcfg Examples**

[httpcfg ssl](#)

[httpcfg urlacl](#)

**httpcfg ssl**

This group of examples shows how to add, show, and delete a certificate in the SSL store.

**Adding an SSL Certificate to the Store**

In the following example, the user types the **set ssl** command, using the **/i**, **/h**, and **/g** parameters to specify the IP address, Thumbprint hash, and GUID, respectively, for the certificate being added.

```
httpcfg set ssl /i 10.0.0.1:80 /h 2c8bfddf59a4a51a2a5b6186c22473108295624d /g "{2bb50d9c-7f6a-4d6f-873d-5aee7fb43290}"
```

After running the command, Httpcfg displays the following text on the screen to confirm the command completed without an error (error code of 0).

```
HttpSetServiceConfiguration completed with 0.
```

**Viewing Certificates in the SSL Store.**

In this example, the user first types the **query ssl** command with the **/i** parameter, specifying an IP address in order to view the meta-information for a particular certificate. Following that, the user types **query ssl** without the **/i** paremeter, to view all certificates in the store.

```
httpcfg query ssl

    SslCtlIdentifier         : (null)
    SslCtlStoreName          : (null)
    Flags                    : 0
-------------------------------------------------------------------------------
```

**Deleting a Certificate from the SSL Store.**

In this example, the user types **delete ssl** with the required **/i** parameter to delete the associated certificate record from the SSL store.

```
httpcfg delete ssl /i 10.0.0.1:80
```

Httpcgf then displays the following text to the screen, verifying that the command completed successfully (error code of 0).

```
HttpDeleteServiceConfiguration completed with 0.
```

**httpcfg urlacl**

This group of examples show how to add, remove, and view URL ACL combinations in the urlacl store.

**Adding a URL ACL combination to the urlacl store**

```
httpcfg set urlacl /u http://woodgrovebank.com:443/ /a "O:DAG:DAD:(A;;GRGX;;;DA)(A;;GA;;;BA)"

HttpSetServiceConfiguration completed with 0.
```

**Viewing all of the URLs that have been assigned an ACL.**

```
httpcfg query urlacl

    URL : http://woodgrovebank.com:443/
    ACL : O:DAG:DAD:(A;;GXGR;;;DA)(A;;GA;;;BA)
-------------------------------------------------------------------------------
    URL : http://woodgrovebank.com:80/
    ACL : O:DAG:DAD:(A;;CCDC;;;SY)(A;;CCDC;;;DA)(OA;;CCDC;bf967aba-0de6-11d0-a285-
00aa003049e2;;AO)(OA;;CCDC;bf967a9c-0d
e6-11d0-a285-00aa003049e2;;AO)(OA;;CCDC;6da8a4ff-0e52-11d0-a286-00aa003049e2;;AO)
(OA;;CCDC;bf967aa8-0de6-11d0-a285-00aa0
03049e2;;PO)(A;;;;;AU)S:(AU;SAFA;CCDCSWWPSDWDWO;;;WD)
-------------------------------------------------------------------------------
```

**Deleting a URL ACL combination from the urlacl store.**

```
httpcfg delete urlacl /u http://woodgrovebank.com:80/

HttpDeleteServiceConfiguration completed with 0.
```

httpcfg iplisten

This group of examples show how to add, delete, and list IP address in the iplisten store.

Adding an IP address to the iplisten store.

```
httpcfg set iplisten -i 10.0.0.1:80

HttpSetServiceConfiguration completed with 0.
```

Viewing all off the IP addresses that the HTTP API is listening on.

```
httpcfg query iplisten

    IP                      : 10.0.0.1:80
-------------------------------------------------------------------------------
    IP                      : 10.0.0.13:80
-------------------------------------------------------------------------------
```

Shows the result of deleting a record from the iplisten store.

```
httpcfg delete iplisten -i 10.0.0.1:80

HttpDeleteServiceConfiguration completed with 0.
```

# Httpcfg Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Httpcfg helps you manage the HTTP API.

#### Httpcfg Syntax

Httpcfg uses the following syntax:

**httpcfg** {**set** | **query** | **delete**} {**ssl** | **query** | **iplisten**} [**/i** *Ip:Port*] [**/h** *SSL Hash*] [**/g"{***GUID***}"**] [**/c** *StoreName*] [**/m** *CheckMode*] [**/r** *RevocationFreshness*] [**/x** *UrlRetrievalTimeout*] [**/t** *SslCtlIdentifier*] [**/n** *SslCtlStoreName*] [**/f** *Flags*] [**/u** {**http://***URL***:***Port***/** | **https://***URL*:*Port***/**}] [**/a** *ACL*]

#### Parameters

"**Action**" commands are: **set**, **query** and **delete**. They are followed by a set of arguments, **ssl**, **urlacl**, and **iplisten**, which are known as "**store**" arguments. Depending on the value of **action** and **store**, different parameters are then available. For example, the **set ssl** command may take a different set of parameters than the **query ssl** command.

- **httpcfg** {**action**} {**store**} [*parameter*]

#### Action commands

**set**

Creates a configuration record containing the values specified by the **ssl**, **urlacl**, or **iplisten** argument. This record is then added to the HTTP API configuration store. The call fails if a record with the specified values already exists. To change a given configuration record, you must first **delete** it, and then recreate it by using **set** with the updated value(s).

**query**

Retrieves one or more HTTP API configuration records.

**delete**

Deletes the specified information, such as IP addresses or SSL certificates, from the HTTP API configuration store, one record at a time.

#### Store arguments

**ssl**

Depending on the **Action** command used, adds (**set**), queries or deletes SSL certificate meta-information. Such meta-information is maintained by the HTTP API in a metastore, and is used to locate certificates for certificate exchange during HTTPS sessions.

**urlacl**

Depending on the **Action** command used, adds (**set**), queries, or deletes namespace reservations. The HTTP API allows administrators to reserve URI namespaces and protect them with Access Control Lists (ACLs), so that only specified HTTP API clients can use them.

**iplisten**

Depending on the **Action** command used, adds (**set**), queries, or deletes Internet Protocol (IP) addresses in the IP Listen List. If this list is present, the HTTP API listens only to addresses on the list.

#### httpcfg set ssl

**/i *Ip:Port***

The **/i** parameter takes a string that specifies the IP-Address:port combination. This serves as the record key identifying the SSL certificate being added. When using **set ssl**, the **/i** parameter is required.

**/h *SSL Hash***

The **/h** parameter takes a string of hexadecimal digits specifying the Thumbprint hash of the certificate being added. This is not a required parameter, however the SSL connection will fail if the hash is invalid.

**/g "{ *GUID* }"**

The **/g** parameter takes a string representing a Globally Unique Identifier (GUID) that identifies the application that added the certificate. In the case of Httpcfg, the GUID must be generated by the user. The enclosing quotation marks and curly braces are required; the **/g** parameter will not work without them. For more information on generating GUIDs, see Generating Interface UUIDs on the Microsoft Developer Network (MSDN).

**/c *StoreName***

The **/c** parameter takes a string that specifies the name of the store where the certificate being added resides. If no string is specified, the name "MY" is used by default.

**/m *CheckMode***

The **/m** parameter takes a string containing one or more numbers representing flags that determine the default mode for checking the certificate. The numbers may consist of one or more of the following flag values:

- 1 - Client certificate will not be verified for revocation.
- 2 - Use cached client certificate revocation.
- 4 - Enable revocation freshness time.
- 65536 - No usage check.

**/r *RevocationFreshness***

The **/r** parameter takes a string of numbers that specify the revocation freshness time for the certificate. Revocation freshness represents the number of seconds after which to check for an updated certificate revocation list (CRL). If this value is absent or zero, the new CRL is updated only when the previous one expires.

**/x *UrlRetrievalTimeout***

The **/x** parameter takes a string of numbers representing the timeout interval, in milliseconds, for retrieving a certificate revocation list from the remote URL.

**/t *SslCtlIdentifier***

The **/t** parameter takes a string that specifies an SSL control identifier, which restricts the group of certificate issuers to be trusted. This group must be a subset of the certificate issuers trusted by the machine being administered.

**/n *SslCtlStoreName***

The **/n** parameter takes a string containing the name of the store in which to look up the control identifier specified by the **/t** parameter.

**/f *Flags***

The **/f** parameter takes a string containing a number that controls how client certificates are handled. This number may consist of one or more of the following values:

- 1 - Use DS Mapper.
- 2 - Negotiate client certificate.
- 4 - Do not route to raw ISAPI filters.

**httpcfg query ssl**

**/i *Ip:Port***

The **/i** parameter takes a string that specifies the IP-Address:port combination. This serves as the record key identifying the SSL certificate being queried. If this parameter is omitted, then the query returns all records in the SSL store.

**httpcfg delete ssl**

**/i *Ip:Port***

The **/i** parameter takes a string specifying the IP-Address:port combination. This serves as the record key identifying the SSL certificate to be deleted. When using **delete ssl**, the **/i** parameter is required.

**httpcfg set urlacl**

**/u {http://*URL:Port*/ | https://*URL:Port*/}**

The **/u** parameter takes a string containing a fully qualified URL that will serve as the record key for the reservation being made. When using **set urlacl**, the **/u** parameter is required.

**/a *ACL***

The **/a** parameter takes a string containing an Access Control List in the form of a Security Descriptor Definition Language (SDDL) string. For more information see Httpcfg Remarks. When using **set urlacl**, the **/a** parameter is required.

**httpcfg query urlacl**

**/u *URL***

The **/u** parameter takes a string containing a fully qualified URL that identifies the reservation being queried. If no string is specified, the query returns all reservations in the store.

**httpcfg delete urlacl**

**/u *URL***

The **/u** parameter takes a string containing a fully qualified URL that identifies the reservation to be deleted. When using **delete urlacl**, the /**u** parameter is required.

**httpcfg set iplisten**

**/i *Ip:Port***

The **/i** parameter takes a string specifying the IP address to be added to the IP-Listen List. This can be either an IPv4 or IPv6 address. When using **set iplisten**, the /**i** parameter is required.

**httpcfg query iplisten**

**/i *Ip:Port***

The **/i** parameter takes a string specifying the exact IP address to be queried. If absent, the query returns all addresses in the store.

**httpcfg delete iplisten**

**/i *Ip:Port***

The **/i** parameter takes a string specifying the IP address to be deleted from the IP-Listen List. This can be either an IPv4 or IPv6 address. When using **delete iplisten**, the /**i** parameter is required.

# Network Services Management Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Network Management Tools**
Tools in this category are used to manage the following Windows features:

- Connection Manager
- DHCP
- DNS
- Internet Authentication Service (IAS)
- Internet Protocol (IP)
- Internet Protocol Security (IPSEC)
- Modems
- Novell NetWare Integration
- Routing and Remote Access
- Quality of Service (QoS)
- Services for Macintosh
- Session Initiation Protocol (SIP)
- TCP/IP
- Telephony
- Virtual Private Networks (VPN)
- Windows ATM services
- Wireless networking

**Notes**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Browstat Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Browstat.exe: Browser Status Utility**
This command-line tool is a general purpose character-based browser diagnostic tool. Use BrowStat to view the status of running browsers in Windows Server 2003 domains. This tool also provides information about the state of the browser, including the name of the master browser.

You can also find out which transports are on a computer. In this context, "transport" refers to the Windows XP or Windows Server 2003 network device name (case-insensitive) for a transport.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Microsoft Windows Server 2003 and Microsoft Windows XP Professional continue to support the browser service. The browser service identifies which resources, domains, and servers are available to a node on the network. It also provides interoperability with domains and computers that are not enabled to use the Active Directory directory service.

**System Requirements**
The following are the system requirements for BrowStat:

- Windows Server 2003

**File Required**

- Browstat.exe

# Browstat Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BrowStat Remarks**

**BrowStat Stats Information**

| Title | Description |
|---|---|
| **NumberOfServerEnumerations** | Number of browse requests for servers |
| **NumberOfDomainEnumerations** | Number of browse requests for domains |
| **NumberOfOtherEnumerations** | Number of "other" browse requests |
| **NumberOfMailslotWrites** | Number of mailslot writes received |
| **NumberOfServerAnnouncements** | Number of server announcements received |
| **NumberOfDomainAnnouncements** | Number of domain (work group) announcements received |
| **NumberOfElectionPackets** | Number of browser election packets received |
| **NumberOfGetBrowserServerListRequests** | Number of GetBrowserServerList requests received |
| **NumberOfMissedGetBrowserServerListRequests** | Number of GetBrowserServerList requests missed |
| **NumberOfDroppedServerAnnouncements** | Number of server announcements dropped |
| **NumberOfDroppedMailslotDatagrams** | Number of mailslot writes dropped because of memory |
| **NumberOfFailedMailslotReceives** | Number of mailslot writes dropped because of transport |
| **NumberOfMasterAnnouncements** | Number of WAN master browser announcements |
| **NumberOfIllegalDatagrams** | Number of illegal datagrams received |

# Browstat Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BrowStat Examples**

**Example 1: Display statistics for a browser**

To display statistics for the current browser, type the following at the command line:

**browstat stats**

Your results will look similar to the following output:

```
Browser statistics since 16:7:27.753 on 3/7/2001
NumberOfServerEnumerations:                     5
NumberOfDomainEnumerations:                     5
NumberOfOtherEnumerations:                      2
NumberOfMailslotWrites:                         0
NumberOfServerAnnouncements:                    18
NumberOfDomainAnnouncements:                    9
NumberOfElectionPackets:                        4
NumberOfGetBrowserServerListRequests:           1
NumberOfMissedGetBrowserServerListRequests:     0
NumberOfDroppedServerAnnouncements:             0
NumberOfDroppedMailslotDatagrams:               0
NumberOfFailedMailslotReceives:                 0
NumberOfMasterAnnouncements:                    0
NumberOfIllegalDatagrams:                       0
```

See Browstat Remarks for more information on interpreting this data.

**Example 2: Display status for a domain**

If you want to display the status of the **reskit** domain, type the following at the command line:

**browstat status -v reskit**

Your results will look similar to the following output:

```
Status for domain reskit on transport \Device\NetBT_Tcpip_{D61DB2EB-6C31-4516
-963B-2AACF0E80516}
    Browsing is active on domain.
    Master browser name is: TRINA
        Master browser is running build 2195
    1 backup servers retrieved from master TRINA
        \\TRINA
    There are 3 servers in domain reskit on transport \Device\NetBT_Tcpip_{D6
1DB2EB-6C31-4516-963B-2AACF0E80516}
        Number of NT Advanced Servers:                  0
        Number of OS/2 Domain controllers:              0
        Number of Windows For Workgroups machines:      2
        Number of Os/2 machines:                        0
        Number of NT machines:                          1

        Number of active WfW browsers:                  2
        Number of browsers:                             3
        Number of backup browsers:                      1
        Number of master browsers:                      1
    There are 1 domains in domain reskit on transport \Device\NetBT_Tcpip_{D61DB2EB-
6C31-4516
-963B-2AACF0E80516}
```

# Browstat Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**BrowStat Syntax**

Browstat uses the following general syntax:

**browstat** *Operation* [*Options*]

To view the command syntax, click an operation.

Browstat dumpnet

Browstat elect

Browstat getblist

Browstat getmaster

Browstat getpdc

Browstat listwfw

Browstat stats

Browstat status

Browstat tickle

Browstat view

**Browstat dumpnet**

Displays the list of transports bound to browser.

**Syntax**

**browstat dumpnet**

**Sample Usage**

```
browstat dumpnet
```

**Browstat elect**

Forces election on a specified domain.

**Syntax**

**browstat elect** *Transport Domain* [**/help**]

**Parameters**

***Transport***

Enter a network device name (case-insensitive) for a transport in one of the following formats:

- **\device***Transport_***{MAC address}*** (for example, **\device\Nbf_{elnk1601}**)
- *****Transport_{MAC address}*
- *Transport*

***Domain***

Enter the domain in which the election will be forced.

**Browstat getblist**

Gets backup list for domain.

**Syntax**

**browstat getblist** *Transport* [[*Domain*] **refresh**] [**/help**]

**Parameters**

***Transport***

Enter a network device name (case-insensitive) for a transport in one of the following formats:

- **\device***Transport_***{MAC address}*** (for example, **\device\Nbf_{elnk1601}**)
- *****Transport_{MAC address}*
- *Transport*

***Domain***

Enter the name of the domain for which the backup list will be displayed.

**refresh**

Generates an updated browser for a segment.

**Browstat getmaster**

Displays the Master Browser name (using NetBIOS) for a specified domain.

**Syntax**

**browstat getmaster** *Transport Domain*

**Parameters**

***Transport***

Enter a network device name (case-insensitive) for a transport in one of the following formats:

- **\device***Transport_***{MAC address}*** (for example, **\device\Nbf_{elnk1601}**)
- *****Transport_{MAC address}*
- *Transport*

***Domain***

Enter the name of the domain for which the Master Browser name will be displayed.

**Browstat getpdc**

Displays the PDC name (using NetBIOS)for a specified domain.

**Syntax**

**browstat getpdc** *Transport Domain*

**Parameters**

***Transport***

Enter a network device name (case-insensitive) for a transport in one of the following formats:

- **\device***Transport_***{MAC address}*** (for example, **\device\Nbf_{elnk1601}**)
- *****Transport_{MAC address}*
- *Transport*

***Domain***

Enter the domain for which the PDC name is retrieved.

**Browstat listwfw**

Lists Windows for Workgroups computers that are acting as a browser.

**Syntax**

**browstat listwfw** *Domain*

**Parameters**

***Domain***

Enter the domain to which the Windows for Workgroups browser belong.

**Browstat stats**
Displays browser statistics.

**Syntax**
**browstat stats** [*****Computer* [**reset**]]

**Parameters**
**\\ *Computer***
Enter the name of the browser from which statistics are retrieved.

**reset**
Resets the statistics to zero.

**Examples**
See Browstat Examples.

**Browstat status**
Displays status about a domain.

**Syntax**
**browstat status** [**-v**] [*Domain*]

**Parameters**
**-v**
Displays a detailed output.

***Domain***
Enter the domain to query.

**Examples**
See Browstat Examples.

**Browstat tickle**
Forces the master browser to stop.

**Syntax**
**browstat tickle** *Transport* {*Domain*|*****Server*} [*EmulatedDomain*]

**Parameters**
***Transport***
Enter a network device name (case-insensitive) for a transport in one of the following formats:

- **\device***Transport_***{MAC address}*** (for example, **\device\Nbf_{elnk1601}**)
- *****Transport_{MAC address}*
- *Transport*

***Domain***
Enter the name of the domain to query.

**\\ *Server***
Enter the name of the server that receives the query.

***EmulatedDomain***
Enter an alternate domain the specified server should use when announcing its presence.

**Browstat view**
Lists the browsers and their browser roles for a server or domain.

**Syntax**
**browstat view** *Transport* [*Domain*|*****Server* [*Flags*|**/domain** [*DomainToQuery*]]]

**Parameters**
***Transport***

Enter the network device name (case-insensitive) for a transport in one of the following formats:

- **\device***Transport_***{MAC address}*** (for example, **\device\Nbf_{elnk1601}**)
- *****Transport_{MAC address}*
- *Transport*

***Domain***
Specifies the domain to query.

**\\ *Server***
Specifies the server that will receive the query.

***Flags***
Filters the list to show certain browser or server roles.

| Flag | Description |
|---|---|
| **AFP** | AFP server |
| **BBR** | Backup browser |
| **BDC** | Backup domain controller |
| **DFS** | Distributed file system |
| **DL** | Dial-in server |
| **DMB** | Domain master browser |
| **MBR** | Master browser |
| **MDC** | Member domain controller |
| **MFPN** | Microsoft File and Print for NetWare |
| **NT** | Windows NT |
| **NV** | Novell |
| **OSF** | OSF server |
| **PBR** | Potential browser |
| **PDC** | Primary domain controller |
| **PQ** | Print server |
| **S** | Server |
| **SQL** | SQL server |
| **SS** | Windows NT member server |
| **TS** | Time source |
| **VMS** | Vax VMS Server |
| **W** | Workstation |
| **W95** | Windows 95 |
| **WFW** | Windows for Workgroups |

| | |
|---|---|
| **XN** | Xenix |

**/domain [*DomainToQuery*]**

Passes the 0x80000000 flag to the query.

***DomainToQuery***

Enter name of the domain to query.

# Dcdiag Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tool Location**
The Dcdiag command-line tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

**Dcdiag.exe: Domain Controller Diagnostic Tool**
This command-line tool analyzes the state of domain controllers in a forest or enterprise and reports any problems to assist in troubleshooting. As an end-user reporting program, Dcdiag encapsulates detailed knowledge of how to identify abnormal behavior in the system. Dcdiag displays command output at the command line.

Dcdiag consists of a framework for executing tests and a series of tests to verify different functional areas of the system. This framework selects which domain controllers are tested according to scope directives from the user, such as enterprise, site, or single server.

**Corresponding UI**
There is no corresponding user interface (UI) for this tool.

**Concepts**
All domain controllers in the same domain are peers of one another and any domain controller can make directory updates.

However, given the way in which directory updates are replicated from one domain controller to another, it is possible that difficulties can arise. For example, if the necessary domain controllers are not connected by a replication topology, the appropriate domain controllers do not receive directory updates when replication occurs.

Also, in order for the (Domain Controller) Locator to find a domain controller, it must have accurate information so that it can properly locate the resource. If a domain controller is incorrectly advertised, the Locator is unable to find it.

**System Requirements**
The following are the system requirements for DCDiag:

- Windows Server 2003 or Windows XP Professional

| **Note** |
| --- |
| The version of Dcdiag that ships with Windows Server 2003 Service Pack 1 (SP1) is enhanced with a new replication security test (CheckSecurityError). You can run the enhanced version of Dcdiag on computers running Windows Server 2003 with no service pack installed and on computers running Windows XP Professional. However, to run the new replication security test (**dcdiag /test:CheckSecurityError**), you must run Dcdiag on a domain controller running Windows Server 2003 with SP1. |

**File Required**

- Dcdiag.exe

# Dcdiag Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DCDiag Remarks**

Two DCDiag tests are new in Windows Server 2003 Service Pack 1 (SP1):

- DNS: Checks the health of Domain Name System (DNS) settings for the enterprise.
- CheckSecurityError: Locates security errors or errors that might be related to security problems, and performs initial diagnosis of the problems.

CheckSecurityError must be run on a domain controller running Windows Server 2003 with SP1. Both tests can be run against domain controllers running Windows 2000 Server with Service Pack 3 (SP3) or a later service pack, Windows Server 2003 with no service pack installed, and Windows Server 2003 with SP1.

**DCDiag Tests**

The following are tests that can be run using DCDiag. The tests are divided into three categories: Domain Controller tests that cannot be skipped, Domain Controller tests that can be skipped, and Non-Domain Controller tests. The tests that can be skipped are further divided into those that run by default and those that do not.

**Domain Controller tests that cannot be skipped**

**Connectivity**

Tests whether domain controllers are DNS registered, can be pinged, and have LDAP/RPC connectivity.

**Domain Contoller tests that can be skipped**

**Tests run by default**

**Replications**

Checks for timely replication and any replication errors between domain controllers.

**NCSecDesc**

Checks that the security descriptors on the naming context heads have appropriate permissions for replication.

**NetLogons**

Checks that the appropriate logon privileges exist to allow replication to proceed.

**Advertising**

Checks whether each domain controller is advertising itself in the roles it should be capable of. This test fails if the Netlogon Service has stopped or failed to start.

**KnowsOfRoleHolders**

Checks whether the domain controller can contact the servers that hold the five operations master roles (also know as flexible single master operations or FSMO roles).

**Intersite**

Checks for failures that would prevent or temporarily hold up intersite replication and tries to predict how long it will take before the KCC is able to recover.

| ⚠Caution |
| --- |
| Results of this test are often not valid, especially in atypical site or KCC configurations or at the Windows Server 2003 forest functional level. |

**FSMOCheck**

Checks that the domain controller can contact a KDC, a Time Server, a Preferred Time Server, a PDC, and a Global Catalog server. This test does not test any of the servers for operations master roles.

**RidManager**

Checks whether the RID master is accessible and to see if it contains the proper information.

**MachineAccount**
Checks whether the machine account has properly registered and the services are advertised. Use **/RecreateMachineAccount** to attempt a repair if the local machine account is missing. Use **/FixMachineAccount** if the machine account flags are incorrect.

**Services**
Checks whether the appropriate domain controller services are running.

**OutboundSecureChannels**
Checks that secure channels exist from all of the domain controllers in the domain to the domains specified by **/testdomain**. The **/nositerestriction** parameter prevents the test from being limited to the domain controllers in the site.

**ObjectsReplicated**
Checks that Machine Account and DSA objects have replicated. Use **/objectdn:***dn* with **/n:***nc* to specify an additional object to check.

**frssysvol**
This test checks that the file replication system (FRS) SYSVOL is ready.

**frsevent**
This test checks to see if there are errors in the file replication system. Failing replication of the SYSVOL share can cause policy problems.

**kccevent**
This test checks that the Knowledge Consistency Checker is completing without errors.

**systemlog**
This test checks that the system is running without errors.

**CheckSDRefDom**
This test checks that all application directory partitions have appropriate security descriptor reference domains.

**VerifyReplicas**
This test verifies that all application directory partitions are fully instantiated on all replica servers.

**CrossRefValidation**
This test verifies the validity of cross-references.

**VerifyReferences**
This test verifies that certain system references are intact for the FRS and Replication infrastructure.

**VerifyEnterpriseReferences**
This test verifies that certain system references are intact for the FRS and Replication infrastructure across all objects in the enterprise on each domain controller.

**/skip: *Test***
Skips the specified test. Should not be run in the same command with **/test**. The only test that cannot be skipped is **Connectivity**.

**Tests not run by default**

**Topology**
Checks that the KCC has generated a fully connected topology for all domain controllers.

**CheckSecurityError**
On domain controllers running Windows Server 2003 with SP1, reports on the overall health of replication with respect to Active Directory security. May be performed against one or all domain controllers in an enterprise. When the test has completed, DCDiag presents a summary of the results, along with detailed information for each domain controller tested and the diagnosis of security errors that are encountered.

The following argument is optional:

**/ReplSource:***SourceDomainController*

to check the ability to create a replication link between a real or potential source domain controller (*SourceDomainController*) and the local domain controller.

**CutoffServers**

Checks for any server that is not receiving replications because its partners are down.

**DNS**

New in Windows Server 2003 SP1. Includes six optional DNS-related tests, as well as the **/connectivity test**, which runs by default. The tests can be run individually or all at once. The tests include the following:

- **/DnsBasic** to confirm that essential services are running and available, necessary resource records are registered, and domain and root zones are present.
- **/DnsForwarders** to determine whether recursion is enabled and that any configured forwarders or root hints are functioning.
- **/DnsDelegation** to confirm that the delegated name server is function and to check for broken delegations.
- **/DnsDymanicUpdate** to verify that the Active Directory domain zone is configured for secure dynamic updates and to perform registration of a test record.
- **/DnsRecordRegistration** to test the registration of all essential DC Locator records.
- **/DnsResolveExtName** to verify basic resolution of either an intranet or Internet name.

**OutboundSecureChannels**

Checks that secure channels exist from all of the domain controllers in the domain to the domains specified by **/testdomain**. The **/nositerestriction** parameter prevents the test from being limited to the domain controllers in the site.

**VerifyReplicas**

This test verifies that all application directory partitions are fully instantiated on all replica servers.

**VerifyEnterpriseReferences**

This test verifies that certain system references are intact for the FRS and Replication infrastructure across all objects in the enterprise on each domain controller.

| **Note** |
| --- |
| Text (for example, naming context names and server names) containing international or unicode characters will be displayed correctly only if appropriate fonts and language support are loaded on the test computer. |

**Non-Domain Controller tests**

**DcPromo**

Tests the existing DNS infrastructure for promotion to domain controller. If the infrastructure is sufficient, the computer can be promoted to domain controller in a domain specified in **/DnsDomain:***Active_Directory_Domain_DNS_Name*. It reports whether any modifications to the existing DNS infrastructure are required. Required argument: **/DnsDomain:***Active_Directory_Domain_DNS_Name* One of the following arguments is required:

**/NewForest**

**/NewTree**

**/ChildDomain**

**/ReplicaDC**

If NewTree is specified, the ForestRoot argument is required: **/ForestRoot:***Forest_Root_Domain_DNS_Name*

**RegisterInDNS**

Tests whether this domain controller can register the Domain Controller Locator DNS records. These records must be present in DNS in order for other computers to locate this domain controller for the *Active_Directory_Domain_DNS_Name* domain. It reports whether any modifications to the existing DNS infrastructure are required. Required argument: **/DnsDomain:***Active_Directory_Domain_DNS_Name*

| **Note** |
| --- |
| All tests except DcPromo and RegisterInDNS must be run on computers after they have been promoted to domain controller. |

# Dcdiag Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DCDiag Syntax**

DCDiag uses the following syntax:

**dcdiag /s:** *DomainController* [**/n:***NamingContext*] [**/u:***Domain**UserName* **/p:**{***** | *Password* | **""**}] [{**/a** | **/e**}] [{**/q** | **/v**}] [**/i**] [**/f:***LogFile*] [**/ferr:***ErrLog*] [**/c** [**/skip:***Test*]] [**/test:***Test*] [**/fix**] [{**/h** | **/?**}] [**/ReplSource:***SourceDomainController*]

**Parameters**

**/s: *DomainController***

Uses *DomainController* as the home server. This parameter is required. It is ignored for DcPromo and RegisterInDns tests which can only be run locally.

**/n: *NamingContext***

Uses *NamingContext* as the naming context to test. Domains may be specified in NetBIOS, DNS or distinguished name format.

**/u: *Domain\UserName* /p:{* | *Password* | ""}**

Uses *Domain**UserName*DCDiag uses the process's or users default credentials. If alternate credentials are needed, use the following options to provide those credentials for binding with *Password* as the password. Use **""** for an empty or null password, or the wildcard character (*****) to prompt for the password.

**/a**

Tests all the servers on this site.

**/e**

Tests all the servers in the entire enterprise. Overrides **/a**.

**/q**

Quiet. Prints only error messages.

**/v**

Verbose. Prints extended information.

**/i**

Ignores superfluous error messages.

**/fix**

Only affects the *MachineAccount* test. It causes the test to fix the SPNs (Service Principal Names) on the domain controller's Machine Account Object.

**/f: *LogFile***

Redirects all output to *LogFile*. The **/f** parameter operates independently of **/ferr**.

**/ferr: *ErrLog***

Redirects fatal error output to a separate file *ErrLog*. The **/ferr** parameter operates independently of **/f**.

**/c**

Comprehensive. Runs all tests except **DCPromo** and **RegisterInDNS**, including non-default tests. Optionally, can be used with **/skip** to skip specified tests. The following tests are not run by default:

**Topology**

**CutoffServers**

**OutboundSecureChannels**

**{ /h | /?}**

Displays a syntax screen at the command prompt.

**/test: *Test***

Runs only this test. The nonskippable test **Connectivity** is also run. Should not be run in the same command with **/skip**.

**Note**

- All tests except **DcPromo** and **RegisterInDNS** must be run on computers that have been promoted to domain controller.

- The test **CheckSecurityError** is available only in the version of Dcdiag that is included with Windows Support Tools in Windows Server 2003 Service Pack 1 (SP1) and must be run on a domain controller that is running Windows Server 2003 with SP1.

**/ReplSource: *SourceDomainController***
Option for **/test:CheckSecurityError**. Tests the connection between the domain controller on which you run the command and the source domain controller. *SourceDomainController* is the DNS name, NetBIOS name, or distinguished name of a real or potential "from" server that is represented by a real or potential connection object.

**DNS Syntax**
The new DNS tests in Windows Server 2003 SP1 use the following syntax:

**dcdiag /test:DNS** [**/DnsBasic** | **/DnsForwarders** | **/DnsDelegation** | **/DnsDynamicUpdate** | **/DnsRecordRegistration** | **/DnsResolveExtName** [**/DnsInternetName:***InternetName*] | **/DnsAll**] [**/f:***LogFile*] [**/ferr:***ErrLog*] **/s:***DomainController* [**/e**] [**/v**]

**Parameters**
**/test:DNS [*DNS test*]**
Performs the specified DNS test. If no test is specified, defaults to **/DnsAll**.

**/DnsBasic**
Performs basic DNS tests, including network connectivity, DNS client configuration, service availability, and zone existence.

**/DnsForwarders**
Performs the **/DnsBasic** tests, and also checks the configuration of forwarders.

**/DnsDelegation**
Performs the **/DnsBasic** tests, and also checks for proper delegations.

**/DnsDynamicUpdate**
Performs **/DnsBasic** tests, and also determines if dynamic update is enabled in the Active Directory zone.

**/DnsRecordRegistration**
Performs the **/DnsBasic** tests, and also checks if the address (A), canonical name (CNAME) and well-known service (SRV) resource records are registered. In addition, creates an inventory report based on the test results.

**/DnsResolveExtName [/DnsInternetName:*InternetName*]**
Performs the **/DnsBasic** tests, and also attempts to resolve *InternetName*. If **/DnsInternetName** is not specified, attempts to resolve the name www.microsoft.com. If **/DnsInternetName** is specified, attempts to resolve the Internet name supplied by the user.

**/DnsAll**
Performs all tests, except for the **DnsResolveExtName** test, and generates a report.

**/f: *LogFile***
Redirects all output to *LogFile*. The **/f** parameter operates independently of **/ferr**.

**/ferr: *ErrLog***
Redirects fatal error output to a separate file *ErrLog*. The **/ferr** parameter operates independently of **/f**.

**/s: *DomainController***
Runs the tests against *DomainController*.

**/e**
Runs all tests specified by **/test:DNS** against all domain controllers in the Active Directory forest.

**/v**
Verbose. Presents extended information about successful test results, in addition to information about errors and warnings. When the **/v** parameter is not used, provides only error and warning information. Use the **/v** switch when errors or warnings are reported in the summary table.

# Dcdiag Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DCDiag Examples**

**Example 1: A normal DC**

In this example, you want to examine the domain controller so you can verify that it is healthy and functioning properly. Type the following command at the command prompt:

```
C:\Program Files\Support Tools>dcdiag /s:reskit-DC1 /u:<username> /p:*
```

Substitute the actual account user name for `<username>`. If you want to specify the domain of the user, use `<domainname>\<username>`. For example, if you want to specify a user account named AlanS from the Contoso domain, type `/u:Contoso\AlanS` to specify the user account. If you use an asterisk (*) for the password, the tool will prompt you for a password. If you want to type the password, you can substitute the actual user account password for the asterisk. However, the password will appear on the screen when you type it.

Output similar to the following appears:

```
Domain Controller Diagnosis

Performing initial setup:
   Done gathering initial info.

Doing initial required tests

   Testing server: Default-First-Site-Name\RESKIT-DC1
      Starting test: Connectivity
         ......................... RESKIT-DC1 passed test Connectivity

**Example 2: Failed DNS registration**

In this example, you have noticed that one of the domain controllers is not replicating properly. After verifying that the domain controller is operational and can be pinged by IP address, use DCDiag to do an enterprise check. Type the following command at the command prompt:

```
C:\Program Files\Support Tools>dcdiag /s:reskit-DC1 /u:<username> /p:* /e
```

Output similar to the following displays:

```
Domain Controller Diagnosis

Performing initial setup:
   Done gathering initial info.

Doing initial required tests

   Testing server: Default-First-Site-Name\RESKIT-DC1
      Starting test: Connectivity
         ......................... RESKIT-DC1 passed test Connectivity

   Testing server: Default-First-Site-Name\RESKIT-DC2
      Starting test: Connectivity
         The host 7594898c-8ba4-4496-a01a-b0f2cadd28a6._msdcs.RESKIT-DOM.reskit.com
could not be resolved to an
         IP address.  Check the DNS server, DHCP, server name, etc
         Although the Guid DNS name
         (7594898c-8ba4-4496-a01a-b0f2cadd28a6._msdcs.RESKIT-DOM.reskit.com)
          couldn't be resolved, the server name
         (reskit-DC2.reskit-sib.RESKIT-DOM.reskit.com) resolved
         to the IP address (172.26.220.34) and was pingable.  Check that the IP
         address is registered correctly with the DNS server.
         ......................... RESKIT-DC2 failed test Connectivity

Doing primary tests

   Testing server: Default-First-Site-Name\RESKIT-DC1
      Starting test: Replications
         [Replications Check,RESKIT-DC1] A recent replication attempt failed:
            From RESKIT-DC2 to RESKIT-DC1
            Naming Context: CN=Configuration,DC=RESKIT-DOM,DC=reskit,DC=com
            The replication generated an error (1722):
            The RPC server is unavailable.
            The failure occurred at 2001-12-21 02:19:04.
            The last success occurred at 2001-12-21 01:57:43.
            1 failures have occurred since the last success.
            The source remains down. Please check the machine.
         ......................... RESKIT-DC1 passed test Replications
      Starting test: NCSecDesc
         ......................... RESKIT-DC1 passed test NCSecDesc
      Starting test: NetLogons
         ......................... RESKIT-DC1 passed test NetLogons

      Starting test: DeadCRTest
         ......................... reskit-sib passed test DeadCRTest
      Starting test: CheckSDRefDom
         ......................... reskit-sib passed test CheckSDRefDom

   Running enterprise tests on : RESKIT-DOM.reskit.com
      Starting test: Intersite
         ......................... RESKIT-DOM.reskit.com passed test Intersite
      Starting test: FsmoCheck
         ......................... RESKIT-DOM.reskit.com passed test FsmoCheck
```

**Note**

If you receive output from diagnostic testing similar to the previous example, there is probably a DNS registration issue. For additional diagnostic procedures and potential resolutions, see Troubleshooting DNS (http://go.microsoft.com/fwlink/?LinkID=48893). Also, see Troubleshooting Active Directory—Related DNS Problems (http://go.microsoft.com/fwlink/?LinkId=130597).

**Example 3: Failed Netlogon Service**

In this example, the Netlogon Service has failed on one of the domain controllers. To troubleshoot, type the following command:

```
C:\Program Files\Support Tools>dcdiag /s:reskit-DC1 /u:<username> /p:*
```

Output similar to the following displays:

```
Domain Controller Diagnosis
```

```
Performing initial setup:
   Done gathering initial info.

         Warning: DcGetDcName(GC_SERVER_REQUIRED) call failed, error 1717
         A Global Catalog Server could not be located - All GC's are down.
         Warning: DcGetDcName(PDC_REQUIRED) call failed, error 1717
         A Primary Domain Controller could not be located.
         The server holding the PDC role is down.
         Warning: DcGetDcName(TIME_SERVER) call failed, error 1717
         A Time Server could not be located.
         The server holding the PDC role is down.
         Warning: DcGetDcName(GOOD_TIME_SERVER_PREFERRED) call failed, error 1717
         A Good Time Server could not be located.
         Warning: DcGetDcName(KDC_REQUIRED) call failed, error 1717
         A KDC could not be located - All the KDCs are down.
         ......................... RESKIT-DOM.reskit.com failed test FsmoCheck
```

**Note**

If you receive output from diagnostic testing similar to the previous example, see the list of related Knowledge Base articles on the Windows Operating System Event ID 5179 Netlogon page (http://go.microsoft.com/fwlink/?LinkId=130599) for additional troubleshooting information. Also, see Troubleshooting Active Directory—Related DNS Problems (http://go.microsoft.com/fwlink/?LinkID=130597).

**Example 4: Unresponsive or inaccessible server**

In this example, you have noticed replication problems. To resolve the issue, type the following at the command line:

```
C:\Program Files\Support Tools>dcdiag /s:reskit-DC1 /u:<username> /p:* /e
```

Output similar to the following displays:

```
Domain Controller Diagnosis

Performing initial setup:
   Done gathering initial info.

Doing initial required tests

   Testing server: Default-First-Site-Name\RESKIT-DC1
      Starting test: Connectivity
         ......................... RESKIT-DC1 passed test Connectivity

   Testing server: Default-First-Site-Name\RESKIT-DC2
      Starting test: Connectivity
         Server RESKIT-DC2 resolved to this IP address 172.26.220.34,
         but the address couldn't be reached(pinged), so check the network.
         The error returned was: Error due to lack of resources.
         This error more often means that the targeted server is
         shutdown or disconnected from the network
         ......................... RESKIT-DC2 failed test Connectivity

Doing primary tests

   Testing server: Default-First-Site-Name\RESKIT-DC1
      Starting test: Replications
         [Replications Check,RESKIT-DC1] A recent replication attempt failed:
            From RESKIT-DC2 to RESKIT-DC1
            Naming Context: CN=Configuration,DC=RESKIT-DOM,DC=reskit,DC=com
```

```
         The replication generated an error (1722):
         The RPC server is unavailable.
         The failure occurred at 2001-12-21 02:19:04.
         The last success occurred at 2001-12-21 01:57:43.
         1 failures have occurred since the last success.
         The source remains down. Please check the machine.

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dhcploc.exe: DHCP Server Locator Utility**
This command-line tool displays the DHCP servers active on the subnet. If it detects any unauthorized DHCP servers, it beeps and sends out alert messages. It also displays packets that it detects from DHCP servers; you can specify whether to display packets from all DHCP servers or only those from unauthorized servers.

You can also use this tool to determine which DHCP servers are available to a DHCP client and to detect unauthorized DHCP servers on a subnet.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Dynamic Host Configuration Protocol (DHCP) is a TCP/IP standard for simplifying management of host IP configuration. The DHCP standards provide for the use of DHCP servers as a way to manage dynamic allocation of IP addresses and other related configuration details to DHCP-enabled clients on your network.

For more information on DHCP, see DHCP Concepts.

**System Requirements**
The following are the system requirements for DHCPLoc:

- Windows XP Professional or Windows Server 2003

**File Required**

- Dhcploc.exe

# Dhcploc Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCPLoc Syntax**

DHCPLoc uses the following syntax:

**dhcploc** [**/p**] [**/a:"***AlertNameList***"**] [**/i:***AlertInterval*] *ComputerIPAddress* [*ValidDHCPServerList*]

**Parameters**

**/p**

Suppresses display of detected packets from any of the authorized DHCP servers specified in *ValidDHCPServerList*.

**/a:" *AlertNameList* "**

Sends alert messages to the names in *AlertNameList* if any unauthorized DHCP servers are found.

**/i: *AlertInterval***

Specifies the alert frequency in seconds.

***ComputerIPAddress***

Specifies the IP address of the computer from which you are running DHCPLoc. If the computer has multiple adapters, you must specify the IP address of the adapter that is connected to the subnet you want to test.

***ValidDHCPServerList***

Specifies the IP addresses of any number of authorized DHCP servers. The tool does not send alerts when it detects packets from the servers in this list; however, it displays those packets unless you use the **/p** parameter.

# Dnscmd Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dnscmd.exe: DNS Server Troubleshooting Tool**
This command-line tool assists administrators in Domain Name System (DNS) management.

DNSCmd displays and changes the properties of DNS servers, zones, and resource records. It manually modifies these properties, creates and deletes zones and resource records, and forces replication events between DNS server physical memory and DNS databases and data files. Some operations of this tool work at the DNS server level while others work at the zone level.

### Note

- DNSCmd enhances the functionality of and replaces Dnsstat.exe, a tool included in some versions of the *Windows NT Resource Kit*.

**Corresponding UI**
To manually view and manage DNS by using the DNS Server snap-in in Windows

1. Click **Start**, point to **Programs**, and then point to **Administrative Tools**.
2. Click **DNS**.
3. For information about how to use DNS, right-click **DNS**, and then click **Help**.

Open DNS Server snap-in now.

**Concepts**
DNS resolves computer names to IP addresses so that users can refer to computers by name rather than by a series of numbers.

For more information about DNS, see "DNS" and "DNS Concepts" in Help for Windows Server 2003.

**System Requirements**
DNSCmd runs on a source computer and acts on a target computer. The target computer can be the same computer as the source computer, or it can be a different computer.

**Source Computer Requirements**
The following are the system requirements for the source computer:

- Dnscmd.exe
- User's membership in the Administrators or Server Operators group on the target computer. Both the user account and the server computer must be members of the same domain or reside within trusted domains.

**Target Computer Requirements**
The DNS service must be installed on the target computer.

**File Required**

- Dnscmd.exe

# Dnscmd Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNSCmd Examples**

**Example 1: Set the current time on a time stamp to resource records**

To set the current time on a time stamp to resource records, type:

```
dnscmd reskit.com /ageallrecords test.reskit.com
```

The following question is displayed:

```
Are you sure you want to force aging on node?
```

Type `y` to apply the time. Output similar to the following displays:

```
DNS Server reskit.com forced aging on records at root of zone test.reskit.com:
     Status = 0 (0x00000000)
Command completed successfully.
```

**Example 2: Display a complete list of zones on a DNS server**

To see a complete list of zones on your DNS server, type:

```
dnscmd reskit.com /enumzones
```

Output similar to the following displays:

```
Enumerated zone list:
     Zone Count = 6.

.                               0 DS            Up=0
0.0.10.in-addr.arpa             0 DS   Rev      Up=1
0.in-addr.arpa                  1 file Rev Auto Up=0
255.in-addr.arpa                1 file Rev Auto Up=0
reskit.com                      1 DS            Up=0
test.reskit.com                 1 file          Up=1

Command completed successfully.
```

**Example 3: Display a list of autocreated zones on a DNS server**

To display a list of autocreated zones that are also reverse lookup zones on the DNS server, type:

```
dnscmd reskit.com /enumzones /auto-created /reverse
```

Output similar to the following displays:

```
Enumerated zone list:
     Zone Count = 2.
0.in-addr.arpa                  1 file Rev Auto Up=0
255.in-addr.arpa                1 file Rev Auto Up=0

Command completed successfully.
```

**Example 4: Display the IsSlave setting from a DNS server**

To display the IsSlave setting from a DNS server, type:

```
dnscmd reskit.com /info isslave
```

Output similar to the following displays:

```
Query result:
Dword: 0 (00000000)
```

```
Command completed successfully.
```

**Example 5: Display the RecursionTimeout setting from a DNS server**
To display the RecursionTimeout setting from a DNS server, type:

```
dnscmd reskit.com /info recursiontimeout
```

Output similar to the following displays:

```
Query result:
Dword: 15 (0000000F)
Command completed successfully.
```

**Example 6: Delete the records from a node**
To delete the records in a node, type:

```
dnscmd reskit.com /nodedelete test.reskit.com node /tree
```

The following question displays:

```
Are you sure you want to delete node's subtree? y
```

Type `y` to delete the subtree.

Output similar to the following displays:

```
DNS Server reskit.com deleted node at node.test.reskit.com:
     Status = 0 (0x00000000)
Command completed successfully.
```

To delete the records in a node using the host, type:

```
dnscmd reskit.com /NodeDelete test.reskit.com host /F
```

Output similar to the following displays:

```
DNS Server reskit.com deleted node at host.test.reskit.com:
     Status = 0 (0x00000000)
Command completed successfully.
```

**Example 7: Display time statistics for a DNS server**
To display time statistics for a DNS server, type:

```
dnscmd reskit.com /statistics 00000001
```

Output similar to the following displays:

```
DNS Server reskit.com statistics:

DNS Server Time Statistics:
Server start time 3/7/2001 1:07:31 PM
Seconds since start 8482
Stats last cleared 3/7/2001 1:07:31 PM
Seconds since start 8482

Command completed successfully.
```

**Example 8: Display NbstatMem statistics for a DNS server**
To display NbstatMem statistics for a DNS server, type:

```
DNSCmd reskit.com /Statistics 00200000
```

Output similar to the following displays:

```
DNS Server reskit.com statistics:

NBStat Memory Usage:
NBStat Buffers:
```

```
     Alloc = 0
     Free = 0
     NetAllocs = 0
     Memory = 0
     Used = 0
     Returned = 0
     InUse = 0
     InFreeList = 0

Command completed successfully.
```

**Example 9: Delete a zone from a DNS server**
To delete the test.reskit.com zone from a server, type:

```
dnscmd reskit.com /zonedelete test.reskit.com
```

The following question is displayed:

```
Are you sure you want to ZoneDelete? (y/n)
```

Type `y` to delete the zone.

Output similar to the following displays:

```
DNS Server reskit.com deleted zone test.reskit.com:
        Status = 0 (0x00000000)
Command completed successfully.
```

**Example 10: Export zone resource records list to a file**
To export the resource record list from the test.reskit.com zone on the reskit.com DNS server, type:

```
dnscmd reskit.com /zoneexport test.reskit.com test.reskit.com.dns
```

Output similar to the following displays:

```
DNS Server reskit.com exported zone
     test.reskit.com to file
C:\Windows\System32\DNS\test.reskit.com.dns
Command completed successfully.
```

**Example 11: Display RefreshInterval setting from the registry**
To display the values in the RefreshInterval entry in the registry, type:

```
dnscmd reskit.com /zoneinfo test.reskit.com refreshinterval
```

Output similar to the following displays:

```
Zone query result:
Dword: 168 (000000A8)
Command completed successfully.
```

**Example 12: Display Aging setting from the registry**
To display the values in the Aging entry in the registry, type:

```
dnscmd reskit.com /zoneinfo test.reskit.com aging
```

Output similar to the following displays:

```
Zone query result:
Dword: 0 (00000000)
Command completed successfully.
```

# Dnscmd Syntax

Updated: November 5, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNSCmd Syntax**

DNSCmd uses the following general syntax:

**dnscmd** *ServerName Command* [*Command Parameters*]

**Operations**

Dnscmd ageallrecords

Dnscmd clearcache

Dnscmd config

Dnscmd createbuiltindirectorypartitions

Dnscmd createdirectorypartition

Dnscmd deletedirectorypartition

Dnscmd directorypartitioninfo

Dnscmd enlistdirectorypartition

Dnscmd enumdirectorypartitions

Dnscmd enumrecords

Dnscmd enumzones

Dnscmd info

Dnscmd nodedelete

Dnscmd recordadd

Dnscmd recorddelete

Dnscmd resetforwarders

Dnscmd resetlistenaddresses

Dnscmd startscavenging

Dnscmd statistics

Dnscmd unenlistdirectorypartition

Dnscmd writebackfiles

Dnscmd zoneadd

Dnscmd zonechangedirectorypartition

Dnscmd zonedelete

Dnscmd zoneexport

Dnscmd zoneinfo

Dnscmd zonepause

Dnscmd zoneprint

Dnscmd zoneresettype

Dnscmd zonerefresh

Dnscmd zonereload

Dnscmd zoneresetmasters

Dnscmd zoneresetscavengeservers

Dnscmd zoneresetsecondaries

Dnscmd zoneresume

Dnscmd zoneupdatefromds

Dnscmd zonewriteback

**Dnscmd ageallrecords**

Sets the current time on a time stamp to resource records at a specified zone or node on a DNS server.

**Syntax**

**dnscmd** [*ServerName*] **/ageallrecords** *ZoneName*[*NodeName*] | [**/tree**]|[**/f**]

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the FQDN name of the zone.

***NodeName***

Specifies a specific node or subtree in the zone.

**Note**

- NodeName specifies the node or subtree in the zone using:
  - **@** for root zone or FQDN.
  - FQDN of a node (name with a '.' at the end).
  - A single label for the name relative to zone root.

**/tree**

Specifies that all child nodes also receive the time stamp. The /tree switch for /ageallrecords will often be desired. Without it the command pertains only to the single node. This may be the desired behavior, but it is often desirable to execute this command on the entire zone or on an entire sub-tree of the zone.

**/f**

Executes the command without asking for confirmation.

**Remarks**

- The **ageallrecords** operation is for backward compatibility between the current version of DNS and previous releases in which aging and scavenging were not supported. It adds a time stamp with the current time to records that do not have one. It will not change the timestamp on records that already have a time stamp.
- Scavenging of records does not occur unless the records are timestamped. NS (name server), SOA (Start of Authority), and WINS records are not included in the scavenging process and are not timestamped even when the **ageallrecords** operation is run.
- This command fails unless scavenging is enabled for the DNS server and the zone. For information about how to enable scavenging for the zone, see the **aging** parameter under Zone-Level Syntax in the Dnscmd config operation in this document.

- The addition of a time stamp to DNS records makes them incompatible with DNS servers that run on operating systems other than Windows 2000, Windows XP, or Windows Server 2003. A time stamp you add by using the **ageallrecords** operation cannot be reversed.

- If none of the optional fields are specified, the command returns all records at the specified node. If a value is specified for at least one of the optional fields, then DNSCmd enumerates only records corresponding to the value or values specified in the optional field or fields.

**Example**
See Dnscmd Examples.

**Dnscmd clearcache**
Clears the DNS cache memory of resource records in the specified DNS server.

**Syntax**
**dnscmd** [*ServerName*] **/clearcache**

**Parameter**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

**Sample Usage**
```
dnscmd dnssvr1.contoso.com /clearcache
```

**Dnscmd config**
Allows the user to change values in the registry for the DNS server and individual zones. Accepts server-level and zone-level settings.

**Caution**

- Do not edit the registry directly unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can degrade performance, damage your system, or even require you to reinstall Windows. You can safely alter most registry settings by using the programs in Control Panel or Microsoft Management Console (MMC). If you must edit the registry directly, back it up first. Read the Registry Editor Help for more information.

**Server-Level Syntax**
**dnscmd** [*ServerName*] **/config** *Parameters*

**Parameters**
***ServerName***
Specifies the DNS server the administrator is planning to manage, represented by local computer syntax, IP address, FQDN, or Host name. If omitted, the local server is used.

***Parameters***
Specify a setting and, optionally, a value. *Parameters* values use this syntax: *Parameter* [*Value*]

The following *Parameters* values are documented in the remainder of this section:

- **/addressanswerlimit**
- **/bindsecondaries**
- **/bootmethod**
- **/defaultagingstate**
- **/defaultnorefreshinterval**
- **/defaultrefreshinterval**
- **/disableautoreversezones**

- **/disablensrecordsautocreation**
- **/dspollinginterval**
- **/dstombstoneinterval**
- **/ednscachetimeout**
- **/enablednsprobes**
- **/enablednssec**
- **/eventloglevel**
- **/forwarddelegations**
- **/forwardingtimeout**
- **/isslave**
- **/localnetpriority**
- **/logfilemaxsize**
- **/logfilepath**
- **/logipfilterlist**
- **/loglevel**
- **/maxcachesize**
- **/maxcachettl**
- **/namecheckflag**
- **/notcp**
- **/norecursion**
- **/recursionretry**
- **/recursiontimeout**
- **/roundrobin**
- **/rpcprotocol**
- **/scavenginginterval**
- **/secureresponses**
- **/sendport**

- **/strictfileparsing**
- **/updateoptions**
- **/writeauthorityns**
- **/xfrconnecttimeout**

**/addressanswerlimit [0|5-28]**
Specifies the maximum number of host records that a DNS server can send in response to a query. The value can be zero (0) or set in the range of 5-28 records. The default value is zero (0).

**/bindsecondaries [0|1]**
Changes the format of the zone transfer so that it can achieve maximum compression and efficiency. However, this efficient format is incompatible with earlier versions of BIND.

**0**
Uses maximum compression. Compatible with BIND versions 4.9.4 and later only.

**1**
Sends only one resource record per message to non-Microsoft DNS servers. Compatible with BIND versions earlier than 4.9.4. This is the default setting.

**/bootmethod [0|1|2|3]**
Determines the source from which the DNS server gets its configuration information.

**0**
No source.

**1**
Loads from the BIND file that is located in the DNS directory; by default, %systemroot%\System32\DNS..

**2**
Loads from the registry.

**3**
Loads from Active Directory and the registry. This is the default setting.

**/defaultagingstate [0|1]**
Determines whether the DNS scavenging feature is enabled by default on newly created zones.

**0**
Disables scavenging. This is the default setting.

**1**
Enables scavenging.

**/defaultnorefreshinterval [0x1-0xFFFFFFFF|0xA8]**
Sets a period of time in which no refreshes are accepted for dynamically updated records. This value is inherited automatically by zones on the server. To change the default, enter a value in the range of 0x1-0xFFFFFFFF. The default value from the server is 0xA8.

**/defaultrefreshinterval [0x1-0xFFFFFFFF|0xA8]**
Sets a period of time that is allowed for dynamic updates to DNS records. This value is inherited automatically by zones on the server. To change the default, enter a value in the range of 0x1-0xFFFFFFFF. The default value from the server is 0xA8.

**/disableautoreversezones [0|1]**
Enables or disables the automatic creation of reverse lookup zones.

**0**
Enables creation of autoreverse zones. This is the default setting.

**1**
Disables creation of autoreverse zones.

**/disablensrecordsautocreation {0|1}**
Specifies whether the DNS server automatically creates NS records for zones that it hosts.

**0**
Automatically creates NS records for zones that it hosts.

**1**
Does not automatically create NS records for zones that it hosts.

**/dspollinginterval 0-3600**
Specifies how often the DNS server polls Active Directory for changes in Active Directory-integrated zones.

| **Note** |
| --- |
| If the DNS server is running Windows Server 2008 or above, setting a value of 0 for dspollinginterval will result in the default interval of 180 seconds being configured, and values of 1-29 are not allowed. |

**/dstombstoneinterval [1-30]**
Amount of time in seconds to keep tombstoned records in Active Directory alive.

**/ednscachetimeout [3600-15724800]**
Specifies the number of seconds that EDns information is cached. The default value is 604,800 seconds (one week).

**/enableednsprobes {0|1}**
Enables or disables EDnsProbes.

**0**
Disables active support for EDnsProbes.

**1**
Enables active support for EDnsProbes.

**/enablednssec {0|1}**
Enables or disables DNSSEC.

**0**
Disables DNSSEC.

**1**
Enables DNSSEC.

**/eventloglevel [0|1|2|4]**
Determines which events are logged in the DNS server log in Event Viewer.

**0**
Logs no events.

**1**
Logs only errors.

**2**
Logs only errors and warnings.

**4**
Logs errors, warnings, and informational events. This is the default setting.

**/forwarddelegations [0|1]**
Determines how a query for a delegated subzone is handled by the DNS server. These queries can either be sent to the subzone referred to in the query or be sent to the list of forwarders named for the DNS server. Entries in the setting are used only when forwarding is enabled.

**0**
Automatically sends queries referring to delegated subzones to the appropriate subzone. This is the default setting.

**1**
Forwards queries referring to the delegated subzone to the existing forwarders.

**/forwardingtimeout [0x1-0xFFFFFFFF|0x5]**
Determines how many seconds (0x1-0xFFFFFFFF) a DNS server waits for a forwarder to respond before trying another. The default value is 0x5, which is 5 seconds.

**/isslave [0|1]**
Determines how the DNS server responds when forwarded queries receive no response.

**0**
Not a subordinate (also known as a *slave*). If the forwarder does not respond, the server attempts to resolve the query itself. This is the default setting.

**1**
A subordinate. If the forwarder does not respond, the server terminates the search and sends a failure to the resolver.

**/localnetpriority [0|1]**
Determines the order in which host records are returned when the server has multiple host records for the same name.

**0**
Returns the records in the order in which they are listed in the DNS database.

**1**
Returns the records that have similar IP network addresses first. This is the default setting.

**/logfilemaxsize [0x10000-0xFFFFFFFF|0x400000]**
Specifies the maximum size in bytes (0x10000-0xFFFFFFFF) of the Dns.log file. When the file reaches its maximum, DNS overwrites the oldest events. The default size is 0x400000, which is 4 MB.

**/logfilepath [*Path+LogFileName*]**
Specifies the path of the Dns.log file. The default path is %systemroot%\System32\Dns\Dns.log. A different path can be specified by using the format *Path+LogFileName*.

**/logipfilterlist *IPAddress* [,*IPAddress*...]**
Specifies which packets are logged in the debug log file. The entries are a list of IP addresses. Only packets going to and from the IP addresses in the list are logged.

**/loglevel [*EventType*]**
Determines which types of events are recorded in the Dns.log file. Each type is represented by a hexadecimal number. If you want more than one event in the log, use hexadecimal addition to add the values, then enter the sum.

**0x0**
The DNS server does not create a log. This is the default entry.

**0x10**
Logs queries.

**0x10**
Logs notifications.

**0x20**
Logs updates.

**0xFE**
Logs non-query.

**0x100**
Logs question transactions.

**0x200**
Logs answers.

**0x1000**
Logs send packets.

**0x2000**
Logs receive packets.

**0x4000**
Logs UDP packets.

**0x8000**
Logs TCP packets.

**0xFFFF**
Logs all packets.

**0x10000**
Logs Active Directory write transactions.

**0x20000**
Logs Active Directory update transactions.

**0x1000000**
Logs full packets.

**0x80000000**
Logs write-through transactions.

**/maxcachesize**
Specifies the maximum size, in kilobytes, of the DNS server's memory cache.

**/maxcachettl [0x0-0xFFFFFFFF|0x15180]**
Determines how many seconds (0x0-0xFFFFFFFF) a record is saved in cache. If the 0x0 setting is used, then the DNS server does not cache records. The default setting is 0x15180 (86,400 seconds or 1 day).

**/maxnegativecachettl [0x1-0xFFFFFFFF|0x384]**
Specifies how many seconds (0x1-0xFFFFFFFF) an entry that records a negative answer to a query remains stored in the DNS cache. The default setting is 0x384 (900) seconds.

**/namecheckflag [0|1|2|3]**
Specifies which character standard is used when allowing DNS names.

**0**
Uses ANSI characters that comply with IETF Requests For Comment (RFCs).

**1**
Uses ANSI characters that do not necessarily comply with IETF RFCs.

**2**
Uses multibyte UTF8 characters. This is the default setting.

**3**
Uses all characters.

**/norecursion [0|1]**
Determines whether a DNS server performs recursive name resolution.

**0**
DNS server performs recursive resolution if it is requested in a query. This is the default setting.

**1**
DNS server does not perform recursive resolution.

**/notcp**
This parameter is obsolete and has no effect in Windows Server 2003.

**/recursionretry [0x1-0xFFFFFFFF|0x3]**
Determines the number of seconds (0x1-0xFFFFFFFF) a DNS server waits before again trying to contact a remote server. The default setting is 0x3 (3 seconds). This value should be increased when recursion occurs over a slow WAN link.

**/recursiontimeout [0x1-0xFFFFFFFF|0xF]**
Determines the number of seconds (0x1-0xFFFFFFFF) a DNS server waits before discontinuing attempts to contact a remote server. The settings range from 0x1 through 0xFFFFFFFF. The default setting is 0xF (15 seconds). This value should be increased when recursion occurs over a slow WAN link.

**/roundrobin [0|1]**
Determines the order in which host records are returned when a server has multiple host records for the same name.

**0**
DNS server does not use round robin; instead, it returns the first record to every query.

**1**
DNS server rotates among the records that it returns from the top to the bottom of the list of matching records. This is the default setting.

**/rpcprotocol [0x0|0x1|0x2|0x4|0xFFFFFFFF]**
Specifies the protocol that RPC uses when making a connection from the DNS server.

**0x0**
Disables RPC for DNS.

**0x1**
Uses TCP/IP.

**0x2**
Uses named pipes.

**0x4**
Uses LPC.

**0xFFFFFFFF**
All protocols. This is the default setting.

**/scavenginginterval [0x0-0xFFFFFFFF|0x0]**
Determines whether the scavenging feature for the DNS server is enabled, and sets the number of hours (0x0-0xFFFFFFFF) between scavenging cycles. The default setting is 0x0, which disables scavenging for the DNS server. A setting greater than 0x0 enables scavenging for the server and sets the number of hours between scavenging cycles.

**/secureresponses [0|1]**
Determines whether DNS filters records that are saved in a cache.

**0**
Saves all responses to name queries to a cache. This is the default setting.

**1**
Saves only the records that belong to the same DNS subtree to a cache.

**/sendport [0x0-0xFFFFFFFF|0x0]**
Specifies the port number (0x0-0xFFFFFFFF) that DNS uses to send recursive queries to other DNS servers. The default setting is 0x0, which means the port number is randomly selected.

**/serverlevelplugindll[*DllPath*]**
Specifies the path of a custom plug-in. When *DllPath* specifies the fully qualified path name of a valid DNS server plug-in, the DNS server calls functions in the plug-in to resolve name queries that are outside the scope of all locally hosted zones. If a queried name is out of the scope of the plug-in, the DNS server performs name resolution using forwarding or recursion, as configured. If *DllPath* is not specified, the DNS server ceases to use a custom plug-in if a custom plug-in was previously configured.

**/strictfileparsing [0|1]**
Determines a DNS server's behavior when it encounters an erroneous record while loading a zone.

**0**
Continues to load even if the server encounters an erroneous record. The error is recorded in the DNS log. This is the default setting.

**1**
Stops loading and records the error in the DNS log.

**/updateoptions *RecordValue***
Prohibits dynamic updates of specified types of records. If you want more than one record type prohibited in the log, use hexadecimal addition to add the values, then enter the sum.

**0x0**
Does not restrict any record types.

**0x1**
Excludes SOA (Start of Authority) records.

**0x2**
Excludes NS (name server) records.

**0x4**
Excludes delegation NS records.

**0x8**
Excludes server host records.

**0x100**
On secure dynamic update, excludes SOA records.

**0x200**
On secure dynamic update, excludes root NS records.

**0x30F**
On standard dynamic update, excludes NS, SOA, and server host records. On secure dynamic update, excludes root NS and SOA records. Allows delegations and server host updates.

**0x400**
On secure dynamic update, excludes delegation NS records.

**0x800**
On secure dynamic update, excludes server host records.

**0x1000000**
Excludes DS records.

**0x80000000**
Disables DNS dynamic update.

**/writeauthorityns [0|1]**
Determines when the DNS server writes name server (NS) records in the Authority section of a response.

**0**
Writes NS records in the Authority section of referrals only. This setting complies with RFC 1034, Domain names—concepts and facilities, and with RFC 2181, Clarifications to the DNS Specification. This is the default setting.

**1**
Writes NS records in the Authority section of all successful authoritative responses.

**/xfrconnecttimeout [0x0-0xFFFFFFFF|0x1E]**
Determines the number of seconds (0x0-0xFFFFFFFF) a primary DNS server waits for a transfer response from its secondary. The default value is 0x1E (30 seconds). After the time-out value expires, the connection is terminated.

**Zone-Level Syntax**

**dnscmd /config** *Parameters*

**Parameters**

***Parameters***
Specify a setting, a zone name, and, optionally, a value. *Parameters* values use this syntax: *ZoneName Parameter* [*Value*]

The following *Parameters* values are documented in the remainder of this section:

- **/aging**
- **/allownsrecordsautocreation**
- **/allowupdate**
- **/forwarderslave**
- **/forwardertimeout**

- **/norefreshinterval**
- **/refreshinterval**
- **/securesecondaries**

**/aging *ZoneName***
Enables or disables scavenging in a specific zone.

**/allownsrecordsautocreation *ZoneName* [*Value*]**
Overrides the DNS server's NS record autocreation setting. NS resource records that were previously registered for this zone are not affected and so must be manually removed if not wanted.

**/allowupdate *ZoneName***
Determines whether the specified zone accepts dynamic updates.

**/forwarderslave *ZoneName***
Overrides the DNS server **/isslave** setting.

**/forwardertimeout *ZoneName***
Determines how many seconds a DNS zone waits for a forwarder to respond before trying another. This value overrides the value set at the server level.

**/norefreshinterval *ZoneName***
Sets a time interval for a zone during which no refreshes can dynamically update DNS records in a specified zone.

**/refreshinterval *ZoneName***
Sets a time interval for a zone during which refreshes can dynamically update DNS records in a specified zone.

**/securesecondaries *ZoneName***
Determines which secondary servers can receive zone updates from the master for this zone.

**Remarks**

- The zone name needs to be specified only for zone-level parameters.

**Dnscmd createbuiltindirectorypartitions**
Creates a DNS application directory partition. When DNS is installed, an application directory partition for the service is created at the forest and domain levels. Use this operation to create DNS application directory partitions that were deleted or never created. With no argument, this operation creates a built-in DNS directory partition for the domain.

**Syntax**
▸ **dnscmd** [*ServerName*] **/createbuiltindirectorypartitions** [**/forest**] [**/alldomains**]

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

**/forest**
Creates a DNS directory partition for the forest.

**/alldomains**
Creates DNS partitions for all domains in the forest.

**Dnscmd createdirectorypartition**
Creates a DNS application directory partition. When DNS is installed, an application directory partition for the service is created at the forest and domain levels. This operation creates additional DNS application directory partitions.

**Syntax**
▸ **dnscmd** [*ServerName*] **/createdirectorypartition** *PartitionFQDN*

**Parameters**
***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***PartitionFQDN***
The fully qualified domain name of the DNS application directory partition that will be created.

**Dnscmd deletedirectorypartition**
Removes an existing DNS application directory partition.

**Syntax**
- **dnscmd** [*ServerName*] **/deletedirectorypartition** *PartitionFQDN*

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***PartitionFQDN***
The fully qualified domain name of the DNS application directory partition that will be removed.

**Dnscmd directorypartitioninfo**
Lists information about a specified DNS application directory partition.

**Syntax**
- **dnscmd** [*ServerName*] **/directorypartitioninfo** *PartitionFQDN* [**/detail**]

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***PartitionFQDN***
The fully qualified domain name of the DNS application directory partition.

**/detail**
Lists all information about the records.

**Dnscmd enlistdirectorypartition**
Adds the DNS server to the specified directory partition's replica set.

**Syntax**
- **dnscmd** [*ServerName*] **/enlistdirectorypartition** *PartitionFQDN*

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***PartitionFQDN***
The fully qualified domain name of the DNS application directory partition.

**Dnscmd enumdirectorypartitions**
Lists the DNS application directory partitions for the specified server.

**Syntax**
- **dnscmd** [*ServerName*] **/enumdirectorypartitions** [**/custom**]

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

**/custom**
Lists only user-created directory partitions.

**Dnscmd enumrecords**
Lists the resource records of a specified node in a DNS zone.

**Syntax**

**dnscmd** [*ServerName*] **/enumrecords** *ZoneName NodeName*[**/type** *RRType RRData*] [**/authority**] [**/glue**] [**/additional**] [**/node** |**/child** |**/startchild***ChildName*] [**/continue** |**/detail**]

**Parameters**

***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone to which the record belongs.

***NodeName***
Specifies the name of the node of the record.

**/type *RRType RRData***
Specifies the type of record to be listed and the type of data expected.

***RRType***
Specifies the type of record to be listed.

***RRData***
Specifies the type of data that is expected when using a certain data type.

**/authority**
Includes authoritative data.

**/glue**
Includes glue data.

**/additional**
Includes all additional information about the records listed.

**{/node | /child | /startchild *ChildName*}**
Filters or adds information to the record display.

**/node**
Lists only the records of the specified node.

**/child**
Lists only the records of a specified child.

**/startchild*ChildName***
Begins the list at the specified child.

**/continue| /detail**
Specifies how the returned data is displayed.

**/continue**
Lists only the records with their type and data.

**/detail**
Lists all information about the records.

**Sample Usage**

```
dnscmd /enumrecords test.contoso.com test /additional
```

**Dnscmd enumzones**

Lists zones that exist on the specified DNS server.

**Syntax**

**dnscmd** [*ServerName*] **/enumzones** [**/primary** | **/secondary** | **/forwarder** | **/stub** | **/cache** | **/auto-created**] [**/forward** | **/reverse** | **/ds** | **/file**] [**/domaindirectorypartition** | **/forestdirectorypartition** | **/customdirectorypartition** | **/legacydirectorypartition** | **/directorypartition** *PartitionFQDN*]

**Parameters**

***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

**/primary | /secondary | /forwarder | /stub | /cache | /auto-created**
Filters the types of zones to display.

**/primary**
Lists all zones that are either standard primary or Active Directory-integrated.

**/secondary**
Lists all standard secondary zones.

**/forwarder**
Lists zones that forward unresolved queries to another DNS server.

**/stub**
Lists all stub zones.

**/cache**
Lists only the zones that are loaded into cache.

**/auto-created**
Lists the zones that were created automatically during the DNS server installation.

**/forward | /reverse | /Ds | /file**
Specifies an additional filter of the types of zones to display.

**/forward**
Lists forward lookup zones.

**/reverse**
Lists reverse lookup zones.

**/ds**
Lists directory-integrated zones.

**/file**
Lists zones that are backed by files.

**/domaindirectorypartition**
Lists zones that are stored in the domain directory partition.

**/forestdirectorypartition**
Lists zones that are stored in the forest DNS application directory partition.

**/customdirectorypartition**
Lists all zones stored in a user-defined application directory partitions.

**/legacydirectorypartition**
Lists all zones stored in the domain directory partition.

**/directorypartition*PartitionFQDN***
Lists all zones stored in the specified directory partition.

**Remarks**

- The **enumzones** operation parameters act as filters on the list of zones. If no filters are specified, then a complete list of zones is returned. When a filter is used, only the zones that meet that filter's criteria are included in the returned list of zones.

**Example**
See Dnscmd Examples or Dnscmd Examples.

**Dnscmd info**
Displays settings from the DNS section of the registry of the specified server:
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Parameters**

**Syntax**
**dnscmd** [*ServerName*] **/info**[*Setting*]

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***Setting***

Any setting returned by the **info** operation can be individually specified. If a setting is not specified, then all settings are returned.

**Remarks**

- This operation displays registry settings that are at the DNS server level. To display zone-level registry settings, use the Dnscmd zoneinfo operation. To see a list of settings that can be displayed with this operation, refer to the Dnscmd config operation Help.

- If you do not specify a value for the parameter when you use the Dnscmd config operation, the parameter's current value is reset to the default value.

**Example**

See Dnscmd Examples or Dnscmd Examples.

**Dnscmd nodedelete**

Deletes all records for a specified host.

**Syntax**

**dnscmd** [*ServerName*] **/nodedelete** *ZoneName NodeName* [**/tree**] [**/f**]

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the name of the zone.

***NodeName***

Specifies the host name of the node to delete.

**/tree**

Specifies to delete all of the child records.

**/f**

Executes the command without asking for confirmation.

**Example**

See Dnscmd Examples.

**Dnscmd recordadd**

Adds a record to a specified zone in a DNS server.

**Syntax**

**dnscmd** [*ServerName*] **/recordadd** *ZoneName NodeName RRType RRData*

**Parameters**

***ServerName***

Specifies the DNS server the administrator is planning to manage, represented by local computer syntax, IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the zone in which the record resides.

***NodeName***

Specifies a specific node in the zone.

***RRType***

Specifies the type of record to be added.

***RRData***
Specifies the type of data that is expected when using a certain data type.

**Note**

- Resource records added with this command are configured to be static unless the /Aging switch is used. See the examples below.

- When you add a record, make sure you use the correct data type and data format. For a list of resource record types and the appropriate data types, see Resource records reference.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /recordadd contoso.com test A 10.0.0.5

dnscmd dnssvr1.contoso.com /recordadd contoso.com test2 /Aging A 10.0.0.6

dnscmd /recordadd test.contoso.com test MX 10 mailserver.test.contoso.com
```

**Dnscmd recorddelete**
Deletes a resource record from a specified zone.

**Syntax**
**dnscmd** *ServerName* **/recorddelete** *ZoneName NodeName RRType RRData*[**/f**]

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the zone in which the record resides.

***NodeName***
Specifies the name of the host.

***RRType***
Specifies the type of record to be deleted.

***RRData***
Specifies the type of data that is expected when using a certain data type.

***/f***
Note

Executes the command without asking for confirmation.

- Because nodes can have more than one resource record, this command requires you to be very specific about the type of record that you want to delete.

  If you specify a data type and do not specify a type of resource record data, then all records with that specific data type for the specified node are deleted. For a list of resource record types and the appropriate data types, see Resource records reference.

**Sample Usage**

```
dnscmd /recorddelete test.contoso.com test MX 10 mailserver.test.contoso.com
```

**Dnscmd resetforwarders**
Selects or resets IP address(es) to which the DNS server forwards DNS queries when it cannot solve them locally.

**Syntax**
**dnscmd** [*ServerName*] **/resetforwarders** [*IPAddress* [,*IPAddress*]...][**/timeout** *TimeOut*] [**/slave**|**/noslave**]

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***IPAddress***
Lists the IP address(es) to which the DNS server forwards unresolved queries.

**/timeout *TimeOut***
Sets the number of seconds that the DNS server waits for a response from the forwarder. By default, this value is 5 seconds.

**/slave|/noslave**
Determines whether the DNS server performs its own iterative queries if the forwarder fails to resolve a query.

**/slave**
Prevents the DNS server from performing its own iterative queries if the forwarder fails to resolve a query.

**/noslave**
Allows the DNS server to perform its own iterative queries if the forwarder fails to resolve a query. This is the default setting.

**Remarks**

- By default, a DNS server performs iterative queries when it cannot resolve a query.
- Setting IP addresses by using the **resetforwarders** operation causes the DNS server to perform recursive queries to the DNS servers at the specified IP addresses. If the forwarders do not resolve the query, the DNS server can then perform its own iterative queries.
- If the **/slave** parameter is used, the DNS server does not perform its own iterative queries. This means the DNS server forwards unresolved queries only to the DNS servers in the list and does not try iterative queries if the forwarders do not resolve it. It is more efficient to set one IP address as a forwarder for a DNS server. The **resetforwarders** operation can be used for internal servers in a network to forward their unresolved queries to one DNS server that has an external connection.
- Listing a forwarder's IP address twice causes the DNS server to try to forward to that server twice.

**Sample Usage**
```
dnscmd dnssvr1.contoso.com /resetforwarders 10.0.0.1 /timeout 7 /slave

dnscmd dnssvr1.contoso.com /resetforwarders /noslave
```

**Dnscmd resetlistenaddresses**
Specifies the IP addresses on a server that listen for DNS client requests.

**Syntax**
**dnscmd** [*ServerName*] **/resetlistenaddresses** [*ListenAddress*]

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ListenAddress***
Specifies an IP address on the DNS server that listens for DNS client requests. If no listen address is specified, then all IP addresses on the server listen for client requests.

**Remarks**

- By default, all IP addresses on a DNS server listen for client DNS requests.

**Sample Usage**
```
dnscmd dnssvr1.contoso.com /resetlistenaddresses 10.0.0.1
```

**Dnscmd startscavenging**
Notifies a DNS server to attempt an immediate search for stale resource records in a specified DNS server.

**Syntax**
**dnscmd** [*ServerName*] **/startscavenging**

**Parameter**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

**Remarks**

- Successful completion of this command triggers an immediate start to a scavenge.
- Although the command to start the scavenge appears to complete successfully, the scavenge does not start unless the following preconditions are met:
  - Scavenging is enabled for both the server and the zone.
  - The zone is started.
  - The resource records have a time stamp.
- For information about how to enable scavenging for the server, see the **scavenginginterval** parameter under Server-Level Syntax in the Dnscmd config operation in this document.
- For information about how to enable scavenging for the zone, see the **aging** parameter under Zone-Level Syntax in the Dnscmd config operation in this document.
- For information about how to start a zone that is paused, see the Dnscmd zoneresume operation in this document.
- For information about how to check resource records for a time stamp, see the Dnscmd ageallrecords operation in this document.
- If the scavenge fails, no warning message displays.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /startscavenging
```

**Dnscmd statistics**

Displays or clears data for a specified DNS server.

**Syntax**

**dnscmd** [*ServerName*] **/statistics** [*StatID*] [**/clear**]

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***StatID***

Specifies which statistic or combination of statistics displays. An identification number is used to specify a statistic. If no statistic ID is specified, all statistics display.

The following table lists numbers that can be specified and the corresponding statistic that lists:

**00000001**
Time

**00000002**
Query

**00000004**
Query2

**00000008**
Recurse

**00000010**
Master

**00000020**
Secondary

**00000040**
WINS

**00000100**
Update

**00000200**
SkwanSec

**00000400**
Ds

**00010000**
Memory

**00100000**
PacketMem

**00040000**
Dbase

**00080000**
Records

**00200000**
NbstatMem

**/clear**
Resets the specified statistics counter to zero.

**Remarks**

- The **statistics** operation displays counters that begin on the DNS server when it is started or resumed.

**Examples**
See Dnscmd Examples or Dnscmd Examples.

**Dnscmd unenlistdirectorypartition**
Removes the DNS server from the specified directory partition's replica set.

**Syntax**
**dnscmd** [*ServerName*] **/unenlistdirectorypartition** *PartitionFQDN*

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***PartitionFQDN***
The fully qualified domain name of the DNS application directory partition that will be removed.

**Dnscmd writebackfiles**
Checks DNS server memory for changes and writes them to persistent storage.

**Syntax**
**dnscmd** [*ServerName*] **/writebackfiles** [*ZoneName*]

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone to be updated.

**Remarks**

- The **writebackfiles** operation updates all dirty zones or a specified zone. A zone is dirty when there are changes in memory that have not yet been written to persistent storage. This is a server-level operation that checks all zones. One zone can be specified in this operation or the Dnscmd zonewriteback operation can be used.

**Sample Usage**
```
dnscmd dnssvr1.contoso.com /writebackfiles
```

**Dnscmd zoneadd**
Adds a zone to the DNS server.

**Syntax**
**dnscmd** [*ServerName*] **/zoneadd** *ZoneName ZoneType* [**/dp** *FQDN*| {**/domain**|**/enterprise**|**/legacy**}] **/load**

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone.

***ZoneType***
Specifies the type of zone to create. Each type has different required parameters.

**/dsprimary**
Creates an Active Directory-integrated zone.

**/primary /file *FileName***
Creates a standard primary zone and specifies the name of the file that will store the zone information.

**/secondary *MasterIPAddress* [*MasterIPAddress*...] /file *FileName***
Creates a file-backed secondary zone. If the /file option is specified, a file is created in the **%windir%\system32\dns** directory.

**/stub *MasterIPAddress* [*MasterIPAddress*...] /file *FileName***
Creates a file-backed stub zone.

**/dsstub *MasterIPAddress* [*MasterIPAddress*...]**
Creates an Active Directory-integrated stub zone.

**/forwarder *MasterIPAddress* [*MasterIPAddress*]... /file *FileName***
Specifies that the created zone forwards unresolved queries to another DNS server.

**/dsforwarder**
Specifies that the created Active Directory-integrated zone forwards unresolved queries to another DNS server.

**/dp *FQDN* {/domain | /enterprise | /legacy}**
Specifies the directory partition on which to store the zone.

***FQDN***
Specifies fully qualified domain name of the directory partition.

**/domain**
Stores the zone on the domain directory partition.

**/enterprise**
Stores the zone on the enterprise directory partition.

**/legacy**
Stores the zone on a legacy directory partition.

***/load***

Required if the new zone is loaded from a file.

**Remarks**

- Specifying a zone type of **/forwarder** or **/dsforwarder** creates a zone that performs conditional forwarding.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zoneadd test.contoso.com /dsprimary

dnscmd dnssvr1.contoso.com /zoneadd secondtest.contoso.com /secondary 10.0.0.2

dnscmd dnssvr1.contoso.com /zoneadd secondtest.contoso.com /secondary 10.0.0.2 /file
secondtest.contoso.com.dns
```

**Dnscmd zonechangedirectorypartition**

Changes the directory partition on which the specified zone resides.

**Syntax**

**dnscmd** [*ServerName*] **/zonechangedirectorypartition** *ZoneName*] {[*NewPartitionName*] | [*ZoneType*] }

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***/ZoneName***

FQDN of the current directory partition on which the zone resides.

***NewPartitionName***

FQDN of the directory partition that the zone will be moved to.

***ZoneType***

Specifies the type of directory partition that the zone will be moved to.

**/domain**

Move the zone to the built-in domain directory partition.

**/forest**

Move the zone to the built-in forest directory partition.

**/legacy**

Move the zone to the directory partition created for pre-Active Directory domain controllers. These directory partitions are not needed when in native mode.

**Dnscmd zonedelete**

Deletes a specified zone.

**Syntax**

**dnscmd** [*ServerName*] **/zonedelete** *ZoneName* [**/dsdel**] [**/f**]

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the name of the zone to be deleted.

**/dsdel**

Deletes the zone from Active Directory.

**/f**

Executes the command without asking for confirmation.

**Example**

See Dnscmd Examples.

**Dnscmd zoneexport**

Creates a text file that lists the resource records of a specified zone.

**Syntax**

**dnscmd** [*ServerName*] **/zoneexport** *ZoneName ZoneExportFile*

**Parameters**

***ServerName***

Specifies the DNS server the administrator is planning to manage, represented by local computer syntax, IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the name of the zone.

***ZoneExportFile***

Specifies the name of the file to create.

**Remarks**

- The **zoneexport** operation creates a file of resource records for an Active Directory-integrated zone for troubleshooting purposes. By default, the file created by this operation is placed in the DNS directory, which is by default the %systemroot%/System32/Dns directory.

**Example**

See Dnscmd Examples.

**Dnscmd zoneinfo**

Displays settings from the section of the registry of the specified zone:
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Parameters\Zones***ZoneName*

**Syntax**

**dnscmd** [*ServerName*] **/zoneinfo** *ZoneName* [*Setting*]

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the name of the zone.

***Setting***

Any setting returned with the **zoneinfo** operation can be individually specified. If a setting is not specified, then all settings are returned.

**Remarks**

- The **zoneinfo** operation displays registry settings that are at the DNS zone level found at **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Parameters\Zones***ZoneName*.
- To display server-level registry settings, use the Dnscmd info operation.
- To see a list of settings that can be displayed with this operation, refer to the Dnscmd config operation.

**Example**

See Dnscmd Examples or Dnscmd Examples.

**Dnscmd zonepause**

Pauses the specified zone, which then ignores query requests.

**Syntax**

**dnscmd** [*ServerName*] **/zonepause** *ZoneName*

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone to be paused.

**Remarks**

- To resume a zone and make it available after it has been paused, use the Dnscmd zoneresume operation.

**Sample Usage**
```
dnscmd dnssvr1.contoso.com /zonepause test.contoso.com
```

**Dnscmd zoneprint**
Lists the records in a zone.

**Syntax**
**dnscmd** [*ServerName*] **/zoneprint** *ZoneName*

**Parameters**
***ServerName***
Specifies the DNS server the administrator is planning to manage, represented by local computer syntax, IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Identifies the zone on which the type will be changed.

**Dnscmd zoneresettype**
Changes the type of the zone.

**Syntax**
**dnscmd** [*ServerName*] **/zoneresettype** *ZoneName ZoneType* [**/overwrite_mem** | **/overwrite_ds**]

**Parameters**
***ServerName***
Specifies the DNS server the administrator is planning to manage, represented by local computer syntax, IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Identifies the zone on which the type will be changed.

***ZoneType***
Specifies the type of zone to create. Each type has different required parameters.

**/dsprimary**
Creates an Active Directory-integrated zone.

**/primary /file *FileName***
Creates a standard primary zone.

**/secondary *MasterIPAddress* [,*MasterIPAddress*...]**
Creates a standard secondary zone.

**/stub *MasterIPAddress* [,*MasterIPAddress*...] /file *FileName***
Creates a file-backed stub zone.

**/dsstub *MasterIPAddress* [,*MasterIPAddress*...]**
Creates an Active Directory-integrated stub zone.

**/forwarder *MasterIPAddress* [,*MasterIPAddress*]... /file *FileName***
Specifies that the created zone forwards unresolved queries to another DNS server.

**/dsforwarder**
Specifies that the created Active Directory-integrated zone forwards unresolved queries to another DNS server.

**/overwrite_mem | /overwrite_ds**
Specifies how to overwrite existing data.

**/overwrite_mem**
Overwrites DNS data from data in Active Directory.

**/overwrite_ds**
Overwrites existing data in Active Directory.

**Remarks**

- Setting the zone type as **/dsforwarder** creates a zone that performs conditional forwarding.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zoneresettype test.contoso.com /primary /file test.contoso.com.dns

dnscmd dnssvr1.contoso.com /zoneresettype second.contoso.com /secondary 10.0.0.2
```

**Dnscmd zonerefresh**

Forces a secondary DNS zone to update from the master.

**Syntax**

**dnscmd** *ServerName* **/zonerefresh** *ZoneName*

**Parameters**

***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone to be refreshed.

**Remarks**

- The **zonerefresh** operation forces a check of the version number in the master's SOA record. If the version number on the master is higher than the secondary's version number, then a zone transfer is initiated, updating the secondary server. If the version number is the same, no zone transfer occurs.

- The forced check occurs by default every 15 minutes. To change the default, use the **dnscmd config refreshinterval** operation.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zonerefresh test.contoso.com
```

**Dnscmd zonereload**

Copies zone information from its source.

**Syntax**

**dnscmd** *ServerName* **/zonereload** *ZoneName*

**Parameters**

***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone to be reloaded.

**Remarks**

- If the zone is Active Directory-integrated, then it reloads from Active Directory.

- If the zone is a standard file-backed zone, then it reloads from a file.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zonereload test.contoso.com
```

**Dnscmd zoneresetmasters**

Resets the IP addresses of the master server that provides zone transfer information to a secondary zone.

**Syntax**

**dnscmd** *ServerName* **/zoneresetmasters** *ZoneName* [**/local**] [*ServerIPs*]

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the name of the zone to be reloaded.

**/local**

Sets a local master list. Used for Active Directory-integrated zones.

***ServerIPs***

The IP addresses of the master server(s) of the secondary zone. Enter this value as *IPAddress* [*IPAddress*]...

**Remarks**

- This value is originally set when the secondary zone is created. Use the **zoneresetmasters** operation on the secondary server. It has no effect if it is set on the master DNS server.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zoneresetmasters test.contoso.com 10.0.0.1

dnscmd dnssvr1.contoso.com /zoneresetmasters test.contoso.com /local
```

**Dnscmd zoneresetscavengeservers**

Changes the IP address(es) of the server(s) that can scavenge the specified zone.

**Syntax**

**dnscmd** [*ServerName*] **/zoneresetscavengeservers** *ZoneName* [*ServerIPs*]

**Parameters**

***ServerName***

Specifies the DNS server the administrator is planning to manage, represented by local computer syntax, IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Identifies the zone to scavenge.

***ServerIPs***

Lists the IP address(es) of the server(s) that can perform the scavenge. If this parameter is omitted, then all servers hosting this zone can scavenge it.

**Remarks**

- By default, all servers hosting a zone can scavenge that zone.
- If a zone is hosted on more than one DNS server, this operation can be used to reduce the number of times a zone is scavenged.
- Scavenging must be enabled on the DNS server and zone affected by this operation.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zoneresetscavengeservers test.contoso.com 10.0.0.1 10.0.0.2
```

**Dnscmd zoneresetsecondaries**

Specifies a list of IP addresses to which a master server responds when asked for a zone transfer.

**Syntax**

**dnscmd** [*ServerName*] **/zoneresetsecondaries** *ZoneName* {**/noxfr** | **/nonsecure** | **/securens** | **/securelist** *SecurityIPAddresses*} {**/nonotify** | **/notify** | **/notifylist** *NotifyIPAddresses*}

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone to have its secondaries reset.

**/noxfr | /nonsecure | /securens | /securelist *SecurityIPAddresses***
Specifies whether only some or all of the secondary servers requesting an update get one.

**/noxfr**
Specifies that no zone transfers are allowed.

**/nonsecure**
Specifies that all zone transfer requests are granted.

**/securens**
Specifies that only the server listed in the NS record for the zone is granted a transfer.

**/securelist**
Specifies that zone transfers are granted only to the list of servers. This parameter must be followed by an IP address or addresses that the master server uses.

***SecurityIPAddresses***
Lists the IP addresses that receive zone transfers from the master server. This parameter is used only with the **/securelist** parameter.

**/nonotify | /notify | /notifylist *NotifyIPAddresses***
Specifies a change notification is sent only to certain secondary servers.

**/nonotify**
Specifies that no change notifications are sent to secondary servers.

**/notify**
Specifies that change notifications are sent to all secondary servers.

**/notifylist**
Specifies that change notifications are sent to only the list of servers. This command must be followed by an IP address or addresses that the master server uses.

***NotifyIPAddresses***
Specifies the IP address(es) of the secondary server(s) to which change notifications are sent. This list is used only with the **/notifylist** parameter.

**Remarks**

- Use the **zoneresetsecondaries** operation on the master server to set how it responds to zone transfer requests from secondary servers.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zoneresetsecondaries test.contoso.com /noxfr /nonotify

dnscmd dnssvr1.contoso.com /zoneresetsecondaries test.contoso.com /securelist 11.0.0.2
```

**Dnscmd zoneresume**
Starts a specified zone that was previously paused.

**Syntax**
**dnscmd** *ServerName* **/zoneresume** *ZoneName*

**Parameters**
***ServerName***
Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***
Specifies the name of the zone to resume.

**Remarks**

- This operation is used to undo the Dnscmd zonepause operation.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zoneresume test.contoso.com
```

**Dnscmd zoneupdatefromds**

Updates the specified Active Directory-integrated zone from Active Directory.

**Syntax**

▸ **dnscmd** *ServerName* **/zoneupdatefromds** *ZoneName*

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the name of the zone to update.

**Remarks**

- Active Directory-integrated zones perform this update by default every 180 seconds (3 minutes). To change this parameter, use the **dnscmd /config /dspollinginterval** operation.

  To view the current value, use the **dnscmd /info /dspollinginterval** operation. The value is displayed in seconds.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zoneupdatefromds
```

**Dnscmd zonewriteback**

Checks DNS server memory for changes relevant to a specified zone and writes them to persistent storage.

**Syntax**

▸ **dnscmd** *ServerName* **/zonewriteback** *ZoneName*

**Parameters**

***ServerName***

Specifies the DNS server the administrator plans to manage, represented by IP address, FQDN, or Host name. If omitted, the local server is used.

***ZoneName***

Specifies the name of the zone to update.

**Remarks**

- This is a zone-level operation. All zones on a DNS server can be updated with the Dnscmd writebackfiles operation.

**Sample Usage**

```
dnscmd dnssvr1.contoso.com /zonewriteback test.contoso.com
```

# Dnslint Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dnslint.exe: DNS Lint**
This command-line tool allows you to verify Domain Name System (DNS) records for a specified domain name. Use DNSLint to help diagnose potential causes of incorrect delegation and other common DNS problems.

**Concepts**
**Incorrect delegation**
System Administrators use DNS delegations to assign the authority for a DNS subdomain to a set of DNS servers. These delegations help administrators implement a DNS infrastructure that is scalable, flexible, and easy to administer.

Incorrect delegation is a common problem with DNS structures. This can occur when the authority for a DNS subdomain has been delegated to a particular DNS server that either does not exist, or does not have authority over the subdomain.

Incorrect delegation problems are compounded when other DNS issues are present in a DNS infrastructure. For example, if DNS domain information is not identical on all authoritative DNS servers, data returned from the servers may differ, leading to intermittent name resolution difficulties. In another scenario, if a Mail Exchange (MX) record exists but the corresponding glue record is missing, then e-mail delivery to that domain may be erratic.

Prior to the development of DNSLint, the nslookup utility was frequently used to diagnose and troubleshoot these types of DNS issues. Nslookup allows users to manually traverse a DNS infrastructure, inspecting the various DNS records. However, DNSLint offers quicker verification that record-level data is correct.

For more information about DNS, see DNS or Concepts in Microsoft Management Console Help.

For more information about troubleshooting DNS, see the chapter Troubleshooting DNS in the Networking Guide of the Windows Server 2003 Resource Kit.

**Common Active Directory DNS Problems**
Verifying a particular set of DNS records on multiple DNS servers can help diagnose and fix problems caused by missing or incorrect DNS records.

For example, when clients are experiencing problems logging on to the domain, verifying that the SRV records that clients use to find LDAP and Kerberos servers are available and accurate, can help determine if DNS is a cause of the problem.

Another scenario example is where you receive reports that customers are having problems accessing your Web site on the Internet. It would be nice to have a tool that quickly checks all the DNS records that are involved with the Web farm on all of the DNS servers that are supposed to have these records. You could quickly determine if there are missing or incorrect DNS records that may be related to the problem.

In a third example, you could be experiencing problems with e-mail delivery. You can send e-mail, but you are not receiving e-mail. Name resolution could be the problem? To confirm this theory or eliminate it as a possibility, you need to check all of the DNS records on all of the DNS servers that are used to resolve the IP address of the e-mail server.

**System Requirements**
DNSLint runs on a source computer and acts on a target computer. The target computer can be the same computer as the source computer, or it can be a different computer.

**Source Computer Requirements**

- Windows 2000, Windows XP, or Windows Server 2003

**Target Computer Requirements**

- The target computer's domain must be registered with an accredited domain registrar, or running DNS in a private namespace.

**File Required**

- Dnslint.exe

# Dnslint Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNSLint Remarks**
**DNSLint Information**
The DNSLint tool streamlines the process of troubleshooting and diagnosing DNS issues on the Internet and private networks. Typically, it traverses a DNS network in under a minute, and then generates a report in HTML format.

DNSLint verifies that all authoritative DNS servers for a domain are responding to DNS queries, and have synchronized zone data. It verifies domain Host (A) records, Name Server (NS) records, Mail Exchange (MX) records, and the glue records associated with the delegation

**DNSLint and E-Mail**
Use the **/c** (connectivity test) parameter to have DNSLint test well-known e-mail ports on all e-mail servers that it finds while inspecting DNS servers for the specified domain name. The tool supports the following protocols:

- The Simple Mail Transfer Protocol (SMTP)
- Post Office Protocol (POP) version 3
- Internet Message Access Protocol (IMAP) version 4

By default, when the **/c** parameter is specified, DNSLint attempts to connect to all three ports on each e-mail server it finds. (for example, TCP port 25 for SMTP, TCP port 110 for POP3, and TCP port 143 for IMAP).

DNSLint reports the following port status: listening, not listening, or no response. In the case of a listening port, DNSLint returns any response the port might have. The following example demonstrates the response DNSLint might return for a listening SMTP port :

```
220 mailsrv.reskit.com Microsoft ESMTP MAIL Service, Version: 5.0.2195.3705 ready at Mon, 13 May 2002
17:08:36 -0700
```

**Using DNSLint /ql to diagnose Active Directory DNS**
DNSLint's /ql (Query List) option provides this functionality. DNSLint reads instructions from the text file specified using the /ql option. Once it has verified that the file is a valid DNSLint input file, it runs the queries that are specified within the file and reports the results in an easy to read HTML report (and optionally in a text report). This input file allows administrators to customize which DNS servers to query and exactly which DNS records to look for on each server. The format of the input file is as follows:

```
DNSLint
[dns~server] 169.254.46.138
www.fourthcoffee.com,a,r
169.254.197.1,ptr,r
[dns~server] 169.254.46.200
fourthcoffee.com,cname,r
fourthcoffee.com,mx,r
_kerberos._tcp.dc._msdcs.fourthcoffee.com,srv,r
```

The file must start with the word "dnslint" at the top of it. This is the first thing DNSLint looks for when the input file is opened. If it is not the first word read when the file is opened, the specified input file is rejected and an error is generated.

```
[dns~server] 169.254.46.138
```

This line specifies the IP address of a DNS server to send queries to. [dns~server] must be specified followed by a valid IP address. If either of these two components is missing, an error is generated and the specified input file is rejected.

Subsequent lines indicate the queries to send to the specified DNS server:

```
www.fourthcoffee.com,a,r
10.1.10.1,ptr,r
```

Format of the queries:

The first field in the line is the name to query. For example www.fourthcoffee.com. The name is then immediately followed by a comma. No spaces are allowed on either side of the comma.

The second field follows the comma immediately after the name to query. The second field is the type of record to query for. Valid types are as follows:

- a = Host
- ptr = Pointer
- cname = Alias
- mx = Mail Exchange
- srv = Service Location

The type of record is then immediately followed by a comma. No spaces are allowed on either side of the comma.

The third field is the type of query. This field immediately follows the comma after the type of record. Valid query types are as follows:

- r = recursive
- i = iterative

Nothing else is required to follow the third field. All three fields are required, and no spaces are allowed anywhere within the query line. A fourth field is optional. Appending ",tcp" to the third field will make DNSLint send the specified query using the TCP protocol instead of the default UDP protocol. Again, no spaces are allowed and nothing should follow this field if it is used.

# Dnslint Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNSLint Syntax**

DNSLint uses the following syntax:

**dnslint /d** *domain_name* | **/ad** | **/ql** {*text_file* | **autocreate**} [**/v**] [**/r** *report_name*] [**/y**] [**/no_open**] [**/s** *alternate_DNS_server_ip_address*] [**/c** *SMTP*|*POP*|*IMAP*] [**/t**] [**/test_tcp**]

**Parameters**

**/d *domain***

Specifies the domain to test. This is a required parameter.

**/ad**

Tests the DNS records used by Active Directory for replication. This is a required parameter. The **/s** parameter is required with this parameter.

**/ql {*text_file* | autocreate}**

Sends DNS queries based on input from a text file containing a list of DNS names. The command **dnslint /ql autocreate** creates an example textfile. The **/ql** parameter supports A, PTR, CNAME, SRV, and MX DNS record types. This is a required parameter. The **/ql** parameter will accept either a text file name or the **autocreate** option, not both.

**/v**

Turns on verbose output.

**/r *report_name***

Specifies a name for the DNSLint report file. The default report name is DNSLint Report.htm.

**Note**

- DNSLint always appends an .htm extension to the file, even if you specify an extension. For example, if you specify *report_name*=my_file.rpt, the resulting file will be called my_file.rpt.htm.

**/y**

Overwrites any existing report file without prompting the user.

**/no_open**

Prevents the DNSLint report from opening after it is generated.

**/s *alternate_DNS_server_ip_address***

This parameter supplies an alternate DNS server, forcing DNSLint to bypass InterNIC. This parameter is useful for testing domain structures that are not availible from the InterNIC database.

**/c *SMTP|POP|IMAP***

Used to perform connectivity tests on well-known e-mail ports when e-mail servers are found while inspecting DNS servers. See "Remarks" for more information.

**/t**

Used to request a plain text file with the same name as the DNSLint report file. (The default filename is DNLint Report.htm, unless the **/r** parameter is used to specify a different name.)

**/test_tcp**

Used to test TCP port 53 as well as UDP port 53. Unless this parameter is specified, DNSLint test the UDP port only.

**Notes**

- You must always specify one of the following parameters: **/d**, **/ad**, and **/ql**. However, they cannot be used together.
- The **/c** parameter cannot be used with the **/ad** or **/ql** parameters.
- When using the **/ad** parameter, **/s** must also be used.

- The **/test_tcp** parameter cannot be used with the **/ql** parameter.

**Sample Usage**

```
dnslint /d fourthcoffee.com

dnslint /ad /s 10.193.36.201

dnslint /ql my_dns_list.txt

dnslint /ql autocreate

dnslint /v /d fourthcoffee.com

dnslint /r newfile /d fourthcoffee.com

dnslint /y /d fourthcoffee.com

dnslint /no_open /d fourthcoffee.com

dnslint /s 10.193.36.201 /d labs.fourthcoffee.com
```

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNSLint Examples**

**Example 1: Sample DNSLint Output with No Errors**

The following command instructs DNSLint to traverse the woodgrovebank.com domain, and return all relevant data about its DNS structure. This domain has no structural errors.

```
dnslint /d woodgrovebank.com
```

The link below shows a sample DNSLint report generated in response to this command.

DNSLint Report Example 1

**Example 2: Sample DNSLint Output with Errors**

The following command instructs DNSLint to traverse the lab.fourthcoffee.com domain. The command uses the /s parameter because lab.fourthcoffee.com is a private domain. As it turns out, this domain contains errors in its structure.

```
dnslint /d lab.fourthcoffee.com /s 10.46.138.20
```

The link below shows a sample DNSLint report generated in response to this command.

DNSLint Report Example 2

# Getsid Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Getsid.exe: Get Security ID**
This command-line tool compares the user security identifiers (SIDs) of two accounts.

You can use it to compare account SIDs between a primary domain controller and backup domain controller when you suspect user database corruption.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
For more information about security in Windows XP and Windows Server 2003, see *Security Model* or *Security and Active Directory* under Security in Help and Support Services.

**System Requirements**
The following are the system requirements for GetSID:

- Windows XP Professional or Windows Server 2003
- Administrative rights

**File Required**

- Getsid.exe

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**GetSID Syntax**

GetSID uses the following syntax:

**getsid** *\\Server1 Account \\Server2 Account*

**Parameters**

***\\Server1***

Specifies the name of the server on which the accounts are found. Enter a netbios or FQDN. *Account* is the account SID.

***Account***

Specifies the name of a user or group account. Getsid will display the SID of this account. If the account name has a space in it, you must use quotation marks.

***\\Server2***

Specifies the name of the server on which the accounts are found. Enter a netbios or FQDN.

**Sample Usage**

- getsid \\reskitdc2 administrator \\reskitdc1 administrator
- getsid \\reskitdc2 "domain admins" \\reskitdc1 "domain admins"

# Iasparse Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Iasparse.exe: IAS Parse Tool**
This command-line tool parses Internet Authentication Service (IAS) and remote access server logs and converts them into a readable format.

IASParse is useful in these situations:

- When calculating billing information.
- For other diagnostic purposes, such as finding out the Remote Access Dial-In User Service (RADIUS) attributes received and sent.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
IAS can create a log file based on the authentication and accounting requests received from the network access servers when using RADIUS authentication. Remote access server can also log such information when using Windows Server 2003 authentication.

Setting up and using such logs helps simplify administration of the service. The logs can be useful for tracking accounting information, such as logon and logoff records for billing purposes. IASParse presents the information in them in a user-friendly way.

**System Requirements**
The following are the system requirements for this tool:

- Windows XP Professional or Windows Server 2003 operating systems

**File Required**

- Iasparse.exe

# Iasparse Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IASParse Remarks**

**IAS Logs**
IAS records the authentication and accounting information that it receives in a log file, which can be in either of two formats:

- **IAS Format** In the Microsoft® Windows® NT version 4.0 version of IAS, the log was formatted using a method by which attributes were logged as attribute-value pairs. This formatting is supported in IAS in Windows 2000, and the logs that use this format are referred to as IAS-formatted log files.

- **ODBC-Compatible Format** The ODBC-compatible format (Open Database Connectivity format) for log files is available starting in Windows 2000. Unlike IAS-formatted log files, ODBC-compatible log files present the data in a standard sequence and using a structure that is identical, regardless of the network access server (NAS) sending the data. This consistent sequence and structure helps simplify accounting and authentication record-keeping. Data can be easily exported to an ODBC database, which supports filtering and analysis by a variety of third-party programs.

The user interface of IAS allows the user to choose the format of the log file. This format can also be changed dynamically, which can produce intermixed records of both formats in the log file. Thus there is a need for a tool that can understand the format of the records logged into the log file dynamically, parse it, and produce an output that helps the user to understand the information logged into the file.

IAS uses the information in the file %windir%\system32\ias\dnary.mdb to find out the ODBC log sequence and also whether to log a particular attribute while logging in IAS format. The tool also reads the information from the same file before parsing the log file. Hence, hard coding these values inside the tool is eliminated.

IAS can also send the output to a pipe instead of a file. IASParse uses this feature to read the input from the pipe and send the output directly to the screen. In effect, this causes the tool to dynamically display the parsed output. This feature can be enabled by choosing the **-p** option. For this functionality to work, the user must configure the IAS to output to a pipe. This can be done by setting the log file directory from the IAS snap-in to \\.\pipe.

# Netcap Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Netcap.exe: Network Monitor Capture Utility**
This command-line tool allows a system administrator to monitor packets on a LAN and write the information to a log file. NetCap uses the Network Monitor Driver to sniff packets on local network segments.

### Notes

- You must run NetCap from the command window.
- If the Network Monitor Driver is not installed, NetCap installs it the first time the tool is run. To remove the driver, use **netcap /remove**.

**Corresponding UI**
This tool provides a command-line interface to some of the capture functionality of Netmon.

**Concepts**
NetCap captures frames directly from the network traffic data stream so they can be examined. You can use it to create capture files for support personnel.

Frames are packages of information transmitted as a single unit over a network. Every frame follows the same basic organization and contains the following:

- Control information such as synchronizing characters
- Source and destination addresses
- Protocol information
- An error-checking value
- A variable amount of data

**System Requirements**
NetCap requires one of the following operating systems:

- Windows Server 2003
- Windows XP Professional
- Windows 2000

**File Required**

- Netcap.exe

# Netcap Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetCap Remarks**

How the Network Monitor Driver Works

Network Monitor tracks the network data stream, which consists of all of the information transferred over a network at any given time. Before transmission, the networking software divides this information into smaller segments, called frames. Each frame contains the following information:

- The source address of the computer that sent the message.
- The destination address of the computer that receives the frame.
- Header information of each protocol used to send the frame.
- The data (or a portion of it) being sent to the destination computer.

All frames on a network segment pass through every computer connected to that segment. However, the network card typically passes only the frames addressed to it as the destination computer, to the networking software. The Windows XP Professional version of Network Monitor can copy frames originating from or sent to the local computer to a temporary capture file. The process by which Network Monitor copies frames is referred to as data capture.

The amount of information that the Network Monitor Driver can capture is limited only by disk space availability, up to one gigabyte. However, you usually need to capture only a small subset of the frames traveling on your network. To isolate a subset of frames, you can design a capture filter, which functions like a database query to isolate the information that you specify. You can filter frames on the basis of source and destination addresses, protocols, protocol properties, and pattern offset.

If you want a running capture to respond to specific conditions as soon as the Network Monitor detects them, you can design a capture trigger. When the Network Monitor detects a particular set of conditions on the network, this capture trigger performs a specified action, such as starting an executable file.

**Note**

- When used with a network adapter that supports promiscuous mode, the full version of Network Monitor (available with Microsoft Systems Management Server version 2.0) can capture all the frames it detects.

The Network Data Stream

Network Monitor monitors the network data stream, which consists of all information transferred over a network at any given time. Prior to transmission, this information is divided by the network software into smaller pieces, called frames or packets.

Frames, whether broadcast, multicast, or directed, are made up of several different pieces that can be analyzed separately. Some of these pieces contain data that Network Monitor can use to troubleshoot networking problems. For example, by examining the destination address, it can be determined whether the frame was a broadcast frame, indicating all hosts had to receive and process this frame, or a directed frame sent to a specific host. By analyzing frames, you can determine the exact cause of the frame, which helps determine whether the service generating these types of frames can be optimized.

# Netcap Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetCap Examples**

Example 1: Capture network packets for 3 minutes

In this example, you monitor your network port for three minutes and capture the information to the C:\Temp folder. Type the following at the command prompt:

```
netcap /c:c:\temp /l:00:03:00
```

NetCap displays the following result:

```
Total frames captured: 229

Capture file name: c:\temp\7D16111E39FA.cap
```

Example 2: Monitor with a trigger

In this example, you want to monitor with a trigger defining when to stop. You want to look for a certain pattern, and when found, keep listening until the trigger is halfway into the buffer. You have previously defined a filter restricting the monitoring to a suspicious host. Type the following at the command prompt:

```
NetCap /B:20 /N:2 /T BP 50 0a ff1f /F:d:\IPFilter.CF
```

NetCap produces the following output:

```
Total frames captured: 85220

Capture file name: c:\temp\7D234C233A3B.cap
```

Example 3: Remove the Network Monitor Driver

In this example, you remove the Network Monitor Driver that NetCap has installed. Type the following at the command prompt:

```
netcap /remove
```

NetCap produces the following output:

```
The NetCap.exe instance of the Network Monitor driver successfully removed.
```

# Netcap Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetCap Syntax**

NetCap uses the following syntax:

**netcap** [**/b:***Number*] [**/t** *Type Buffer HexadecimalOffset HexadecimalPattern*] [**/f:** *FilterFile*] [**/c:** *CapturePath*] [**/n:** *Number*] [**/l:** *HH:MM:SS*] [**/tcf:** *FolderName*] [**/remove**]

**Parameters**

**/b: *Number***

Specifies the buffer size in megabytes. *Number* can be from 1 to 1000. The default is 1 (MB).

**/t *Type Buffer HexadecimalOffset HexadecimalPattern***

Specifies the use of a trigger to determine when to stop capturing. If the trigger is omitted, NetCap captures until the buffer is full, then stops. The **/t N** option continues to capture until the spacebar is pressed, using the buffer as a queue. If the buffer becomes full Netcap will overwrite the oldest entries.

***Type***

**B** = Buffer

**P = Pattern**

**BP = Buffer then pattern**

**PB = Pattern then buffer**

**N = No trigger**

***Buffer***

**Percent buffer size. Options are 25, 50, 75, and 100. It is used with B, BP, PB, but not P.**

***HexadecimalOffset***

**Hexadecimal offset from start of frame. Used with P, BP, PB, but not B.**

***HexadecimalPattern***

**Hexadecimal pattern to match. Used with P, BP, PB, but not B. The pattern must be an even number of hexadecimal digits.**

**/f: *FilterFile***

**Specifies a filter to use during the capture. A filter file is created using Network Monitor in versions 2.x and after. A filter file has a .cf extension.**

**/c: *CapturePath***

**Specifies a location where Netcap will move the temporary capture files. This can be any valid local or remote path. If /c is not specified, the capture path remains in the default temporary capture folder.**

**/n: *Number***

**Specifies which network adapter to capture from, based on the network adapter index number. Run Netcap with the /? parameter to assign index numbers to the network adapters on the computer.**

**/l: *HH:MM:SS***

**Specifies how long the capture will last in hours, minutes, and seconds (maximum = 99:99:99).**

**Note**

- **This option overrides the default 100 percent trigger, unless /t *Type* is also specified.**

**/tcf: *FolderName***

**Sets the location where the temporary capture files are stored. The path must be on a fixed local hard drive. Once set, you only need to use the option again to change the directory.**

**/remove**

**Removes the NetCap instance of the Network Monitor Driver.**

# Netdiag Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Netdiag.exe: Network Connectivity Tester**
This command-line diagnostic tool helps to isolate networking and connectivity problems by performing a series of tests to determine the state of your network client. These tests and the key network status information they expose give network administrators and support personnel a more direct means of identifying and isolating network problems. Moreover, because this tool does not require parameters or switches to be specified, support personnel and network administrators can focus on analyzing the output rather than on training users how to use the tool.

### Notes

- You must run NetDiag from the command window.
- TCP/IP must be bound to one or more adapters before using this tool. In most cases, this binding already exists.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
The TCP/IP protocol stack is the primary communications protocol used in networks today. To access the Internet, you need to be using TCP/IP.

This tool provides diagnostic features that are useful for troubleshooting Windows Server 2003 operating system configurations. However, because this tool has been designed primarily for system administrators and support personnel, its output may be difficult to analyze. In this case, you should review the appropriate troubleshooting sections in the Windows Deployment and Resource Kits. For more information, search for network connectivity in the Windows Deployment and Resource Kits.

**System Requirements**
The following are the system requirements for NetDiag:

- Windows XP Professional or Windows Server 2003

**File Required**

- Netdiag.exe

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetDiag Remarks**
**NetDiag Features**
The NetDiag tool:

- Gathers static network information and tests the network driver, protocol driver, send/receive capability, and well-known target accessibility.
- Can be used by network administrators in conjunction with the Scheduler Service, to generate reports at regularly scheduled intervals.

# Netdiag Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetDiag Examples**
**Sample Scenario**
In this scenario, you have a problem connecting to a network resource. You receive only a "Network path not found" error message and no further assistance. You have no idea where to start troubleshooting the problem.

Assuming that the reason for the failure in this case is that the DNS server is down, the solution can be found with NetDiag.

At the command line, type:

```
netdiag
```

When executed in this scenario, NetDiag performs tests on each network adapter, and a set of global tests. The tests on the network adapters are performed in the following order:

- Netcard queries test
- IpConfig test
- Autoconfiguration test (APIPA)
- Default gateway test
- NetBT name test
- WINS Service test

Next in this example NetDiag performs a set of global tests in the following order:

- Domain membership test
- NetBT transports test
- Autonet address test (APIPA)
- IP loopback ping test
- Default gateway test
- NetBT name test
- Winsock test
- DNS test
- Redir and Browser test
- DC discovery test
- DC list test
- Trust relationship test

- Kerberos test
- LDAP test
- Bindings test
- WAN configuration test
- Modem configuration test
- IP Security test

The results of these tests show that the network adapter protocol, bindings, and IP address tests succeed. The DNS ping test fails and reports that the DNS server cannot be contacted.

With this information, the administrator knows that either the DNS server address is incorrect, or the DNS server is not responding. Because the DNS address is also displayed as output, you can easily verify whether it is correct.

After the problem is isolated, the administrator can perform additional troubleshooting to determine why the DNS server is down.

For more information on interpreting output from the NetDiag tool see the Interpreting NetDiag Output topic on the Netdiag Remarks page.

**Sample NetDiag Output**

```
.....................................

    Computer Name: RKSRVR-2
    DNS Host Name: rksrvr-2.reskita.microsoft.com
    System info : Windows 2000 Server (Build 2467)
    Processor : x86 Family 6 Model 6 Stepping 0, GenuineIntel
    List of installed hotfixes :
        Q147222

Netcard queries test . . . . . : Passed
    [WARNING] The net card 'Intel(R) PRO/100+ Management Adapter' may not be working.

# Netdiag Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetDiag Syntax**

NetDiag uses the following syntax:

**netdiag** [/**q**] [**/v**] [**/l**] [**/debug**] [**/d:***DomainName*] [**/fix**] [**/DcAccountEnum**] [**/test:***TestName*] [**/skip:***TestName*] [**/?**]

**Parameters**

**/q**
Specifies quiet output (errors only).

**/v**
Specifies verbose output.

**/l**
Sends output to Netdiag.log. This log file is created in the same directory where Netdiag.exe was run.

**/debug**
Specifies even more verbose output. With this parameter, NetDiag takes a few minutes to complete.

**/d: *DomainName***
Finds a domain controller in the specified domain.

**/fix**
Fixes minor problems.

**/DcAccountEnum**
Enumerates domain controller computer accounts.

**/test: *TestName***
Runs only the listed test(s). TCP/IP must be bound to one or more adapters before running any of the tests. Nonskippable tests are still run. A detailed explanation of the switches can be found on the Netdiag Remarks page.

Valid *TestName* values are:

| Value | Description |
|---|---|
| **Autonet** | Automatic Private IP Addressing (APIPA) address test. Tests whether APIPA is in use for the network adapters. |
| **Bindings** | Bindings test. Lists all bindings, including interface name, lower module name, upper module name, whether the binding is currently enabled, and the owner of the binding. |
| **Browser** | Redirector and Browser test. Lists the protocols bound to the Browser service and the redirector. |
| **DcList** | Domain controller list test. Obtains a list of domain controllers for the domain. |
| **DefGw** | Default gateway test. Attempts to contact each configured default gateway. |
| **DNS** | DNS test. Tests the availability of the configured DNS servers and verifies the current client's DNS registrations. |
| **DsGetDc** | Domain controller discovery test. First finds a generic domain controller from directory service, then finds the primary domain controller. Then, finds a Windows 2000 domain controller (DC). If the tested domain is the primary domain, checks whether the domain GUID stored in Local Security Authority (LSA) is the same as the domain GUID stored in the DC. If not, the test returns a fatal error; if the **/fix** option is on, DsGetDC tries to fix the GUID in LSA. |
| **IpConfig** | IP address configuration test. Enumerates the TCP/IP configuration information for each network adapter. |

| | |
|---|---|
| **IpLoopBk** | IP address loopback ping test. Pings the IP loopback address of 127.0.0.1 for each adapter. |
| **IPSec** | IP Security test. Tests whether IP Security is enabled and displays a list of active IP Security policies for the computer. |
| **IPX** | IPX test. Lists statistics for the IPX protocol installed on the computer. |
| **Kerberos** | Kerberos test. Checks whether the Kerberos package information is up-to-date. |
| **Ldap** | Lightweight Directory Access Protocl (LDAP) test. Contacts all available domain controllers and determines which LDAP authentication protocol is in use. |
| **Member** | Domain membership test. Checks to confirm details of the primary domain, including computer role, domain name, and domain GUID. Checks to see if NetLogon service is started, adds the primary domain to the domain list, and queries the primary domain security identifier (SID). |
| **Modem** | Modem diagnostics test. Lists configuration information for each modem found. |
| **NbtNm** | NetBT name test. Similar to the **nbtstat -n** command. It checks that the workstation service name `<00>` is equal to the computer name. It also checks that the messenger service name `<03>`, and server service name `<20>` are present on all interfaces and that none of these names are in conflict. |
| **Ndis** | Netcard queries test. Lists the network adapter configuration details, including the adapter name, configuration, media, globally unique identifier (GUID), and statistics. If this test shows an unresponsive network adapter, the remaining tests are aborted. |
| **NetBTTransports** | NetBT transports test. Lists the transport protocols that are bound to NetBT. |
| **Netstat** | Netstat information test. Lists protocol statistics and current TCP/IP connections. |
| **Netware** | Netware test. Queries the nearest Netware server for current login information. |
| **Route** | Routing table test. Lists static routes and whether they are persistent. |
| **Trust** | Trust relationship test. Tests trust relationships to the primary domain only if the computer is a member workstation, member server, or a Backup Domain Controller (BDC) domain controller that is not a PDC emulator. Checks that the primary domain security identifier (SID) is correct. Contacts an active DC. Connects to the SAM server on the DC. Uses the domain SID to open the domain to verify whether the domain SID is correct. Queries info of the secure channel for the primary domain. If the computer is a BDCDC, reconnects to the PDC emulator. If the computer is a member workstation or server, sets secure channel to each DC on the DC list for this domain. |
| **WAN** | Wide Area Network (WAN) configuration test. Lists settings and status on each COM port currently in use. |
| **WINS** | Windows Internet Name Service (WINS) service test. Tests the availability of the configured WINS server and the validity of the client registrations. |
| **Winsock** | Winsock test. Lists protocols and ports available to the WinSock service. |

**/skip:** ***TestName***

Skips the test specified by *TestName*. Nonskippable tests will still run. Valid *TestName* values are:

| Value | Description |
|---|---|
| **Autonet** | Automatic Private IP Addressing (APIPA) address test. |
| **Bindings** | Bindings test. |
| **Browser** | Redir and Browser test. |
| **DcList** | Domain controller list test. |

| | |
|---|---|
| **DefGw** | Default gateway test. |
| **DNS** | DNS test. |
| **DsGetDc** | Domain controller discovery test. |
| **IpConfig** | IP address configuration test. |
| **IpLoopBk** | IP address loopback ping test. |
| **IPX** | IPX test. |
| **Kerberos** | Kerberos test. |
| **Ldap** | Lightweight Directory Access Protocol (LDAP) test. |
| **Modem** | Modem diagnostics test. |
| **NbtNm** | NetBT name test. |
| **Netstat** | Netstat information test. |
| **Netware** | Netware test. |
| **Route** | Routing table test. |
| **Trust** | Trust relationship test. |
| **WAN** | Wide Area Network (WAN) configuration test. |
| **WINS** | Windows Internet Name Service (WINS) test. |
| **Winsock** | Winsock test. |

# Netdom Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Netdom.exe: Windows Domain Manager**
This command-line tool enables administrators to manage Windows Server 2003 and Windows 2000 domains and trust relationships from the command line.

You can use NetDom to:

- Join a Windows XP Professional-based computer to a Windows Server 2003 or Windows 2000 or Windows NT 4.0 domain.
    - Provide an option to specify the organizational unit for the computer account.
    - Generate a random computer password for initial join.
- Manage computer accounts for domain member workstations and member servers. Management operations include:
    - Add, Remove, Query.
    - An option to specify the organizational unit for the computer account.
    - An option to move an existing computer account for a member workstation from one domain to another while maintaining the security descriptor on the computer account.
- Establish one-way or two-way trust relationships between domains, including the following kinds of trust relationships:
    - From a Windows 2000 or Windows Server 2003 domain to a Windows NT 4.0 domain.
    - From a Windows 2000 or Windows Server 2003 domain to a Windows 2000 or Windows Server 2003 domain in another enterprise (an "uplevel" external trust).
    - Between two Windows 2000 or Windows Server 2003 domains in an enterprise (a shortcut trust).
    - The Windows Server 2003 or Windows 2000 Server half of an interoperable Kerberos realm.
- Verify and/or reset the secure channel for the following configurations:
    - Member workstations and servers.
    - BDCs in a Windows NT 4.0 domain.
    - Specific Windows Server 2003 or Windows 2000 replicas.
- Manage trust relationships between domains, including the following operations:
    - Enumerate trust relationships (direct and indirect).
    - View and change some attributes on a trust.

**Note**

- You must run NetDom from the command window.

Corresponding UI

Much of the functionality of NetDom can be accessed from the Microsoft Management Console Active Directory Users and Computers snap-in, which is part of Windows Server 2003. More functionality can be accessed from the Active Directory: Domains and Trust snap-in which is the corresponding UI for NetDom's Trust Management functionality.

Concepts

A trust relationship is a defined affiliation between domains that enables pass-through authentication.

A one-way trust relationship between two domains means that one domain (the trusting domain) allows users who have accounts on the other domain (the trusted domain), access to its resources.

The one-way trust relationship described here is helpful in master domain models, but it is not the only kind of trust relationship. When two one-way trusts are established between domains, it is known as a two-way trust. In two-way trusts, each domain treats the users from the trusted (and trusting) domain as its own users.

System Requirements

The following are the system requirements for NetDom:

- Windows Server 2003 or Windows XP Professional

  **Note**

  - The Windows Server 2003 Administration Tools Pack must be installed on computers running Windows XP Professional for Netdom.exe to work. This tools pack is installed by default for computers running Windows Server 2003.

**File Required**

- Netdom.exe

# Netdom Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetDom Remarks**

**Using the /Verbose Parameter**

By default, only the result of an operation is reported. For example, if you use the **join** operation you see output similar to the following:

```
success: mywksta joined to mycompany domain
```

If you specify the **/verbose** parameter, the output lists the success or failure of each transaction necessary to perform the operation. For example, this time when you use the **join** operation, you see output similar to the following:

```
success: adding machine account for mywksta to mycompany domain
success: configuring lsa on mywksta
success: mywksta joined to mycompany domain
```

**Using the /Reboot Parameter**

The **/reboot** parameter specifies that the computer being acted upon by the specified NetDom operation is shut down and automatically rebooted after the completion of the operation. When you specify the **/reboot** parameter, the following message and a countdown timer display on the workstation screen, prior to the restart:

```
The system is shutting down. Please save
all work in progress and logoff. Any unsaved changes
will be lost. This shutdown was initiated because the
domain which this machine belongs to was changed by
nnn.
```

The name of the administrator entered by using the **/uo** parameter is substituted for *nnn*.

The default delay before computer restart is 20 seconds.

# Netdom Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetDom Examples**

**Example 1: Add a Workstation or Member Server to a Windows NT 4.0 Domain**

To add the workstation **mywksta** to the Windows NT 4.0 domain**reskita**, type the following at the command line:

```
netdom add /d:reskita mywksta /ud:mydomain\admin /pd:password
```

**Example 2: Add a Workstation or Member Server to a Windows Server 2003 Domain**

To add the workstation mywksta to the Windows Server 2003 domain devgroup.example.com in the organizational unit (OU) Dsys/workstations, type the following at the command prompt:

```
netdom add/d:devgroup.example.com mywksta /OU:OU=Dsys,OU=Workstations,DC=microsoft,DC=com
```

### Note

- If the **/ou** parameter is not specified, the account is created in the Computers container.

**Example 3: Move a Windows NT 4.0 BDC to a new domain**

To join myBDC to the Windows NT 4.0 domain reskita type the following at the command prompt:

```
netdom mybdc moveNT4BDC /domain:reskita
```

**Example 4: Add an alternate name for a Windows Server 2003 domain controller**

To give an alternate name for the domain controller DC in the example.com domain, use the following syntax:

```
netdom computername dc /add:altDC.example.com
```

A name must first exist as an alternate before it can be made the primary name of a computer.

**Example 5: Rename a domain controller in a Windows Server 2003 domain**

To rename the domain controller DC to altDC in the example.com domain use the following syntax:

```
netdom computername dc /makeprimary:altdc.example.com
```

To rename a member server you must choose one of the existing alternate names for the computer and make it the new primary name.

**Example 6: Rename a Member Server**

To rename the member server member to member1, type the following at the command prompt:

```
netdom renamecomputer member /newname:member1.example.com /userd:administrator
```

**Example 7: Join a Workstation or Member Server to a Domain**

To join mywksta to the devgroup.example.com domain in the Dsys/workstations organizational unit, type the following at the command prompt:

```
netdom join /d:devgroup.example.com mywksta /OU:OU=Dsys,OU=Workstations,DC=microsoft,DC=com
```

Besides adding the computer account to the domain, the workstation is modified to contain the appropriate shared secret to complete the **join** operation.

**Example 8: Remove a Workstation or Member Server from a Domain**

To remove mywksta from the mydomain domain and make the workstation a part of a workgroup, type the following at the command prompt:

```
netdom remove /d:mydomain mywksta /ud:mydomain\admin /pd:password
```

**Example 9: Move a Workstation or Member Server from One Domain to Another**

To move mywksta from its current domain into the mydomain domain, type the following at the command prompt:

```
netdom move /d:mydomain mywksta /ud:mydomain\admin /pd:password
```

If the destination is a Windows 2000 domain, the Security ID history (SIDHistory) for the workstation is updated, retaining the security permissions that the computer account had previously.

**Example 10: Reset the secure channel for a workstation, member server, or Windows NT 4.0 BDC**
To reset the secure channel secret maintained between mywksta and devgroup.example.com (regardless of OU), type the following at the command prompt:

```
netdom reset /d:devgroup.example.com mywksta
```

To reset the secure channel between the Windows NT 4.0 PDC for Northamerica and the backup domain controller NABDC, type the following at the command prompt:

```
netdom reset /d:Northamerica NABDC
```

**Example 11: Force a Secure Channel Session Between a Member and a Specific Domain Controller**
Members often establish secure channel sessions with non-local domain controllers. To force a secure channel session between a member and a specific domain controller by using the **/server** parameter with the **reset** operation, type the following at the command prompt:

```
netdom reset /d:devgroup.example.com mywksta /Server:mylocalbdc
```

**Example 12: Verify a Workstation or Member Server Secure Channel**
To verify the secure channel secret is maintained between mywksta and devgroup.example.com, type the following at the command prompt:

```
netdom verify /d:devgroup.example.com mywksta
```

**Example 13: Establish a One-Way Trust Relationship**
When used with the **trust** operation, the **/d:***Domain* parameter always refers to the trusted domain.

To set the Windows NT 4.0 resource domain USA-Chicago to trust the Windows NT 4.0 account domain Northamerica, type the following at the command prompt:

```
netdom trust /d:Northamerica USA-Chicago /add /Ud:Northamerica\admin /Pd:* /Uo:USA-Chicago\admin /Po:*
```

Press Enter and the following prompt is displayed:

```
Password for Northamerica\admin:
```

Enter the password for Northamerica\admin and press Enter. The following prompt is displayed:

```
Password for USA-Chicago\admin:
```

Enter the password for USA-Chicago\admin and press Enter.

The user must have credentials for both domains. The **/pd** parameter can be used to specify the password for Northamerica\admin and the **/po** parameter can be used to specify the password for USA-Chicago\admin. If passwords are not provided on the command line, the user is prompted for both.

If you then want to specify a two-way trust, type the following at the command prompt

```
netdom trust /d:marketing.example.com engineering.example.com /add /twoway /Uo:admin@engineering.example.com
/Ud:admin@marketing.example.com:
```

**Example 14: Establish a One-Way Trust Relationship from a Windows Domain to a Non-Windows Kerberos Realm**
To establish a one-way trust where Northamerica trusts the non-Windows Kerberos realm ATHENA, type the following at the command prompt:

```
netdom trust /d:ATHENA Northamerica /add /PT:password /realm
```

The **/d** parameter specifies the trusted domain and the **/realm** parameter indicates that this is a non-Windows Kerberos realm. The order of the domains is not important. Credentials to the Windows 2000 domain can be supplied if needed.

### Note

- Verifying a specific trust relationship requires credentials unless the user has domain administrator privileges on both domains.

If you want to set the Kerberos realm ATHENA to trust the Northamerica domain, type the following at the command prompt:

```
netdom trust /d:Northamerica ATHENA /add
```

### Note

- To make the trust two-way, you can specify the **/twoway** parameter.

Non-Windows Kerberos trusts are created as non-transitive. If you want to change the trust from ATHENA to Northamerica as transitive, type the following at the command prompt:

```
netdom trust Northamerica /d:ATHENA /trans:yes
```

To display the transitive state, type the following at the command prompt:

```
netdom trust Northamerica /d:ATHENA /trans
```

The order of the two domains above is not important. Either can be the non-Windows Kerberos domain.

**Example 15: Break a One-Way Trust Relationship**
To undo the trust that USA-Chicago has for Northamerica, type the following at the command prompt:

```
netdom trust /d:Northamerica USA-Chicago /remove
```

**Example 16: Break a Two-Way Trust Relationship**
To break a two-way trust relationship, type the following at the command prompt:

```
netdom trust /d:marketing.example.com Engineering.example.com /remove /twoway
/Uo:admin@engineering.example.com /Ud:admin@marketing.example.com
```

**Example 17: Verify a Specific Trust Relationship**
To verify the one-way trust that USA-Chicago has for Northamerica, type the following at the command prompt:

```
netdom trust /d:Northamerica USA-Chicago /verify
```

To verify a two-way trust between the Northamerica and Europe domains, type the following at the command prompt:

```
netdom trust /d:Northamerica EUROPE /verify /twoway
```

The **/verify** parameter checks that the appropriate shared secrets are synchronized between the two items involved in the trust.

**Example 18: Reset a Specific Trust Relationship**
To reset the secure channel for the one-way trust between Northamerica and USA-Chicago, type the following at the command prompt:

```
netdom trust /d:Northamerica USA-Chicago /Ud:Northamerica\admin /reset
```

The **/reset** parameter synchronizes the appropriate shared secrets if they are not already synchronized.

**Example 19: Verify Kerberos Functionality**
To verify Kerberos authentication between a workstation and a service located in the domain devgroup.example.com, type the following at the command prompt:

```
netdom trust /d:devgroup.example.com /verify /KERBEROS
```

When you use the **NetDom trust** operation with the **/verify /kerberos** parameters, it seeks a session ticket for the Kerberos Admin service in the target domain. If successful, you can conclude that all Kerberos operations (for example KDC referrals) are operating correctly between the workstation and the target domain.

### Note

- This operation cannot be executed remotely. It must be run on the workstation being tested.

**Example 20: View All Workstation Members in a Domain**
To list all the workstations in the domain Northamerica, type the following at the command prompt:

```
netdom query /d:Northamerica WORKSTATION
```

**Example 21: View All Server Members in a Domain**
To list all of the servers in Northamerica, type the following at the command prompt:

```
netdom query /d:Northamerica SERVER
```

**Example 22: View All Domain Controller Members in a Domain**
To list all the domain controllers in the domain Northamerica, type the following at the command prompt:

```
netdom query /d:Northamerica DC
```

**Example 23: View All Organizational Unit Members in a Domain**
To list all of the OUs in devgroup.example.com, type the following at the command prompt:

```
netdom query /d:devgroup.example.com OU
```

**Example 24: List the Primary Domain Controller Member in a Domain**
To list the PDC for Northamerica, type the following at the command prompt:

```
netdom query /d:Northamerica PDC
```

**Example 25: List the Primary Domain Controller Emulator in a Domain**
To list the current PDC emulator for devgroup.example.com, type the following at the command prompt:

```
netdom query /d:devgroup.example.com FSMO
```

**Example 26: Perform Secure Channel Batch Repair**
You can use the **query** operation with the **/verify** and **/reset** parameters to perform these operations together. You can pipe the output of the **query** operation to the **NetDom verify** or **NetDom reset** operation.

To list all servers and verify secure channel secret, type the following at the command prompt:

```
netdom query /d:Northamerica SERVER /verify
```

To list all workstations and reset any unsynchronized secure channel secrets, type the following at the command prompt:

```
netdom query /d:Northamerica WORKSTATION /reset
```

**Example 27: View Domain Trusts**
To view all the direct trust relationships for the domain Northamerica, type the following at the command prompt:

```
netdom query /d:Northamerica /Ud:Northamerica\admin DOMAIN /Direct
```

To view all the direct and indirect trust relationships for the domain Northamerica, type the following at the command prompt:

```
netdom query /d:Northamerica /Ud:Northamerica\admin DOMAIN
```

To view all trust relationships and check their status, type the following at the command prompt:

```
netdom query /d:devgroup.example.com DOMAIN /verify
```

**Example 28: List the routed name suffixes for the trust between my TestDomain and the trustpartnerdomain**
**Note**

- The **/d** parameter is not needed for this operation which is an exception from other trust operations.

To list the routed name suffixes for the trust between my TestDomain abd the trustpartnerdomain, type the following at the command prompt:

```
netdom trust myTestDomain /namesuffixes:trustpartnerdomain
```

This will list out all the routed name suffixes for the trust between myTestDomain and the trustpartnerdomain. The trust **must** be either a Cross Forest trust or Non-Windows Realm Trust with the Forest Transitive attribute set.

**Sample Output**

```
C:\nt\ds\netapi\netdom\obj\i386>netdom trust shasandom2 /namesuffixes:powermatic

   Name, Type, Status, Notes

1. *.flotsam.org, Name Suffix, Enabled

2. *.powermatic.nttest.microsoft.com, Name Suffix, Enabled

3. *.jetsam.com, Name Suffix, Enabled

4. *.blah.com, Name Suffix, Conflicting, With shasandom2.nttest.microsoft.com

5. unisaw.powermatic.nttest.microsoft.com, Domain DNS name, Enabled

6. UNISAW, Domain NetBIOS name, Enabled, For unisaw.powermatic.nttest.microsoft.
```

```
com
7. s-1-5-21-1550512861-723516995-420396236, Domain SID, Enabled, For unisaw.powe
rmatic.nttest.microsoft.com
8. powermatic.nttest.microsoft.com, Domain DNS name, Enabled
9. POWERMATIC, Domain NetBIOS name, Enabled, For powermatic.nttest.microsoft.com

10. s-1-5-21-1390067357-1757981266-527237240, Domain SID, Enabled, For powermati
c.nttest.microsoft.com

The command completed successfully.
```

**Example 29: Enable/disable the first routed name suffix in the list generated by the previous command**

**Note**

- **/ToggleSuffix** must be used with **/NameSuffixes**. Use **/NameSuffixes** immediately before using **/ToggleSuffix** because the order in which the name suffixes are listed may change.

To enable/disable the first routed name suffix in the list generated by the previous command, type the following at the command prompt:

```
netdom trust myTestDomain /namesuffixes:foresttrustpartnerdomain /togglesuffix:1
```

**Sample Output**

**Note**

- The output generated reflects the routed name suffix list after the Toggling.

```
C:\nt\ds\netapi\netdom\obj\i386>netdom trust shasandom2 /ns:powermatic /ts:1
   Name, Type, Status, Notes
1. *.flotsam.org, Name Suffix, Admin-Disabled
2. *.powermatic.nttest.microsoft.com, Name Suffix, Enabled
3. *.jetsam.com, Name Suffix, Enabled
4. *.blah.com, Name Suffix, Conflicting, With shasandom2.nttest.microsoft.com
5. unisaw.powermatic.nttest.microsoft.com, Domain DNS name, Enabled
6. UNISAW, Domain NetBIOS name, Enabled, For unisaw.powermatic.nttest.microsoft.
com
7. s-1-5-21-1550512861-723516995-420396236, Domain SID, Enabled, For unisaw.powe
rmatic.nttest.microsoft.com
8. powermatic.nttest.microsoft.com, Domain DNS name, Enabled
9. POWERMATIC, Domain NetBIOS name, Enabled, For powermatic.nttest.microsoft.com

10. s-1-5-21-1390067357-1757981266-527237240, Domain SID, Enabled, For powermati
c.nttest.microsoft.com
```

```
The command completed successfully.
```

**Example 30: Adding/Removing TLN Suffixes**

To add the DNS name suffix blah.com to the Forest Trust Info with trustpartnerdomain, type the following at the command prompt:

```
Netdom trust myTestDomain /d:trustPartnerDomain /AddTln:blah.com
```

### Note

- This is only allowed for a trust with a Forest Transitive, Non-Windows Realm Trust. This is also true for:
    - Netdom trust myTestDomain /d:trustPartnerDomain /RemoteTln:blah.com
    - Netdom trust myTestDomain /d:trustPartnerDomain /AddTLNEx:something.blah.com (must have a TLN entry present for the parent Naming context, in this case blah.com, otherwise operation will be disallowed)
    - Netdom trust myTestDomain /d:trustPartnerDomain /RemoveTLNEx:something.blah.com

**List the name suffixes on a Non-Windows Realm Trust**

```
C:\nt\ds\netapi\netdom\obj\i386>netdom trust shasandom2 /ns:blah.mit.org

   Name, Type, Status, Notes

1. *.bowwow.com, Name Suffix, Enabled

2. *.meow.com, Name Suffix, Enabled

The command completed successfully.
```

**Add another TLN**

```
C:\nt\ds\netapi\netdom\obj\i386>netdom trust shasandom2 /d:blah.mit.org /addtln:

dude.com

The TLN or Exclusion was successfully added to the Forest Trust Info.

The command completed successfully.
```

**Add an invalid TLN exclusion**

```
C:\nt\ds\netapi\netdom\obj\i386>netdom trust shasandom2 /d:blah.mit.org /addtlne

x:dude.com

The Forest Trust Info for the specified trust could not be stored.

The parameter is incorrect.

Try "NetDom HELP" for more information.
```

**Add an valid TLN exclusion**

```
C:\nt\ds\netapi\netdom\obj\i386>netdom trust shasandom2 /d:blah.mit.org /addtlne

x:cool.dude.com
```

```
The TLN or Exclusion was successfully added to the Forest Trust Info.

The command completed successfully.
```

**View the result of previous operations**

```
C:\nt\ds\netapi\netdom\obj\i386>netdom trust shasandom2 /ns:blah.mit.org

   Name, Type, Status, Notes

1. *.cool.dude.com, Exclusion

2. *.bowwow.com, Name Suffix, Enabled

3. *.meow.com, Name Suffix, Enabled

4. *.dude.com, Name Suffix, Enabled

The command completed successfully.
```

# Netdom Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetDom Syntax**
NetDom uses the following general syntaxes:

- **NetDom** *Operation* [*Computer*] [{/**d: | /domain:**}*Domain*] [*Options*]
- **NetDom help** *Operation*

**NetDom add**
Adds a workstation or server account to the domain.

**Syntax**
- **NetDom add** *Computer* {**/d: | /domain:**}*Domain* [{**/ud: | /userd:**}[*Domain*\]*User* {**/pd: | /passwordd:**}{*Password*|*}] [{**/s: | /server:**}*Server*] [**/ou:***OUPath*] [**/dc**] [**/help | /?**]

**Parameters**
***Computer***
Specifies the name of the computer to be added.

**{/d: | /domain:} *Domain***
Specifies the domain in which to create the account. If this parameter is omitted, then the domain that the current computer belongs to is used.

**{/ud: | /userd:}[ *Domain*\] *User***
Specifies the user account that makes the connection with the domain that is specified in the **/d** or **/domain** parameter. If this parameter is omitted, the current user account is used.

**{/pd: | /passwordd:}{ *Password*|*}**
Specifies the password of the user account that is specified in the **/ud** or **/userd** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/s: | /server:} *Server***
Specifies the name of a domain controller that performs the add.

**/ou: *OUPath***
Specifies the organizational unit (OU) under which to create the account. This must be the full RFC 1779 distinguished name of the OU. If omitted, the account is created under the default OU for machine objects for that domain.

**/dc**
Specifies that a domain controller's machine account is to be created. This allows the computer accounts for new Windows 2000, Windows Server 2003 domain controllers, and new Windows NT 4.0 backup domain controllers (BDCs) to be pre-created. If installing a new Windows NT 4.0 BDC into an existing Windows 2000 or Windows Server 2003 domain, the computer account must be pre-created. This parameter cannot be used with the **/ou** parameter.

**{/help | /?}**
Displays command-line help for the **add** operation.

**Sample Usage**
```
netdom add /d:reskit.ms.com mywksta

netdom add /d:reskit.ms.com mynt4dc /dc
```

**NetDom computername**
Manages the primary and alternate names for a computer. This command can safely rename Windows Server 2003 and Windows 2000 domain controllers as well as member servers.

**Syntax**
- **NetDom computername** *Computer* [**usero:***User* [**/passwordo:**[*Password*|*]] [**userd:***User* [**/passwordd:**[*Password*|*]] {**/add:***NewAltDNSName* | **/remove:***AltDNSName* | **/makeprimary:***ComputerDNSNam*

**Parameters**
***Computer***
Specifies the name of the computer to be added.

**/usero:[*domain*\]*UserName***
Specifies the user account to be used for the originating domain.

**/passwordo:[*Password* | *]**
Specifies the password to be used for the originating domain. If the wildcard character (*****) is used, then the user will be prompted for the password.

**/userd:[*Domain*\]*UserName***
Specifies the user account to be used for the destination domain.

**/passwordd:[*Password* | *]**
Specifies the password to be used for the destination domain. If the wildcard character (*****) is used, then the user will be prompted for the password.

**/add: *NewAltDNSName***
Specifies that a new alternate name should be created. The name must be a fully qualified domain name (computer name followed by primary DNS suffix, such as comp1.example.com).

**/remove: *AltDNSName***
Specifies that an existing alternate name should be deleted. The name must be a fully qualified domain name (computer name followed by primary DNS suffix, such as comp1.example.com).

**/makeprimary: *ComputerDNSName***
Specifies that an existing alternate name should be made into the primary name. The name must be a fully qualified domain name (computer name followed by primary DNS suffix, such as comp1.example.com).

**/enumerate[:{ALTERNATENAMES | PRIMARYNAME | ALLNAMES}]**
Lists the primary and/or any alternate names. The following valid values can be specified:

| Value | Description |
|---|---|
| **ALTERNATENAMES** | Lists the alternate names only. |
| **PRIMARYNAME** | Lists the primary name only. |
| **ALLNAMES** | Lists the primary and any alternate names. This is the default. |

**/verify**
Checks if there is a DNS A record and an Service Principal Name (SPN) for each computer name.

**{/help | /?}**
Displays command-line help for the **computername** operation.

**Sample Usage**
```
netdom computername reskit /enumerate:primaryname
```

**NetDom join**
Joins a workstation or member server to a domain. The act of joining a computer to a domain creates an account for the computer on the domain, if it does not already exist.

**Syntax**

**NetDom join** *Computer* {**/d: | /domain:**}*Domain* [**/ou:***OUPath*] [{**/ud: | /userd:**}[*Domain*\]*User* [{**/pd: | /passwordd:**}{*Password*|*}]] [{**/uo: | /usero**}*User* [{**/po: | /passwordo**} {*Password*|*}] [**/reboot**[**:***Delay*]] [**/help | /?**]

**Parameters**

**Note**

- When joining a computer running Windows NT 4.0 or earlier to the domain, the operation is not transacted. This means that a failure during the operation might leave the computer in an undetermined state with respect to the domain to which it was meant to join.

***Computer***
Specifies the name of the computer to be joined.

**{/d: | /domain:}*Domain***
Specifies the domain to which the account is joined. If this parameter is omitted, then the domain that the current computer belongs to is used.

**/ou: *OUPath***
Specifies the organizational unit (OU) under which to create the account. This must be the full RFC 1779 distinguished name of the OU. If omitted, the account is created under the default OU for machine objects for that domain.

**{/ud: | /userd:}[*Domain*\]*User***
Specifies the user account that makes the connection with the domain specified in the **/d** or **/domain** parameter. If this parameter is omitted, the current user account is used.

**{/pd: | /passwordd:}{*Password*|*}**
Specifies the password of the user account that is specified in the **/ud** or **/userd** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/uo: | /usero}*User***
Specifies the user account that makes the connection with the computer to be joined. If this parameter is omitted, the current user account is used.

**{/po: | /passwordo}{*Password*|*}**
Specifies the password of the user account that is specified in the **/uo** or **/usero** parameter. Use the wildcard character (*****) to be prompted for the password.

**/reboot[:*Delay*]**
Specifies that the computer shuts down and automatically reboots after the join has completed. The *Delay* value is the number of seconds before automatic shutdown occurs. The default *Delay* value is 20 seconds.

**{/help | /?}**
Displays command-line usage for the **join** operation.

**Sample Usage**
```
netdom join /d:reskit.ms.com mywksta
```

**NetDom move**
Moves a workstation or member server to a new domain. The act of moving a computer to a new domain creates an account for the computer on the domain, if it does not already exist.

**Syntax**
**NetDom move** *Computer* {**/d: | /domain:**}*Domain* [**/ou:***OUPath*] [{**/ud: | /userd**}[*Domain*\]*User* [{**/pd: | /passwordd**}{*Password*|*}] [{**/uo: | /usero**}[*Domain*\]*User* [{**/po: | /passwordo**} {*Password*|*}]] [{**/uf: | /userf**}[*Domain*\]*User* [{**/pf: | /passwordf**}{*Password*|*}]] [**/reboot**[**:***Delay*]] [{**/help | /?**}]

**Parameters**

**Notes**

- When moving a computer running Windows NT 4.0 or earlier to the domain, the operation is not transacted. This means that a failure during the operation might leave the computer in an undetermined state with respect to the domain of its intended move.
- When moving a computer to a new domain, the old computer account in the previous domain is not deleted. If credentials are supplied for the former domain, the old computer account is disabled.
- The act of moving a computer to a new domain will create an account for the computer on the domain if it does not already exist.

***Computer***
Specifies the name of the computer to be moved.

**{/d: | /domain:}*Domain***
Specifies the domain to which the account is moved. If the parameter is omitted, then the domain that the current computer belongs to is used.

**/ou: *OUPath***
Specifies the organizational unit (OU) under which to create the account. This must be the full RFC 1779 distinguished name of the OU. If omitted, the account is created under the default OU for machine objects for that domain.

**{/ud: | /userd}[*Domain*\]*User***
Specifies the user account that makes the connection with the domain specified in the **/d** or **/domain** parameter. If this parameter is omitted, the current user account is used.

**{/pd: | /passwordd}{*Password*|*}**
Specifies the password of the user account that is specified in the **/ud** or **/userd** parameter. Use an asterisk (*) to be prompted for the password.

**{/uo: | /usero}*User***
Specifies the user account to make the connection with the computer to be moved. If this parameter is omitted, the current user account is used.

**{/po: | /passwordo}{*Password*|*}**
Specifies the password of the user account that is specified in the **/uo** or **/usero** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/uf: | /userf}*User***
Specifies the user account to make the connection with the computer's former domain (of which the computer had been a member prior to the move). This parameter is used to disable the old computer account.

**{/pf: | /passwordf}{*Password*|*}**
Specifies the password of the user account that is specified in the **/uf** or **/userf** parameter. Use the wildcard character (*****) to be prompted for the password.

**/reboot[:*Delay*]**
Specifies that the computer shuts down and automatically reboots after the move has completed. The *Delay* value is the number of seconds before automatic shutdown occurs. The default *Delay* value is 20 seconds.

**{/help | /?}**
Displays command-line usage for the **move** operation.

**Sample Usage**
```
netdom move /d:newdomain mywksta
```

**NetDom query**
Queries the domain for information such as membership and trust.

**Syntax**
**NetDom query** {**/d: | /domain:**}*Domain* [{**/s: | /server:**}*Server*] [{**/ud: | /userd:**}[*Domain*\]*User* {**/pd: | /passwordd**}{*Password*|*}] [**/verify**] [**/reset**] [**/direct**] {**WORKSTATION**|**SERVER**|**DC**|**OU**|**PDC**|**FSMO**|**TRUST**} [{**/help | /?**}]

**Parameters**
**{/d: | /domain:}*Domain***

Specifies the domain to query for the information. If this parameter is omitted, then the domain that the current computer belongs to is used.

**{/s: | /server:}*Server***
Specifies the name of a domain controller that performs the query.

**{/ud: | /userd:}[*Domain*\]*User***
Specifies the user account that makes the connection with the domain in the **/d** or **/domain** parameter. If this parameter is omitted, the current user account is used.

**{/pd: | /passwordd}{*Password*|*}**
Specifies the password of the user account that is specified in the **/ud** or **/userd** parameter. Use the wildcard character (*****) to be prompted for the password.

**/verify**
Specifies verification of the secure channel secrets for all enumerated memberships or trusts, and displays them. Unless the user is an enterprise-level administrator, it will not be possible to verify all secure channel secrets.

**/reset**
Specifies resynchronization ofthe secure channel secrets for all enumerated memberships or trusts which are currently broken. The **/reset** parameter implies the **/verify** parameter. Unless the user is an enterprise-level administrator, it might not be possible to reset all enumerated trusts or memberships.

**/direct**
Indicates that the query for trust relationships returns only direct trust relationships, rather than direct and indirect relationships. This parameter is valid only when *Domain* is specified with the **/d** parameter.

**WORKSTATION|SERVER|DC|OU|PDC|FSMO|TRUST**
Specifies the type of list to generate.

| Object | Description |
|---|---|
| **WORKSTATION** | Queries the domain for the list of workstations. |
| **SERVER** | Queries the domain for the list of servers. |
| **DC** | Queries the domain for the list of domain controllers. |
| **OU** | Queries the domain for the list of OUs under which the specified user can create a machine object. |
| **PDC** | Queries the domain for the current primary domain controller. |
| **FSMO** | Queries the domain for the current list of operations master (also know as flexible single master operations or FSMO) owners. |
| **TRUST** | Queries the domain for the list of its trusts. |

**{/help | /?}**
Displays command-line usage for the **query** operation.

**Sample Usage**
```
netdom query /d:reskit.ms.com DC
```

**NetDom remove**
Removes a workstation or server from the domain.

**Syntax**
▸ **NetDom remove** *Computer* {**/d: | /domain:**}*Domain* [{**/ud: | /userd:**}[*Domain*\]*User* [{**/pd: | /passwordd**}{*Password*|*}]] [{**/uo: | /usero**}*User* [{**/po: |/passwordo**}{*Password*|*}]] [**/reboot**[**:***Delay*]] [{**/help | /?**}]

**Parameters**
***Computer***
Specifies the name of the computer to be removed.

**{/d: | /domain:}*Domain***
Specifies the domain from which the account is to be removed. If this parameter is omitted, then the domain that the current computer belongs to is used.

**{/ud: | /userd:}[ *Domain*\]*User***
Specifies the user account that makes the connection with the domain in the **/d** or **/domain** parameter. If this parameter is omitted, then the current user account is used.

**{/pd: | /passwordd}{*Password*|*}**
Specifies the password of the user account that is specified in the **/ud** or **/userd** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/uo: | /usero}*User***
Specifies the user account to make the connection with the computer to be removed. If this parameter is omitted, then the current user account is used.

**{/po: |/passwordo}{*Password*|*}**
Specifies the password of the user account that is specified in the **/uo**or **/usero** parameter. Use the wildcard character (*****) to be prompted for the password.

**/reboot[:*Delay*]**
Specifies that the computer shuts down and automatically restarts after the **remove** operation has completed. The *Delay* value is the number of seconds before automatic shutdown occurs. The default *Delay* value is 20 seconds.

**{/help | /?}**
Displays command-line usage for the **remove** operation.

**Sample Usage**
```
netdom remove /d:reskit.ms.com mywksta
```

**NetDom movent4bdc**
Renames a Windows NT 4.0 backup domain controller to reflect a domain name change. This can assist in Windows NT 4.0 domain renaming efforts.

**Syntax**
▸ **netdom movent4bdc** *Computer* [{**/d: | /domain:**}*Domain*] [**/reboot**[**:***Delay*]] [{**/help | /?**}]

**Parameters**
***Computer***
Specifies the name of the backup domain controller to rename.

**{/d: | /domain:}*Domain***
Specifies the new name of the domain.

**/reboot[:*Delay*]**
Specifies that the computer shuts down and automatically reboots after the **rename** operation has completed. The *Delay* value is the number of seconds before automatic shutdown occurs. The default *Delay* value is 20 seconds.

**{/help | /?}**
Displays command-line usage for the **movent4bdc** operation.

**Sample Usage**
```
netdom movent4bdc /d:newdomain BDC51
```

**NetDom renamecomputer**
Renames a domain computer and its corresponding domain account. Use this command to rename domain workstations and member servers only. To rename domain controllers, use the NetDom

computername command.

**Syntax**

**NetDom renamecomputer** *Computer* **/newname:***NewComputerName* **/userd:**[*Domain*\]*UserName* [**/passwordd:**[*Password* | *]] **/usero:**[*Domain*\]*UserName* [**/passwordo:**[*Password* | *]] [**/reboot[:***Delc*

**Parameters**

***Computer***
Specifies the name of the computer to rename.

**/newname: *NewComputerName***
Specifies the new name of the computer.

**/userd:[*domain*\]*UserName***
Specifies the user account to be used for the destination domain.

**/passwordd:[*password* | *]**
Specifies the password of the user account that is specified in the **/ud** or **/userd** parameter. If the wildcard character (*****) is used, then the user will be prompted for the password.

**/usero:[*domain*\]*UserName***
Specifies the user account to be used for the originating domain.

**/passwordo:[*password*| *]**
Specifies the password of the user account that is specified in the **/uo** or **/usero** parameter. If the wildcard character (*****) is used, then the user will be prompted for the password.

**/force[:*Delay*]**
The user will be prompted for confirmation unless the **/force** parameter is specified.

**/reboot[:*Delay*]**
Specifies that the computer shuts down and automatically reboots after the **rename** operation has completed. The *Delay* value is the number of seconds before automatic shutdown occurs. The default *Delay* value is 20 seconds.

**{/help | /?}**
Displays command-line usage for the **renamecomputer** operation.

Note

- Do not use **renamecomputer** to rename Windows Server 2003 or Windows 2000 domain controllers. Using the **renamecomputer** operation to rename a domain controller may result in the domain controller no longer functioning as a domain controller on the network. To rename Windows Server 2003 and Windows 2000 servers and domain controllers, use the **computername** operation.

**NetDom reset**
Resets the secure connection between a workstation and a domain controller.

**Syntax**

**NetDom reset** *Computer* {**/d: | /domain:**}*Domain* [{**/s: | /server:**}*Server*] [{**/uo: | /usero:**}*User* {**/po: | /passwordo**}{*Password*|*}] [{**/help | /?**}]

**Parameters**

***Computer***
Specifies the name of the computer for which the connection is to be reset.

**{/d: | /domain:}*Domain***
Specifies the domain with which to establish the secure connection. If this parameter is omitted, then the domain that the current computer belongs to is used.

**{/s: | /server:}*Server***
Specifies the name of the domain controller to use to establish the secure connection.

**{/uo: | /usero:}*User***
Specifies the user account that makes the connection with the computer to be reset. If this parameter is omitted, then the current user account is used.

**{/po: | /passwordo}{*Password*|*}**
Specifies the password of the user account that is specified in the **/uo** or **/usero** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/help | /?}**
Displays command-line usage for the **reset** operation.

**Sample Usage**

```
netdom reset /d:reskit.ms.com redmond
```

**NetDom resetpwd**
Resets the machine account password for a Domain Controller.

**Syntax**

**NetDom resetpwd** {**/s: | /server:**}*Server* {**/ud: | /userd:**}[*Domain*\]*User* {**/pd: | /passwordd:**}{*Password*|*}] [{**/help | /?**}]

**Parameters**

**{/s: | /server:}*Server***
Specifies the name of the domain controller to use for setting the machine account password.

**{/ud: | /userd:}[*Domain*\]*User***
Specifies the user account that makes the connection with the domain specified in the **/s** parameter. This must be in *Domain**User* format. If this parameter is omitted, then the current user account is used.

**{/pd: | /passwordd:}{*Password*|*}**
Specifies the password of the user account that is specified in the **/ud** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/help | /?}**
Displays command-line usage for the **resetpwd** operation.

**NetDom trust**
Establishes, verifies, or resets a trust relationship between domains.

**Syntax**

**NetDom trust** *TrustingDomainName* {**/d: | /domain:**} *TrustedDomainName* [{**/ud: | /userd:**}[*Domain*\]*User* [{**/pd: | /passwordd:**}{*Password*|*}] [{**/uo: | /usero:**}*User*] [{**/po: | /passwordo:**} {*Password*|*}] [**/verify**] [**/reset**] [**/passwordt:***NewRealmTrustPassword*] [**/add** [**/realm**]] [**/remove** [**/force**]] [**/twoway**] [**/kerberos**] [**/transitive**[**:**{**YES**|**NO**}]] [**/oneside:**{**TRUSTED** | **TRUSTING**}] [**/force**] [**/**
[**/togglesuffix:**#]] [**/EnableSIDHistory**] [**/ForestTRANsitive**] [**/SelectiveAUTH**][**/AddTLN**][**/AddTLNEX**][**/RemoveTLN**] [**/RemoveTLNEX**][{**/help | /?**}]

**Parameters**

***TrustingDomainName***
Specifies the name of the trusting domain.

**{/d: | /domain:}*TrustedDomainName***
Specifies the name of the trusted domain. If this parameter is omitted, then the domain that the current computer belongs to is used.

**{/ud: | /userd:}[*Domain*\]*User*]**
Specifies the user account that makes the connection with the domain specified in the **/d** or **/domain** parameter. If this parameter is omitted, then the current user account is used.

**/pd:{*Password*|*}**
Specifies the password of the user account that is specified in the **/ud** or **/userd:** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/uo: | /usero:}*User***
Specifies the user account that makes the connection with the trusting domain. If this parameter is omitted, then the current user account is used.

**{/po: | /passwordo:}{ *Password*|*}**
Specifies the password of the user account that is specified in the **/uo** or **/usero** parameter. Use the wildcard character (*****) to be prompted for the password.

**/verify**
Verifies the secure channel secrets upon which a specific trust is based.

**/reset**
Resets the trust secret between trusted domains or between the domain controller and the workstation.

**/passwordt: *NewRealmTrustPassword***
Specifies a new trust password. This parameter is valid only with the **/add** parameter, and only if one of the domains specified is a non-Windows Kerberos realm. The trust password is set on the Windows domain only, which means that credentials are not needed for the non-Windows domain.

**/add**
Specifies to create a trust.

**/realm**
Indicates that the trust is created to a non-Windows Kerberos realm. The **/realm** parameter is valid only with the **/add** and **/passwordt** parameters.

**/remove**
Specifies to break a trust.

**/force**
Removes both the trusted domain object and the cross-reference object for the specified domain from the forest. Use this option to clean up decommissioned domains that are no longer in use, and cannot be removed by using the Active Directory Installation wizard. This problem can occur if the domain controller for that domain was disabled or damaged and there were no domain controllers, or if it was not possible to recover the domain controller from backup media. This parameter is valid only when the **/remove** parameter is specified.

**/twoway**
Specifies establishment ofa two-way trust relationship rather than a one-way trust relationship.

**/kerberos**
Specifies exercisingthe Kerberos protocol between a workstation and a target domain. This parameter is valid only when the **/verify** parameter is specified.

**/transitive[:{YES|NO}]**
Specifies whether to set a transitive or non-transitive trust. This parameter is valid only for a non-Windows Kerberos realm. Non-Windows Kerberos trusts are created as non-transitive. If no value is specified, then the current transitivity state is displayed.

| Value | Description |
|---|---|
| **YES** | Sets the realm to a transitive trust. |
| **NO** | Sets the realm to a non-transitive trust. |

**/oneside:{TRUSTED| TRUSTING}**
Denotes that the trust object should only be created or removed on one domain.

| Value | Description |
|---|---|
| **TRUSTED** | Indicates that the trust object is created or removed on the trusted domain specified by the **/d** or **/domain** parameter). |
| **TRUSTING** | Indicates that the trust object is to be created or removed on the trusting domain. Valid only with the **/add** or /REMove parameter. The **/passwordt** parameter is required when using with the /ADD or /REMove option |

**/quarantine[:{YES | NO}]**
Sets or clears the domain quarantine attribute. If no value is specified then the current quarantine state is displayed.

| Value | Description |
|---|---|
| **YES** | Specifies that only SIDs from the directly trusted domain will be accepted for authorization data returned during authentication. SIDS from any other domains will be removed. |
| **NO** | Specifies that any SID will be accepted for authorization data returned during authentication. This is the default value. |

**/namesuffixes: *TrustName***
Lists the routed name suffixes for *TrustName* on the domain named by *TrustingDomainName*. The **/usero** and **/passwordo** parameters can be used for authentication. The **/domain** parameter is not required.

**/togglesuffix:#**
Changes the status of a name suffix. Used with the **/namesuffixes** parameter. The number of the name entry specified by the **/namesuffixes** parameter must be provided to indicate which name will have its status changed. Names that are in conflict cannot have their status changed until the name in the conflicting trust is disabled. Always precede this command with the **/namesuffixes** parameter because LSA will not always return the names in the same order.

**/EnableSIDistory**
Specifying yes allows users who migrate to the trusted forest from any other forest to use SID history to access resources in this forest. Valid only for an outbound forest trust. This should be done only if the trusted forest administrators can be trusted enough to specify SIDs of this forest in the SID history attribute of their users appropriately. Specifying no would disable the ability of the migrated users in the trusted forest to use SID history to access resources in this forest. Specifying /EnableSIDHistory without yes or no will display the current state.

**/ForestTRANsitive**
Specifying yes marks this trust as forest transitive. Specifying no marks this trust as not forest transitive. Specifying **/ForestTRANsitive** without yes or no will display the current state of this trust attribute. Valid only for non-Windows real trusts and can only be performed on the root domain for a forest.

**/SelectiveAUTH**
Specifying no disables selective authentification across this trust. Specifying **/SelectiveAUTH** without yes or no displays the currrent state of this trust attribute. Specifying yes enables selective authentification across this trust. Valid only on outbound forest and external trusts.

**/AddTLN**
Adds the specified top level name (DNS name suffix) to the forest trust info for the specified trust. Valid only for a forest transitive non-Windows realm trust and can only be performed on the root domain for a forest. Refer to the **/NameSuffixes** operation for a list of name suffixes.

**/AddTLNEX**
Adds the specified top level name exclusion(DNS name suffix) to the forest trust info for the specified trust. Valid only for a forest transitive non-Windows realm trust and can only be performed on the root domain for a forest. Refer to the **/NameSuffixes** operation for a list of name suffixes.

**/RemoveTLN**
Removes the specified top level name (DNS name suffix) from the forest trust info from the specified trust. Valid only for a forest transitive non-Windows realm trust and can only be performed on the root domain for a forest. Refer to the **/NameSuffixes** operation for a list of name suffixes.

**/RemoveTLNEX**
Removes the specified top level name exclusion (DNS Name Suffix) from the forest trust info from the specified trust. Valid only for a forest transitive non-Windows realm trust and can only be performed on the root domain for a forest. Refer to the **/NameSuffixes** operation for a list of name suffixes.

**{/help | /?}**

Displays command-line usage for the **trust** operation.

**Sample Usage**

```
netdom trust /d:masterdom resourcedom
```

**NetDom verify**

Verifies the secure connection between a workstation and a domain controller.

**Syntax**

▸ **NetDom verify** *Computer* {**/d: | /domain:**}*Domain* [{**/uo: | usero**}*User* {**/po: | /passwordo**}{*Password*|*}] [{**/help | /?**}]

**Parameters**

***Computer***

Specifies the name of the computer whose secure connection is verified.

**{/d: | /domain:}*Domain***

Specifies the domain with which to verify the secure connection. If this parameter is omitted, then the domain that the current computer belongs to is used.

**{/uo: | usero}*User***

Specifies the domain with which to verify the secure connection. If this parameter is omitted, then the current user account is used.

**{/po: | /passwordo}{*Password*|*}**

Specifies the password of the user account that is specified in the **/uo** or **/usero** parameter. Use the wildcard character (*****) to be prompted for the password.

**{/help | /?}**

Displays command-line usage for the **verify** operation.

**Sample Usage**

```
netdom verify /d:resourcedom yourwksta
```

# Nltest Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Nltest.exe: NLTest**
This command-line tool helps perform network administrative tasks. You can use NLTest to:

- Get a list of domain controllers.
- Force a remote shutdown.
- Query the status of trust.
- Test trust relationships and the state of domain controller replication in a Windows domain.
- Force a user-account database to synchronize on Windows NT version 4.0 or earlier domain controllers.

NLTest can test and reset the secure channel established by the NetLogon service. This secure channel is established between clients and the domain controller that logs them on. NLTest does not work for clients using Kerberos for authentication since this secure channel is not used with Kerberos.

### Note

- You must run NLTest from the command window.

**Corresponding UI**
There is no corresponding user interface for this tool.

Concepts

A discrete communication channel, known as the secure channel, exists between trusted domains in a Windows NT 4.0 environment and parent domains and their immediate children in an Active Directory environment. In a Windows NT 4.0 environment these channels are also used to authenticate user accounts when a remote user connects to a network resource and the user account exists in a trusted domain. This is called pass-through authentication.

This tool provides diagnostic features that are useful for troubleshooting Windows Server 2003 operating system configurations. However, because this tool has been designed primarily for system administrators and support personnel, its output may be difficult to analyze. In this case, you should review the appropriate troubleshooting sections in the Windows Deployment and Resource Kits. Search for any of the keywords from the bulleted list in the tool description above.

System Requirements

The following are the system requirements for NLTest:

- Windows Server 2003 or Windows XP Professional

**File Required**

- Nltest.exe

# Nltest Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NLTest Examples**

Example 1: Verify DCs in a domain

In this example, the **/dclist** parameter is used to create a list of domain controllers of the domain fourthcoffee.com

```
nltest /dclist:fourthcoffee
```

Output displays similar to the following:

```
Get list of DCs in domain 'ntdev' from '\\fourthcoffee-dc-01'.
    fourthcoffee-dc-01.forthcoffee.com       [DS] Site: Rome
    fourthcoffee-dc-03.forthcoffee.com       [DS] Site: LasVegas
    fourthcoffee-dc-04.forthcoffee.com       [DS] Site: LA
    fourthcoffee-dc-09.forthcoffee.com       [DS] Site: NYC
    fourthcoffee-dc-12.forthcoffee.com       [DS] Site: Paris
    fourthcoffee-dc-24.forthcoffee.com       [DS] Site: Chattaroy
    fourthcoffee-dc-32.forthcoffee.com       [DS] Site: Haifa
    fourthcoffee-dc-99.forthcoffee.com       [DS] Site: Redmond
    fourthcoffee-dc-63.forthcoffee.com [PDC] [DS] Site: London
The command completed successfully
```

Example 2: Advanced information about users

In this example, you want to find out detailed information about a certain user. At the command prompt, type:

```
nltest /user:"TestAdmin"
```

Output displays similar to the following:

```
User: User1
Rid: 0x3eb
Version: 0x10002
LastLogon: 2ee61c9a 01c0e947 = 5/30/2001 13:29:10
PasswordLastSet: 9dad5428 01c0e577 = 5/25/2001 17:05:47
AccountExpires: ffffffff 7fffffff = 9/13/30828 19:48:05
PrimaryGroupId: 0x201
UserAccountControl: 0x210
CountryCode: 0x0
CodePage: 0x0
BadPasswordCount: 0x0
LogonCount: 0x33
AdminCount: 0x1
SecurityDescriptor: 80140001 0000009c 000000ac 00000014 00000044 00300002 000000
02 0014c002 01050045 00000101 01000000 00000000 0014c002 000f07ff 00000101 05000
000 00000007 00580012 00000003 00240000 00020044 00000501 05000000 00000015 22cd
b7b4 7112b3f1 2b3be507 000003eb 00180000 000f07ff 00000201 05000000 00000020 000
00220 00140000 0002035b 00000101 01000000 00000000 00000201 05000000 00000020 00
000220 00000201 05000000 00000020 00000220
AccountName: User1
Groups: 00000201 00000007
LmOwfPassword: fb890c9c 5c7e7e09 ee58593b d959c681
NtOwfPassword: d82759cc 81a342ac df600c37 4e58a478
NtPasswordHistory: 00011001
LmPasswordHistory: 00010011
The command completed successfully
```

The detailed information provided can be used to troubleshoot many issues.

Example 3: Verify trust relationship with a specific server

In this example, you want to verify that the server a-dc1 has a valid trust relationship with the domain. At the command prompt, type:

```
nltest.exe /server:fourthcoffee-dc-01 /sc_query:fourthcoffee
```

Output displays similar to the following:

```
Flags: 30 HAS_IP  HAS_TIMESERV
Trusted DC Name \\fourthcoffee-dc-01.forthcoffee.com
Trusted DC Connection Status Status = 0 0x0 NERR_Success
The command completed successfully
```

Example 4: Determine the PDC emulator for a domain

In this example, you want to determine which DC in your domain the Windows NT 4.0–based computers are looking to as the PDC. At the command prompt, type:

```
nltest /dcname:fourthcoffee
```

Output displays similar to the following:

```
PDC for Domain fourthcoffee is \\fourthcoffee-dc-01
The command completed successfully
```

You can see that a-dcp is the PDC emulator for your domain.

Example 5: Show trust relationships for a domain

In this example, you want to view the established trust relationships for your domain. At the command prompt, type:

```
nltest /domain_trusts
```

Output displays similar to the following:

```
List of domain trusts:
    0: forthcoffee forthcoffee.com (NT 5) (Forest Tree Root) (Primary Domain)
The command completed successfully
```

This example shows that one domain is trusting itself and no others.

# Nltest Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NLTest Syntax**

NLTest uses the following syntax:

- **nltest** [**/server:***servername*] [*operation*[*parameter*] ...

**/server: *ServerName***

Runs NLTest at the specified remote domain controller. If this parameter is not specified, the command is executed on the local computer (domain controller).

**Operations**

**/query**

Reports on the state of the secure channel the last time it was used. This is the secure channel established by the NetLogon service.

**/repl**

Forces a synchronization with the PDC. Only changes not yet replicated to the BDC are synchronized. This command is for NT 4.0 BDCs only and is not for Active Directory replication. Administrative rights are required to perform this command.

**/sync**

Forces an immediate synchronization with the PDC of the entire SAM database. This command is for NT 4.0 BDCs only and is not for Active Directory replication. Administrative rights are required to perform this command.

**/pdc_repl**

Forces the PDC to send a synchronize notification to all BDCs. This command is for NT 4.0 PDCs only and is not for Active Directory replication. Administrative rights are required to perform this command.

**/sc_query: *DomainName***

Reports on the state of the secure channel the last time it was used. This is the secure channel established by the NetLogon service. Also, lists the name of the domain controller that was queried on the secure channel.

**/sc_reset:[ *DomainName*]**

Removes and then rebuilds the secure channel established by the NetLogon service. Administrative rights are required to perform this command.

**/sc_verify:[ *DomainName*]**

Checks the status of the secure channel established by the NetLogon service. If the secure channel is not working, this operation removes the existing channel and builds a new one. Administrative rights are required to perform this command. This operation is only valid on Windows 2000 with Service Pack 2 and Windows Server 2003 domain controllers.

**/sc_change_pwd:[ *DomainName*]**

Changes the password for the trust account of the specified domain. If this command is run on a domain controller, and an explicit trust relationship exists, then the password for the interdomain trust account is reset. Otherwise, the computer account password for the specified domain is changed. This command is only for computers that are Windows 2000, Windows XP, and Windows Server 2003.

**/dclist:[ *DomainName*]**

Lists all domain controllers in the domain. In an NT 4.0 domain environment, this command uses the Browser service to retrieve the list of domains. In an Active Directory environment, this command first queries Active Directory for a list of domain controllers. If this is unsuccessful the Browser service is used.

**/dcname:[ *DomainName*]**

Lists the primary domain controller or the primary domain controller emulator for *DomainName*.

**/dsgetdc:[ *DomainName*]**

Queries the DNS server for a list of domain controllers and their corresponding IP addresses. Contacts each domain controller to check for connectivity.

Use the following flags to filter the list of domain controllers or specify alternate names types in the syntax.

- **/PDC** Returns only the PDC (NT 4.0) or domain controller designated as the PDC emulator (Windows 2000 or Windows Server 2003).
- **/DS** Returns only those domain controllers that are Windows 2000 or Windows Server 2003 servers.
- **/DSP** Requests that Windows 2000 or Windows Server 2003 domain controllers be returned. If no Windows 2000 or Windows Server 2003 server is found, then this operation returns NT domain controllers.
- **/GC** Returns only those domain controllers designated as Global Catalog servers.
- **/KDC** Returns only those domain controllers designated as Kerberos key distribution centers.
- **/TIMESERV** Returns only those domain controllers designated as time servers.
- **/GTTIMESERV** Returns only those domain controllers designated as master time servers.
- **/NetBIOS** Use this command when specifying computer names in the syntax as NetBIOS names.
- **/DNS** Use this command when specifying computer names in the syntax as FQDNs.
- **/IP** Returns only domain controllers that have IP addresses. Domain controllers not using TCP/IP as their protocol stack are not returned.
- **/FORCE** Forces the computer to run the command against the DNS server instead of looking in cache for the information.

**/dnsgetdc: *DomainName***

Queries the DNS server for a list of domain controllers and their corresponding IP addresses.

Use the following flags to filter the list of domain controllers.

- **/PDC** Returns only only those domain controllers that are PDCs (NT 4.0) or designated as PDC emulators.
- **/GC** Returns only those domain controllers designated as Global Catalogs.
- **/KDC** Returns only those domain controllers designated as Kerberos key distribution centers.
- **/WRITABLE** Returns only those domain controllers that can accept changes to the directory database. All Active Directory domain controllers will be returned. Only NT 4.0 BDCs will not be returned with this command.
- **/LDAPONLY** Returns servers that are running an LDAP application. With this command LDAP servers are returned that are not necessarily DCs.
- **/FORCE** Forces the computer to run the command against the DNS server instead of looking in cache for the information.
- **/SITE:***Sitename* Sorts the returned records so that the ones pertaining to the site are listed first.
- **/SITESPEC** Filters the returned records so only those pertaining to the site are displayed. This operation can only be used with the **/SITE** operation.

**/dsgetfti: *DomainName*[ /UpdateTDO]**

Returns information about interforests trust(s). This operation is only for a Windows Server 2003 domain controller that is in the root of the forest. If no interforest trusts exist, this operation will return an error.

**/UpdateTDO** Updates the locally stored information on the interforest trust.

**/dsgetsite**
Returns the name of the site in which the domain controller resides.

**/dsgetsitecov**
Returns the name of the site that the domain controller covers. A domain controller can cover a site that has no local domain controller of its own.

**/parentdomain**
Returns the name of the parent domain of the server.

**/dsregdns**
Refreshes the registration of all domain controller-specific DNS records.

**/dsderegdns: *DnsHostName***
Deregisters DNS host records from DNS for the host specified with the *DnsHostName* parameter./DOM: /DOMGUID: /DSAGUID:.

Use the following flags to specify which records will be deregistered.

- **/DOM:** Specifies a DNS domain name for the host to use when searching for records in the DNS server. If not specified, the suffix of the DnsHostName is assumed to be the DNS domain name
- **/DOMGUID:** Deletes DNS records that are GUID based.
- **/DSAGUID** Deletes DSA records that are GUID based.

**/whowill: *Domain/ User***
Finds the domain controller that has the specified user account. Use this command to determine whether the account information has been replicated to other domain controllers.

**/finduser: *User***
Finds which directly trusted domain to which the specified user account belongs. Use this operation to troubleshoot logon issues of older client operating systems.

**/transport_notify**
Flushes the negative cache to force the discovery of a domain controller. Use this operation on NT 4.0 domain controllers only. This operation is done automatically when clients log on to Windows 2000 and Windows Server 2003 domain controllers.

**/dbflag: *HexadecimalFlags***
Sets a new debug flag. For most purposes, use 0x2000FFFF as the value for *HexadecimalFlags*. The entry in the Windows Server 2003registry for debug flags is HKLM\System\CurrentControlSet\Services\Netlogon\Parameters\DBFlag.

**/user: *UserName***
Displays many of the attributes for the specified user account that are maintained in the SAM account database. This operation will not work for user accounts stored in Active Directory.

**/time: *HexadecimalLSL HexadecimalMSL***
Converts Windows NT GMT time to ASCII. *HexadecimalLSL* is a hexadecimal value for least significant longword. *HexadecimalMSL* is a hexadecimal value for most significant longword.

**/logon_query**
Queries the cumulative number of NTLM logon attempts at the console or over the network.

**/domain_trusts**
Returns a list of trusted domains. /Primary /Forest /Direct_Out /Direct_In /All_Trusts /v.

Use the following flags to filter the list of domains.

- **/Primary** Returns only the domain to which the computer account belongs.
- **/Forest** Returns only those domains that are in the same forest as the primary domain.
- **/Direct_Out** Returns only the domains that are explicitly trusted with the primary domain.

- **/Direct_In** Returns only the domains that explicitly trust the primary domain.
- **/All_Trusts Returns all trusted domains.**
- **/v** Displays verbose output including domain SIDs and GUIDs if available.

**/dsquerydns**
Queries for the status of the last update for all DC-specific DNS records.

**/bdc_query: *DomainName***
Queries for a list of backup domain controllers in *DomainName* and displays their state of synchronization and replication status. This operation is only for NT 4.0 domain controllers.

**/sim_sync: *DomainName ServerName***
Simulates full synchronization replication. This operation is useful in test environments.

**/list_deltas: *FileName***
Displays the contents of the change log file *FileName*, which lists changes to the user account database. Netlogon.chg is the default name. This log file resides only on NT 4.0 BDCs.

**/cdigest: *Message* /domain: *DomainName***
Displays the current digest (calculation derived from the password) used by the client for the secure channel. Also, displays the digest based on the previous password. The secure channel is used for logons between client computers and a domain controller, or DC to DC for directory service replication. Use this operation in conjunction with the **/sdigest** operation to check trust account password synchronization.

**/sdigest: *Message* /rid: *RID_In_Hexadecimal***
Displays the current digest (calculation derived from the password) that the server is using for the secure channel. Also, displays the digest for the previous password. If the digest from the server matches the digest from the client (retrieved using the **/cdigest** operation), then the passwords used for the secure channel are synchronized. If the digests do not match, then a password change may not have replicated yet.

**/shutdown: *Reason*[ *Seconds*]**
Performs a remote shutdown of the *ServerName* for *Reason*, a string, after *Seconds*, an integer. For a complete description, see the Platform SDK documentation for **InitiateSystemShutdown**.

**/shutdown_abort**
Terminates a system shutdown.

# Portqry Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Portqry.exe: Port Query**
This command-line tool reports the status of TCP and UDP ports on a target computer. PortQry is used to troubleshoot TCP/IP connectivity issues. It provides an additional level of detail on port status not provided by other port scanning tools. You can use PortQry to query a single port, an ordered list of ports, or a sequential range of ports.

Note

- PortQry is a troubleshooting tool, not a security assessment tool.

**Concepts**
A TCP or UDP port is a mechanism that allows multiple sessions to use one IP address.

Port scanning tools search for and identify processes engaged at the port level. These processes may originate from, for example, operating system services such as DNS or WINS, or third-party applications or services. Generally, port scanning tools report only whether a port is busy or not, that is, whether there is a process on it. PortQry provides specific status information by analyzing the response from a process on a target port.

See the appendix from the Windows Server 2003 Internetworking Guide for information on TCP and UDP Ports and Protocol Numbers.

**System Requirements**

- Windows 2000, Windows XP, or Windows Server 2003
- A TCP/IP network connection

**File Required**

- Portqry.exe

# Portqry Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PortQry Remarks**

**Special Features**
PortQry improves on typical port scanning utilities by giving additional UDP-port status detail, and by providing protocol-specific support.

Determining the status of UDP ports depends on a response from the process that is listening on each UDP port. If an unformatted zero-length or fixed-length message is sent to a target UDP port, the port may not respond.

If the target port does respond, it is characterized as listening. If an "ICMP destination unreachable" message is returned from the port, the port is characterized as not listening. However, some port scanning utilities report that the port is listening simply if an "ICMP destination unreachable" message is *not* returned from a target port. This may, in fact, be inaccurate, because no response to a directed datagram may also indicate that the target port is being *filtered*. Usually only a properly-formatted message using the session layer or application layer protocol that the listening service or application understands, elicits a response from the target port.

When you are troubleshooting a connectivity problem, especially in an environment with firewalls, it is useful to know whether a port is first being filtered, or if it is actually listening. PortQry pinpoints this distinction on selected ports.

If there is no response from a target UDP port, PortQry reports that the port is "Listening or Filtered." Then, PortQry sends a properly-formatted message, using the session layer or application layer protocol that the listening service or application understands, to determine if the port is in fact listening.

PortQry supports the following session/application layer protocols

**NetBIOS Name Service**
By default, this service listens on UDP port 137. If PortQry receives no response from port 137, it reports that the port is "Listening or Filtered," and then determines whether the port is actually listening. If NetBIOS is available on the computer that is running PortQry, PortQry sends a NetBIOS adapter status query to the target computer. If the target computer responds to the query, PortQry reports the port status as Listening and returns the target computer's Media Access Control (MAC) address to the user.

**DNS**
PortQry can also send a properly formatted DNS query, by using UDP and TCP. PortQry first sends a DNS query, then waits for a response from the server. Whether the DNS response to the query is negative or positive is irrelevant, because any response indicates to PortQry that the port is listening.

**RPC**
PortQry can send a query to the RPC endpoint mapper (by using UDP and TCP) and interpret the response. This query dumps all of the endpoints that are currently registered with the RPC endpoint mapper. The response from the endpoint mapper is parsed, formatted, and returned to the user. Portqry Examples.

**LDAP**
PortQry can send an LDAP query (by using UDP and TCP) and interpret an LDAP server's response to the query. The response from the LDAP server is parsed, formatted, and returned to the user.

To query LDAP, PortQry automatically resolves UDP port 389 by using the %SystemRoot%\System32\Drivers\Etc\Services file that every Windows Server 2003, Windows XP, and Windows 2000-based computer has by default. If PortQry resolves the port to the LDAP service, it sends an unformatted user datagram to UDP port 389 on the target computer. However, PortQry does not receive a response from the port because the LDAP service responds only to a properly-formatted LDAP query. So, again, PortQry initially reports that the port is "Listening or Filtered."

PortQry then sends a properly-formatted LDAP query to UDP port 389. If PortQry receives a response to this query, it returns the entire response to the user, and reports that the port is Listening. If PortQry does not receive a response to the query, it reports that the port is Filtered. Portqry Examples.

**Port Status Reporting**
PortQry characterizes port status as one of the following three states:

- **Listening**

  A process is listening on the target port. PortQry received a response from the port.

- **Not Listening**

  No process is listening on the target port. PortQry received an Internet Control Message Protocol (ICMP) "Destination Unreachable - Port Unreachable" message back from the target UDP port. Or, if the target port is a TCP port, PortQry received a TCP Acknowledgement packet with the Reset flag set.

- **Filtered**

  The target port on the target computer is being filtered. PortQry dides not receive a response from the target port. A process may or may not be listening on the port. By default, TCP ports are queried three times; UDP ports are queried once before reporting that the target port is Filtered.

While PortQry supports querying a range of ports, its performance has not been optimized for security assessment. In particular, querying large ranges of TCP ports can be time-consuming and is not recommended.

**PortQry Errorlevels**
When using the **/q** parameter with PortQry from within a batch file, PortQry returns errorlevels based on the status of the target port. PortQry returns an errorlevel 0 if the port is Listening, 1 if the port is Not Listening, and 2 if the port is Listening or Filtered.

**The Services File**
In order to send protocol-specific queries, PortQry must first determine what protocol to use. On computers running Windows 2000 or later, this information is stored in the Services file, located in the %SystemRoot%\system32\drivers\etc directory. PortQry also uses the Services file to resolve the port name.

**Using PortQry in a Batch File**
You can use the **/q** parameter when running PortQry from a batch file, to report errorlevels based the status of the target port. PortQry returns an errorlevel 0 if the port is listening, 1 if the port is not listening, and 2 if the port is listening or filtered.

**Querying Filtered TCP Ports**
PortQry was developed as a trouble-shooting tool, rather than a security assessment tool. While PortQry supports querying a range of ports (by using the **/r** parameter), its performance has not been optimized to handle querying large ranges of TCP ports that may be filtered.

# Portqry Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PortQry Examples**

**Example 1: PortQry Default Behavior**

To see the results of PortQry executed in its simplest form, type:

```
portqry /n 10.193.36.210
```

This command instructs PortQry to query TCP port 80, and determine whether it is listening on the target host (in this case 10.193.36.210).

PortQry displays results similar to the following output:

```
Querying target system called:

 10.193.36.210

Attempting to resolve IP address to a name...

IP address resolved to MYSERVER

TCP port 80 (http service): LISTENING
```

**Example 2: Querying RPC Ports**

To see the results of PortQry executed on an RPC port, type:

```
portqry /n 10.193.36.210 /p udp /e 135
```

PortQry displays results similar to the following output:

```
Querying target system called:

 10.193.36.210

Attempting to resolve IP address to a name...

IP address resolved to RKTLABDC2

UDP port 135 (epmap service): LISTENING or FILTERED
Querying Endpoint Mapper Database...
Server's response:

UUID: a00c021c-2be2-11d2-b678-0000f87a8f8e PERFMON SERVICE
ncacn_np:\\\\RKTLABDC2[\\pipe\\000003b8.000]

...

UUID: d049b186-814f-11d1-9a3c-00c04fc9b232 NtFrs API
ncacn_np:\\\\RKTLABDC2[\\pipe\\000003b8.000]

Total endpoints found: 69

==== End of RPC Endpoint Mapper query response ====

UDP port 135 is LISTENING
```

**Example 3: Querying an LDAP Port**
To see the results of PortQry executed on an LDAP port, type:

```
portqry /n 10.193.36.210 /p udp /e 389
```

For more information on how PortQry works on an LDAP port, see Portqry Remarks.

PortQry displays results similar to the following output:

```
Querying target system called:

 10.193.36.210

Attempting to resolve IP address to a name...

IP address resolved to RKTLABDC2

UDP port 389 (unknown service): LISTENING or FILTERED

Sending LDAP query to UDP port 389...

LDAP query response:

# Portqry Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Portqry Syntax**

PortQry uses the following syntax:

- **portqry** /**n** name [/**p** protocol] [/**e** || /**r** || /**o** endpoint(s)] [/**l** logfile] [/**s**] [/**q**] [/**i**]

**Parameters**

**/n name**

A required parameter used to specify the target system by host name or IP address. No embedded spaces are allowed in either. If PortQry attempts to resolve an IP address from a host name and cannot, then it reports an error and quits. If PortQry attempts to resolve a host name from an IP address and cannot, then it reports an error, but continues processing.

**/p *protocol***

An optional parameter that specifies the type of port or protocol used to connect to the target port. Valid entries for protocol are *tcp*, *udp*, or *both*. The default is TCP. If you set the option to BOTH, you must also specify the port number by using the **/e** parameter. PortQry then sends queries to both the TCP and UDP port specified by the **/e** parameter.

**/e *port***

An optional parameter. Use **/e** to query a single port within the valid range of 1-65535. The **/e** parameter cannot be used with **/r** or **/o**.

**/r *start port:end port***

An optional parameter. Use **/r** to specify a range of port numbers to be queried in sequential order within the valid range of 1-65535. No spaces are allowed between the port numbers and the colon. The **/r** parameter cannot be used with **/o** or **/e**.

**/o *port,port,port...***

An optional parameter. Use **/o** to query a series of port(s) in a specific order (not sequential), within the valid range of 1-65535. No spaces are allowed between port numbers and commas. The **/o** parameter cannot be used with **/r** or **/e**.

**/l *filename***

An optional parameter. Use **/l** to copy the PortQry output to a text (log) file in the directory where you are running PortQry. Filename is the name (with extension) of the log file. If a log file with the same name already exists, PortQry prompts you to specify whether you want the existing file overwritten.

**/s**

An optional parameter. Use **/s** to request that Portqry wait longer for responses to UDP queries.

**/q**

An optional parameter. Use **/q** to suppress all output to the screen other than error messages. The **/q** parameter can be used with **/e**, but not with **/o**, **/r**, or **/p** with the BOTH option. For more information about errorlevel reporting, see Portqry Remarks.

**/i**

Bypasses default IP address-to-host-name lookup. This parameter is ignored unless an IP address is specified using the /**n** parameter. When an IP address is specified using /**n**, PortQry attempts to resolve the IP address to a host name. This process can be time consuming, particularly if the IP address cannot be successfully resolved. Specifying /**i** in this case allows you to bypass the default lookup, and instead, query the target port(s) immediately.

# Performance Monitoring Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Monitoring and Status Tools**
Tools in this category are used to manage the following Windows features:

- Device Manager
- Event Viewer
- Network monitoring
- Performance
- SNMP

**Notes**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Exctrlst Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Exctrlst.exe: Extensible Performance Counter List**
This GUI tool lists all services and applications that provide registry-based performance counters on local and remote Windows 2000, Windows XP Professional, and Windows Server 2003 systems. It displays the names and locations of the dynamic link libraries (DLLs) that support performance counters, indicates disabled counters, and lets you enable and disable the performance counters for a service.

Unlike most performance tools, which load performance counters in order to collect data, Exctrlst displays information directly from the Performance subkeys in the registry (HKLM\SYSTEM\CurrentControlSet\Services*ServiceName*\Performance). As a result, Exctrlst lists all registered performance DLLs, even those that do not load or operate properly.

Performance counter developers can use this tool to find the DLLs, basic functions, and indexes of performance counters provided by a service. Administrators can use this tool to determine which services have installed performance counters on the system and to identify counters that are disabled or do not load properly.

Exctrlst displays the following information about performance counters:

- Services and applications that provide performance counters
- Names and locations of performance counter DLLs
- Enabled and disabled performance counters
- Indexes of performance objects, counter names, and help text provided by the service
- Names of the open, collect, and close procedure of each counter DLL
- The highest index on the system used for performance counters and their help text.

**Corresponding UI**
Exctrlst provides its own user interface.

**Concepts**
Windows collects data about system resources, such as disks, memory, processors, and network components. In addition, applications and services that you might be running on your system can also perform data collection. By default, the operating system obtains performance data for system resources using the registry.

When you use performance tools to access registry functions for performance data, the system collects the data from the appropriate system object managers, such as the Memory Manager, the input/output (I/O) subsystem, and so forth.

**System Requirements**
The following are the system requirements for Exctrlst:

- Windows Server 2003 or Windows XP Professional

**For More Information**
For information about counter types and for descriptions of the performance counters installed on Windows Server 2003, see the Performance Counters Reference of the Windows Server 2003 Resource Kit.

For information about the run-time reliability tests for performance counters, and to customize the tests for your system, search for "Configuration Flags" in the Registry Reference of the Windows Server 2003 Resource Kit.

For instructions on writing performance counter DLLs and loading performance counter data in the registry, see Adding Performance Counters in the Platform Software Development Kit (SDK).

For a list of performance counters that load and operate correctly, use Typeperf, System Monitor, or Showperf.

To see a graphic display of performance counter data, use System Monitor. To run System Monitor, at the command prompt or in the **Run** dialog box, type **Perfmon**.

To list the performance counters on a local or remote system from the command line, use Typeperf, a tool included in Windows XP Professional and Windows Server 2003. Typeperf lists only the counters that are enabled and load and operate properly. For more information about Typeperf, see "Typeperf" in Help for Windows Server 2003.

**File Required**

- Exctrlst.exe

# Exctrlst Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Exctrlst Remarks**

**Exctrlst Data Source**

Exctrlst displays data directly from the Performance subkeys in the registry (HKLM\SYSTEM\CurrentControlSet\Services*ServiceName*\Performance). A Performance subkey is created when a service, application, or device registers a performance DLL.

Exctrlst provides a complete list of all performance counter DLLs registered on the system, including counter DLLs that do not load or operate properly, and disabled counter DLLs. Exctrlst is often used with tools that attempt to load and run the performance counters, such as Typeperf or System Monitor. By comparing the list of all counter DLLs in Exctrlst with the list of operating counter DLLs in System Monitor or Typeperf, you can detect counters that are not loading or operating properly. Typeperf is especially useful because it lists counters in the order in which they load (alphabetical order by service name), making it easier to detect which counter failed to load.

**Extensible Performance Counters**

In Windows NT and earlier systems, Exctrlst only displayed information about *extensible* performance counters, that is, custom counters that are not built into the operating system. However, in Windows 2000, Windows XP Professional, and Windows Server 2003, system counters and extensible counters are loaded and stored in the registry in the same way, and Exctrlst displays both types.

**Performance Counters for a Service**

Each performance counter DLL can support counters for one or more components and services. In the registry and, therefore, in Exctrlst, each DLL is listed in the subkey of the service that installed it.

**System Counters**

*System counters* are the performance counters that are built into the operating system. These counters appear in Exctrlst. You can use Exctrlst to enable and disable the system counters. However, because system counter names and explain text are not stored and accessed through the registry, their indexes appear as 0x0 or N/A in Exctrlst.

In Windows XP Professional and Windows Server 2003, system counters are defined in the following libraries and drivers:

| Service | Library | Objects |
|---|---|---|
| PerfOS | PerfOs.dll | Cache, Memory, Object, Paging File, Processor, System |
| PerfDisk | PerfDisk.dll | LogicalDisk, PhysicalDisk |
| PerfNet | PerfNet.dll | Browser, Redirector, Server |
| PerfProc | PerfProc.dll | Job Object, Job Object Details, Process, Thread, Thread Details |
| Spooler | Winspool.drv | Print Queue |
| TapiSrv | TapiPerf.dll | Telephony |
| Tcpip | Perfctrs.dll | IP, ICMP, NBT Connection, Network Interface, TCP, UDP |

**WMI Performance Counters**

Exctrlst lists all registry-based performance counter DLLs, including counter DLLs that are loaded by using the Windows Management Instrumentation High-Performance provider, Wbemperf.dll. However, because native WMI performance counters do not create Performance subkeys in the registry, Exctrlst cannot display information about these counters.

**Monitoring Remote Computers**

You can use Exctrlst to view the performance counters installed on remote computers. However, you must have permission to read the required files, you must have permission to read from the registry remotely, and the Remote Registry Service must be running on the remote computer. To enable or disable performance counters, you must also have permission to set values in the registry. For detailed instructions on configuring remote permissions, see *Monitoring Remote Computers* in the Windows XP Professional Resource Kit.

If Exctrlst cannot connect to a remote computer (for any reason), then it continues to monitor the computer that was

monitoring before the new computer name was entered. The name in the **Machine Name** box reverts to the name of the previously monitored computer, but Exctrlst does not display an error message.

**Disabled Performance Objects**
You can use Exctrlst to determine whether the performance counters for a service are enabled or disabled, and to enable and disable the performance counters for a service.

The system disables performance counters automatically when the performance counter DLL for a service does not pass the reliability tests that the system runs when it loads a counter in System Monitor or another performance monitoring tool.

Typically, users disable counters during testing or to prevent a malfunctioning counter DLL from loading. After replacing or repairing a counter DLL, you can use Exctrlst to re-enable the counters.

To disable the performance objects for a service, the system adds the **Disable Performance Counters** registry entry to the Performance subkey for the service (HKLM\SYSTEM\CurrentControlSet\Services*ServiceName*\Performance) and sets the value of the entry to 1.

To re-enable performance objects after the DLL is replaced or repaired, use Exctrlst, or set the value of the **Disable Performance Counters** registry entry to 0 or delete the entry.

For more information about the **Disable Performance Counters** registry entry, see the Registry Reference in the Windows XP Professional Resource Kit.

**Tip**
Event Viewer is one of the most valuable tools for diagnosing problems with performance counters. When the system detects a serious error in a performance counter DLL, it disables the counter and records Event 1016 in the Application Log in Event Viewer. If a performance counter does not appear in System Monitor, or if it does not operate properly, check the Application log for events generated by Perflib.

# Exctrlst Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Exctrlst Examples**

**Example 1: Find the performance objects installed on a remote computer**

The following procedure uses Exctrlst to find the performance counter objects installed on a remote computer, RK-USER-16. You can use this procedure to determine whether the performance features are installed correctly on a user's system, and you can use the information as an indirect indication of whether a service is installed on the user's system.

In this case, a user is complaining that he cannot monitor the Terminal Services performance counters. You have verified that the counters do not appear in System Monitor.

1. Start Event Viewer, connect to the RK-USER-16 computer, and search the Application Log for events recorded by Perflib. In this case, none of the events report a problem with the Terminal Services counters.

2. Start Exctrlst.

3. In the **Machine Name** box, type `RK-USER-16`, and then click **Refresh**.

4. In the **Sort Order** section, click **Service**.

The **Extensible Performance Counter** box now lists all of the performance counters installed on the remote computer. In this case, the Terminal Services service, TermService service and its DLL, Perfts.dll, do not appear in the list. This indicates that Terminal Services performance counters are not installed on the user's computer.

Note

- You cannot copy or export a list from Exctrlst. However, you can use the **query** operation of Reg.exe, a command-line tool in %windir%\system32, to list all services that have installed performance counters on a system.

  At the command prompt, type:

  ```
  reg query HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services /v Performance /s > PerfServices.txt
  ```

  This command creates a file called PerfServices.txt with the names of all services that have Performance subkeys in the registry. It also lists occurrences of the **Disable Performance Counters** registry entry and its value.

**Example 2: Find a missing performance object**

The following procedure determines why the performance object for a fictitious service, Reskit, does not appear in System Monitor. This procedure compares performance object lists from Exctrlst and Typeperf, a tool included in Windows XP Professional and Windows Server 2003. Because Typeperf only displays objects that load and run properly, objects that appear in Exctrlst but not in Typeperf are likely to have errors.

1. Check the Application Log in Event Viewer for events recorded by Perflib. When a counter DLL fails the reliability tests of the system or does not install properly, Perflib records errors in the log.

   In this case, there are no events pertaining to the Reskit service.

2. Use Exctrlst to verify that the counter is installed on the system.

   If a counter does not appear in the Exctrlst display, then it is not installed or properly registered in the system. In this case, the Reskit service is listed in Exctrlst, and its performance counter DLL, Reskit.dll, is listed in its proper location.

3. Use Exctrlst to determine whether the counter DLL for the Reskit service is disabled.

   In this case, when you click the Reskit service item, the **Performance Counters Enabled** check box is checked, indicating

that the Reskit service performance DLL passed the run-time reliability tests of the system.

4. Use Typeperf to load and display all properly loading performance counters on the system. Then, look for the **Reskit** performance object in the Typeperf list.

   The following command writes a list of all properly loading performance counters to the C:\Counters.txt file:

   ```
   typeperf -q -o C:\Counters.txt
   ```

   In this case, the Reskit object does not appear in the list. This indicates that the Reskit performance DLL passed the basic reliability tests, but does not load properly in Typeperf. This rare situation occurs when a DLL has a fault that is not evident in basic testing but appears later, such as when the service is stressed by high use or retrieves extreme data values not anticipated in the program design.

Counter DLLs might also be enabled but not load properly in Typeperf because one or more of the run-time reliability tests have been turned off, or because the system is prevented from disabling performance counters that fail its tests. To check for this occurrence, find the value of the **Configuration Flags** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib\Configuration Flags). The default value, which permits the system to disable faulty counters, is 0x10.

For information about the **Configuration Flags** registry entry, search the Registry Reference of the Windows Server 2003 Resource Kit.

**Example 3: Re-enable performance counters**
The following procedure re-enables the performance counter DLL for Reskit, a fictitious service.

To protect the performance monitoring capabilities of the system, the Performance Library (Perflib) tests all performance DLLs when they load and disables performance DLLs that fail its run-time reliability tests. In this case, when the system found that the Reskit performance DLL, Rkperf.dll, generated an exception, it disabled the DLL. The developer repaired Rkperf.dll, but it is still disabled in the system.

The following procedure uses Exctrlst to re-enable the performance counters for the Reskit service:

1. Start Exctrlst.

2. In the **Extensible Performance Counters** list, click the Reskit service.

3. Click to select the **Performance Counters Enabled** check box.

4. Click **Refresh**.

5. Use Typeperf to verify that the counter DLL loads and runs properly.

Typeperf attempts to load and run all installed performance counter DLLs. It lists the performance objects that successfully loaded in the order in which they load (alphabetical order by service name). In this case, the performance objects created by Rkperf.dll appear in Typeperf, indicating that the DLL repair was successful and the Reskit performance objects and counters are enabled and ready for use.

Note

- You cannot copy or export a list of disabled performance DLLs from Exctrlst. However, you can use Regfind, a command-line tool in the Windows 2000 Server Resource Kit, to list all instances of the **Disable Performance Counters** registry entry in the Services subkeys. When the value of this entry is 1, the performance DLL for the service, and the objects and counters it creates, are disabled.

  At the command prompt, type:

  ```
  regfind "Disable Performance Counters" -n -p HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services >
  Disabled.txt
  ```

  This command creates a file called Disabled.txt with the names of all services that have the registry entry. You can then

search the file for entries with a value of 1.

**Example 4: Find the performance objects for a service**
The following procedure comprises one method for determining which performance objects are associated with a service:

1. To list all performance counters that are enabled and operating properly on the system, use Typeperf, a tool included in Windows XP Professional and Windows Server 2003. For information about this tool, see "Typeperf" in Help for Windows Server 2003. At the command prompt, type:

   ```
   typeperf /q > all.txt
   ```

   This command saves the performance counter list in the All.txt file.

2. To disable the performance counters for the service, use Exctrlst.

3. Run Typeperf again. At the command prompt, type:

   ```
   typeperf /q > no_svc.txt
   ```

   This command saves the revised performance counter list in the No_Svc.txt file. This time, the disabled performance counters do not appear in the list.

4. Use a comparison tool, such as Ec, to compare the output from the Typeperf runs. For information about using Ec, see "Ec" in Help for Windows Server 2003. The counters that are missing from the No_Svc.txt file are those associated with the service.

5. Use Exctrlst to re-enable the counters for use.

# Exctrlst UI

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Exctrlst UI**

Exctrlst displays all registry-based performance counters installed on the system.

**Exctrlst dialog box**

**To run Exctrlst**

- At the command prompt or in the **Run** dialog box, type **Exctrlst**.

**To configure Exctrlst**

1. Select a computer.

   The **Machine Name** box displays the name of the computer being monitored. The default is the local computer.

   To monitor a remote computer, delete the name in the **Machine Name** box, type the name of the remote computer (preceded by backslashes), and click **Refresh**.

2. Select a sort order.

   Click a button in the **Sort Order** section to sort the items in the **Extensible Performance Counters** box.

   - **Library File**. Lists the performance DLLs installed on the system and the service that supports each DLL. The list is sorted in alphabetical order by service name.
   - **Service**. Lists the services that have installed performance DLLs and the name and location of the DLL for each service. The list is sorted in alphabetical order by the fully qualified path to the DLL.
   - **Counter ID**. Lists the services that have installed performance DLLs and the starting index for the performance

object installed by the service. The list is sorted in numerical order by index.

This starting index is the location of the performance object in the performance registry (HKEY_PERFORMANCE_DATA). Each object is assigned a range of indices within which it stores the counter names and explain text for the object.

**Note**

Performance objects that the system installs do not store their counter names in the performance registry. The index for these objects appears as 0x0 or N/A.

1. Select a service or DLL.

   The **Extensible Performance Counters** box displays a list of all registry-based performance DLLs on the system.

   Clicking an item in the **Extensible Performance Counters** displays information about the item in the fields below the box.

2. View, select, or clear the **Performance Counters Enabled** check box.

   The **Performance Counters Enabled** check box indicates whether the performance counters for the service are enabled or disabled.

   - To disable all performance counters for a service, clear the check box, and then click **Refresh**.
   - To enable all performance counters for a service, select the check box, and then click **Refresh**.

   The system automatically disables all performance counters for a service if the performance DLL fail the system's run-time reliability tests for performance DLLs. For more information, see Exctrlst Remarks in *Exctrlst Notes*.

**To interpret the Exctrlst display**

The following tables list and describe the fields in the Exctrlst dialog box.

- The system data in the upper section of the dialog box comes from the Perflib subkey in the registry.

| Item | Description |
|---|---|
| Last System Counter ID | Displays the highest index used to store a counter name, as recorded by the Performance Library (Perflib). Must match the value of **Last Counter Text ID.**<br><br>This field displays the value of the **Last Counter** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib\Last Counter). |
| Last Counter Text ID | Displays the highest index actually used to store a counter name.<br><br>This value is derived from the highest index used in the **Counter** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib*LanguageCode*\Counter). |
| Last System Help ID | Displays the highest index used to store explain text for a counter, as recorded by the Performance Library (Perflib). Must match the value of **Last Help Text ID.**<br><br>This field displays the value of the **Last Help** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib\Last Help). |
| Last Help Text ID | Displays the highest index actually used to store explain text.<br><br>This value is derived from the highest index used in the **Help** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib*LanguageCode*\Help). |

- The DLL-specific data in the lower section of the dialog box comes from the Performance subkeys in the registry. This data changes when you select an item from the **Extensible Performance Counters** dialog box.

| Item | Description |
|---|---|
| DLL Name | Displays the name and fully qualified path of the DLL that provides performance data for this service.<br><br>If the system cannot find the DLL file in this path, the registry records an error in the Application Log in Event Viewer. |
| Open Procedure | Displays the name of the DLL function that initializes the performance collection features of the service.<br><br>The open procedure must be exported by the DLL and it must return a successful status. Otherwise, the registry cannot collect performance data from this service. If this function is not found in the DLL or if it returns an error, the registry records an error in the Application Log in Event Viewer. |
| Collect Procedure | Displays the name of the DLL function that collects the performance data for the service.<br><br>The registry calls the collect function when a performance tool, such as System Monitor, requests performance data. If this function cannot be found in the DLL, the registry records an error in the Application Log in Event Viewer. |
| Close Procedure | Displays the name of the DLL function that terminates and completes the performance data collection features of the service.<br><br>The registry calls the close function when a performance tool, such as System Monitor, closes the registry interface. If this function cannot be found in the DLL, or it has a fault or causes an error, the registry records an error in the Application Log in Event Viewer. |
| Counter ID Range | Displays the range of index values that were assigned to the service to store counter names.<br><br>The values shown here must match the indices actually used, as shown in the value of the **Counter** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib*LanguageCode*\Counter).<br><br>"N/A" is displayed for system counters, which do not store counter names in the registry. If the value is **Not Found**, then the counters were not installed properly and will not appear correctly in tools such as System Monitor. |
| Help ID Range | Displays the range of index values that were assigned to the service to store explain text for its counters.<br><br>The values shown here must match the indices actually used, as shown in the value of the **Help** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib*LanguageCode*\Help).<br><br>"N/A" is displayed for system counters, which do not store explain text in the registry. If the value is **Not Found**, then the counters were not installed properly and will not appear correctly in tools such as System Monitor. |

# Gflags.exe

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gflags.exe: Global Flags Editor (with Page Heap Verification)**
This tool allows you to enable and disable advanced internal system diagnostics and troubleshooting features on computers running Windows 2000, Windows XP Professional, and Windows Server 2003. Gflags is designed as a debugging tool for application developers. It is most often used to turn on indicators that other tools track, count, and log. You can run Gflags from the command line or use its graphical user interface dialog box.

Use Gflags to activate the following debugging features:

- Registry. Set systemwide debugging features for all Windows processes. These settings are stored in the registry. They take effect when you restart the system and remain effective until you change them.
- Kernel mode settings. Set debugging features for this session. These settings are effective immediately, but are lost when the system stops. The settings affect processes started after this command completes.
- Image file settings. Set debugging features for a particular program. These settings are stored in the registry. They take effect when you restart the program and remain effective until you change them.
- Debugger. Specify that a particular program always runs in a debugger. This setting is stored in the registry. It is effective immediately and remains effective until you change it. (This feature is available only from the Gflags dialog box.)
- Launch. Run a program with the specified debugging settings. The debugging settings are effective until the program stops. (This feature is available only from the Gflags dialog box.)
- Page heap verification. Enable, disable, and configure page heap verification for a program. When enabled, page heap monitors dynamic heap memory operations, including allocations and frees, and causes a debugger break when it detects a heap error.

### Caution

- Use Gflags only in consultation with Microsoft Product Support Services. It is an optional component provided solely for troubleshooting purposes. Incorrect use of this tool can degrade system performance or prevent the system from starting, requiring you to reinstall the operating system.

### Important

- Pool tagging is permanently enabled on all versions of Windows Server 2003. On these systems, the **Enable pool tagging** check box on the Gflags dialog box is dimmed and commands to enable or disable pool tagging fail.

**Corresponding UI**
This version of Gflags incorporates the functions of Pageheap.exe, a heap allocation monitoring tool formerly included in the Support Tools folder.

**System Requirements**
The following are the system requirements for Gflags:

- This version of Gflags runs only on Windows XP Professional and Windows Server 2003. A version of Gflags for Windows 2000 is included in the Support Tools directory of Windows 2000 Server.
- The user must be a member of the Administrators group on the computer.
- Gflags is a local computer tool. You cannot use it to set flags on a remote computer.

**File Required**

- Gflags.exe

# Gflags Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gflags Remarks**
**General Information**

- To display the Gflags dialog box, at the command line, type `Gflags` (with no parameters).
- To set flags in the registry or in kernel mode or to enable page heap verification, you must be a member of the Administrators group on the computer. However, users with at least Guest account access can launch a program from the Gflags dialog box.
- Gflags system-level registry settings appear in the registry immediately, but do not take effect until you restart the system.
- Gflags image file registry settings appear in the registry immediately, but do not take effect until you restart the process.
- The debugger and launch features in the Gflags dialog box are program specific. You can only set them on one image file at a time.
- For information about kernel special pool, see the Windows Driver Development Kit (DDK).
- For information about debuggers and to obtain debuggers and documentation, see Microsoft Debugging Tools.

**Flag Details**

- To clear all flags, set the flag to -FFFFFFFF. Setting the flag to 0 adds 0 to the current flag value.
- When you set the flags for an image file to FFFFFFFF (0xFFFFFFFF), Windows clears all flags and deletes the **GlobalFlag** entry in the image file subkey. The subkey is retained.

**Dialog Box and Command Line**
You can run Gflags by using its handy dialog box or from the command line. Most features are available in both forms, with the following exceptions.

**Dialog box only**

- Debugger. Specify that a particular program always runs in a debugger.
- Launch. Run a program with the specified debugging settings.
- Kernel Special Pool Tag. Detects kernel pool errors.

**Command line only**

- Set the size of the user mode stack trace database (**/tracedb**).
- Set page heap verification options.

**Gflags and Page Heap**
This version of Gflags includes the functionality of Pageheap.exe, a heap allocation monitoring tool formerly included in the Support Tools folder. The page heap feature reserves memory at the boundary of each allocation to trap access beyond the allocation that might otherwise go undetected.

The page heap options in Gflags let you select *standard heap verification*, which writes fill patterns at the end of each heap allocation and examines the patterns when the allocations are freed, or *full-page heap verification*, which places an inaccessible page at the end of each allocation so that the program stops immediately if it accesses memory beyond the allocation. Because full heap verification uses a full page of memory for each allocation, its widespread use can cause system memory shortages.

Use the following syntax variations to enable page heap verification:

- To enable standard page heap verification for all processes, use **gflags /r +hpa** or **gflags /k +hpa**.
- To enable standard page heap verification for one process, use **gflags /p /enable***ImageFile*.
- To enable full page heap verification for one process, **gflags /i***ImageFile***+hpa** or **gflags /p /enable***ImageFile***/full**.

All page heap settings, except **/k**, are stored in the registry and remain effective until you change them.

Use care in interpreting the **Enable page heap** check box for an image file in the Gflags dialog box. It indicates that page heap verification is enabled for an image file, but it does not indicate whether it is full or standard page heap. If the check results from selecting the check box, then full page heap verification is enabled for the image file. However, if the check results from use of the command-line interface, then the check can represent the enabling of either full or standard page heap verification for the image file.

To determine whether a full or standard page heap verification is enabled for a program, at the command line, type **gflags /p**. In the resulting display, **traces** indicates that standard page heap verification is enabled for the program and **full traces** indicates that full page heap verification is enabled for the program.

**Registry Information**
Debugging settings saved between sessions are stored in the registry. You can use the registry APIs, Regedit.exe, or Reg to query or change these values. For information about using Reg see "Reg" in Help for Windows Server 2003. The following table lists the types of settings and where they are stored in the registry.

| | |
|---|---|
| Systemwide debugging values. ("Registry") | HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager**GlobalFlag** |
| Program-specific debugging values. ("Image file") | HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution Options*ImageFile***GlobalFlag** |
| Page heap options for an image file | HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution Options*ImageFile***PageHeapFlags** |
| User mode stack trace database size (**tracedb**) | HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution Options*ImageFile***StackTraceDatabaseSizeInMb** |
| Create user mode stack trace database (ust, 0x1000) for an image file | Windows adds the image file name to the value of the **USTEnabled** registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution Options**USTEnabled**). |
| Kernel Special Pool Tags | HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management**PoolTag** |
| Verify Start / Verify End | HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management**PoolTagOverruns**. The **Verify Start** option sets the value to 0. The **Verify End** option sets the value to 1. |

# Gflags Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gflags Examples**
**Example 1: Display flags**
The following command displays the current value of the system-level **GlobalFlag** registry entry (HKLM\System\CurrentControlSet\Control\Session Manager\GlobalFlag). It uses the **/r** parameter to specify the system-level registry entry.

```
gflags /r
```

In response, Gflags displays a single hexadecimal value representing the sum of all flags set and a list of the flags set.

```
Current Boot Registry Settings are: 40001400
    ptg - Enable pool tagging
    ust - Create user mode stack trace database
    bhd - Enable bad handles detection
```

In this example, the results show that there are three tags set, with a combined value of 0x40001400.

- Enable pool tagging (ptg) = 0x400
- Create user mode stack trace database (ust) = 0x1000
- Enable bad handles detection (bhd) = 0x40000000

Remember that the value in the registry might not be the current value. Changes to the registry are not effective until the process is restarted.

You can use similar commands to display the debugging values for the current session, known as *kernel mode*, and debugging values for a particular image file.

The following command displays the debugging values for the current session. It uses the **/k** parameter to indicate kernel mode.

```
gflags /k
```

The following command displays the debugging values set in the registry for Notepad.exe. This value is stored in a **GlobalFlag** registry entry located in the program-specific subkey, HKLM\System\CurrentControlSet\Control\Session Manager\Image File Execution Options\Notepad.exe. It uses the **/i** parameter to indicate image file mode and specifies the image file.

```
gflags /i notepad.exe
```

Remember that the value in the registry might not be the current value. Changes to the registry are not effective until the process is restarted.

**Example 2: Set a flag by using a flag abbreviation**
The following command sets the Show loader snaps flag in the **GlobalFlag** registry entry for the Notepad.exe image file. Show loader snaps takes snapshots of the load process, capturing in detail the loading and unloading of executable images and their supporting library modules.

The command uses the **/i** parameter to indicate image file mode and specifies the name of the image file, Notepad.exe. To identify the flag, the command uses **sls**, the abbrevation for Show loader snaps and it precedes the abbreviation with a plus sign (+) to indicate that the flag is set. Without the plus sign, the command has no effect.

```
gflags /i notepad.exe +sls
```

In response, Gflags displays the current flags for Notepad.exe. The display indicates that the command is successful. The Show loader snaps flag is enabled for all new instances of the Notepad.exe process.

```
Current Registry Settings for notepad.exe executable are: 00000002
    sls - Show Loader Snaps
```

**Example 3: Set a flag by using its hexadecimal value**
The following command sets the Enable page heap flag in the systemwide **GlobalFlag** registry entry. Enable page heap adds a guard page and other tracking features to each heap allocation.

The command uses the **/r** parameter to indicate system registry mode. To identify the flag, the command uses **2000000**, which represents 0x2000000, the hexadecimal value for Enable page heap.

Although the command sets a flag, it omits the plus sign. When using hexadecimal values, the sign is optional and add (+) is the default.

```
gflags /r 2000000
```

In response, Gflags displays the current value of **GlobalFlag**. The display indicates that the command is successful. The Enable page heap flag is set when you restart the system.

```
Current Boot Registry Settings are: 02000000
    hpa - Enable page heap
```

**Example 4: Set multiple flags**
The following command sets the following three debugging flags for the current session:

- Enable heap free checking (hfc, 0x20)
- Enable heap parameter checking (hpc, 0x40)
- Enable heap validation on call (hvc, 0x80)

This command uses the **/k** parameter to specify kernel mode (session only). It sets the value for kernel mode to **E0** (0xE0), the sum of the hexadecimal values of the flags.

```
gflags /k e0
```

In response, Gflags displays the current value of **GlobalFlag**. The display indicates that the command is successful and that the correct three flags are, indeed, set.

```
Current Running Kernel Settings are: 000000e0
    hfc - Enable heap free checking
    hpc - Enable heap parameter checking
    hvc - Enable heap validation on call
```

Please note that each of the following commands has the same effect as the command used in this example and can be used interchangeably:

```
gflags /k +20 +40 +80
```

```
gflags /k +E0
```

```
gflags /k +hfc +hpc +hvc
```

Flags set in kernel mode are effective immediately and remain effective until the system stops.

**Example 5: Clear a flag**
The following command clears the Enable page heap flag from the systemwide **GlobalFlag** registry entry. The command uses the **/r** parameter to indicate the systemwide registry and **hpa**, the abbreviation for the Enable page heap flag. The minus sign (-) specifies that the flag is to be cleared.

```
gflags /r -hpa
```

In response, Gflags displays the current value of **GlobalFlag**. The display indicates that the command is successful and that there are no longer any flags set in the registry value.

```
Current Boot Registry Settings are: 00000000
```

Please note that the following command, which uses the hexadecimal value of the Enable page heap flag, has the same effect as the command used in this example and can be used interchangeably:

```
gflags /r -02000000
```

**Example 6: Clear all flags**
There are two different ways to clear all flags set for a particular debugging mode:

- Clear the current flags.
- Clear all flags.

### Note

- The methods demonstrated by this example clear flags only. They do not reset the maximum stack trace size or kernel special pool tag to the default values.

**Clear the current flags**
The following command uses the first method for clearing flags. It clears the current value of **GlobalFlag** by clearing the flags set. In this example, the current value is 0xE0.

```
gflags /r -E0
```

In response, Gflags displays the current value of **GlobalFlag**. The display indicates that the command is successful and that there are no longer any flags set in the registry value.

```
Current Boot Registry Settings are: 00000000
```

Please note that the following commands have the same effect as the command used in this example and can be used interchangeably:

```
gflags /r -20 -40 -80
```

```
gflags /r -hfc -hpc -hvc
```

**Clear all flags**
The following command uses the second method for clearing flags. It clears all possible values set for **GlobalFlag**.

```
gflags /r -ffffffff
```

In response, Gflags displays the current value of **GlobalFlag**. The display indicates that the command is successful and that there are no longer any flags set in the registry value.

```
Current Boot Registry Settings are: 00000000
```

### Note

- Type this command into Notepad, then save the file as ClearFlag.bat. Thereafter, to clear all flags, just type `ClearFlag`.

Finally, the following example demonstrates that the intuitive method of clearing all flags does not work.

The following command should set the value of the systemwide **GlobalFlag** registry entry to 0 intuitively but it does not. In this example, the current value of **GlobalFlag** is 0xE0.

```
gflags /r 0
```

In response, Gflags displays the value of **GlobalFlag** after the command completes:

```
Current Boot Registry Settings are: 000000e0
    hfc - Enable heap free checking
    hpc - Enable heap parameter checking
    hvc - Enable heap validation on call
```

The command has no effect because it adds the value 0 to the current value of **GlobalFlag**.

**Example 7: Clear all flags for an image file**
The following command clears all flags and image debugger options for an image file. The command adds high-values (0xFFFFFFFF) to the current flag value. Gflags responds by deleting the **GlobalFlag** entry for the image file, thereby deleting all of the values it stores.

This method does not clear flags set in the systemwide registry entry or in kernel mode.

```
gflags /i notepad.exe ffffffff
```

In response, Gflags displays a message indicating that there are no flags set for the image file:

```
No Registry Settings for notepad.exe executable
```

To determine which image files have flags set, use the **query** operation of Reg.exe, a tool included in %windir%\system32, to search the registry subkeys in the Image file Execution Options subkey.

The following command searches for **GlobalFlag** in the specified path. The **/v** parameter directs Reg query to search for the value **GlobalFlag**. The /s parameter specifies to search all subkeys and values recursively.

```
reg query "HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options" /v
GlobalFlag /s
```

In response, Reg query displays all image file subkeys with **GlobalFlag** registry entries. It also displays the value of the entry. Because the **gflags** command deleted the entry for Notepad.exe, it does not appear in the Reg query list.

```
HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execu
tion Options
    f32main.exe
        GlobalFlag = 0x000000c0
    dgsetup.exe
        GlobalFlag = 0x00000080
```

### Note

- Type the **reg query** command into Notepad, then save the file as Images.bat. Thereafter, to find image files for which flags have been set, just type `Images`.

**Example 8: Enlarge the user mode stack trace database**
The following command increases the maximum size of the user mode stack trace database for the MyApp.exe process from 8 MB to 24 MB.

The command uses the **/i** parameter to specify the image file. It uses the **/tracedb** parameter to set the maximum stack trace database size and the value **24** to indicate the desired MB size in decimal units. (Hexadecimal units are not valid.)

```
            gflags /i MyApp.exe /tracedb 24
```

As the following error message indicates, this command fails because the "Create user mode stack trace database" (+ust) flag is not set for the process. You cannot set the size of a trace database until you create one.

```
Failed to set the trace database size for `MyApp.exe'
The user mode stack trace database flag (+ust) must be enabled before setting /tracedb.
```

The following commands fix the error. The first command creates a trace database for MyApp.exe and the second command sets the maximum size of the trace database to 24 MB. These commands cannot be combined into a single command. The listing below shows the commands and the success message from Gflags.

```
            gflags /i MyApp.exe +ust

Current Registry Settings for MyApp.exe executable are: 00001000
    ust - Create user mode stack trace database

gflags /i MyApp.exe /tracedb 24
```

```
Trace database size for `MyApp.exe' set to 24 Mb.
```

Gflags can change the size of the user mode stack trace database, but it does not display it. To display the trace database size, use registry APIs, Regedit.exe, or Reg, to check the value of the **StackTraceDatabaseSizeInMB** registry entry (HKLM\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options*ImageFileName***StackTraceDatabaseSizeInMB**).

The following command uses Reg.exe to query the value of **StackTraceDatabaseSizeInMB**:

```
reg query "HKLM\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\MyApp.exe" /v
StackTraceDatabaseSizeInMB
```

In response, Reg.exe returns the value of **StackTraceDatabaseSizeInMB**, which confirms that the new value, 24 (0x18), was set. This value becomes effective when you restart the MyApp.exe.

```
! REG.EXE VERSION 3.0

HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execu
tion Options\MyApp.exe
    StackTraceDatabaseSizeInMB  REG_DWORD       0x18
```

### Notes

- Type the **reg query** command into Notepad, then save the file as TraceDb.bat. Thereafter, to display the value of **StackTraceDatabaseSizeInMB**, just type `TraceDb`.

- To see the registry locations of values set by Gflags, see Gflags Remarks.

#### Example 9: Detect a pool memory leak

The following example uses Gflags to set the **Enable pool tagging** flag in the registry entry for the system. Then, it uses Poolmon Overview, a Windows Support Tool, to display the size of the memory pools. Poolmon uses pool tags to monitor the bytes in the paged and nonpaged memory pools. By running Poolmon periodically, you can identify pools that expand continuously over time. This pattern often indicates a memory leak.

### Notes

- Pool tagging is permanently enabled on all versions of Windows Server 2003. On these systems, the **Enable pool tagging** check box on the Gflags dialog box is dimmed and commands to enable or disable pool tagging fail.

- If pool tagging is not enabled, Poolmon fails and diplays the following message: "Query pooltags Failed c0000002."

1. Set the Enable pool tagging flag in the systemwide registry entry.

   Use one of the following methods. These methods have the same effect and can be used interchangeably.

   - In the Gflags dialog box, click the **Registry** button, click the **Enable pool tagging** check box, and then click **Apply**.

   - At the command line, use the **/r** parameter to specify the systemwide registry entry, and the **ptg** abbreviation to specify the flag.

     ```
     gflags /r +ptg
     ```

   - At the command line, use the **/r** parameter to specify the systemwide registry entry, and the **0x400** hexadecimal value to specify the flag. The plus sign (+) is optional in this format.

     ```
     gflags /r +400
     ```

2. Restart the computer to make the registry change effective.

3. Run Poolmon periodically by using the following command. In this command, the **/b** parameter sorts the pools in descending size order.

   ```
   poolmon /b
   ```

   In response, Poolmon displays a table of memory pool size, including the number of allocs and frees, and the amount of memory remaining in the pool (in the Bytes column).

   ```
   Memory: 16224K Avail: 4564K PageFlts: 31 InRam Krnl: 684K P: 680K
    Commit: 24140K Limit: 24952K Peak: 24932K  Pool N: 744K P: 2180K

    Tag  Type    Allocs          Frees         Diff   Bytes      Per Alloc
   ---------------------------------------------------------------------

    CM   Paged    1283 (   0)    1002 (   0)    281 1377312 (     0) 4901
   Strg  Paged   10385 (  10)    6658 (   4)   3727  317952 (   512)   85
    Fat  Paged    6662 (   8)    4971 (   6)   1691  174560 (   128)  103
   MmSt  Paged     614 (   0)     441 (   0)    173   83456 (     0)  482
   ```

   If the value of Bytes in a pool expands continuously for no obvious reason, there might be a memory leak in that pool.

4. Turn off Enable pool tagging.

   The following command line uses the flag abbreviation method, but you can identify the flag by its hexadecimal value or use the **Global Flags** dialog box:

   ```
   gflags /r -ptg
   ```

5. Restart the system to make the registry change effective.

### Note

- Use the append symbol (>>) to redirect the Poolmon output to a log file. Later, you can examine the log file for pool size trends. For example:

  ```
  poolmon.exe /b >> poolmon.log
  ```

#### Example 10: Get a complete dump of active heaps in a process

This example uses Gflags and Umdh.exe (User Mode Dump Heap), a tool available from Microsoft Product Support Services.

To detect a leak in heap memory in Notepad.exe:

1. Set the Create user mode stack trace database flag for the Notepad.exe image file.

   The following command uses Gflags to set the Create user mode stack trace database flag. It uses the **/i** parameter to identify the image file and the **ust** abbreviation for the flag.

   ```
   gflags /i Notepad.exe +ust
   ```

   As a result of this command, a user mode stack trace is created for all new instances of the Notepad process.

2. Set the symbol file path.

   The following command creates an environment variable that stores the path to the directory of symbol files:

   ```
   set _NT_SYMBOL_PATH=C:\Windows\symbols
   ```

3. Start Notepad.

4. Find the process identifier (PID) of the Notepad process.

   You can find the PID of any running process from Task Manager or Tasklist, a tool included in Windows XP Professional and Windows Server 2003 operating systems. In this example, the Notepad PID is 1228.

5. Run Umdh.exe

   The following command runs Umdh.exe. It uses the **-p:** parameter to specify the PID which, in this example, is 1228. It uses the **/f:** parameter to specify the name and location of the output file for the heap dump, Notepad.dmp.

   ```
   umdh -p:1228 -f:notepad.dmp
   ```

   In response, Umdh writes a complete dump of all active heaps to the Notepad.dmp file.

**Example 11: Enable page heap verification**
The following command enables standard page heap verification for the MyApp.exe program.

```
gflags /p /enable myapp.exe
```

The following commands enable full page heap verification for the MyApp.exe program. Although these commands create different settings in the registry, they are all functionally equivalent to selecting the **Enable page heap** check box for the MyApp.exe image file in the Gflags dialog box. These methods can be used interchangeably.

```
gflags /p /enable myapp.exe /fullgflags /i myapp.exe +hpagflags /i myapp.exe +02000000
```

The following commands disable full or standard page heap verification for the Myapp.exe program, regardless of the command or dialog box method used to enable page heap verification.

```
gflags /p /disable myapp.exegflags /i myapp.exe -hpagflags /i myapp.exe -02000000
```

### Note

- When using the **/debug** or **/kdebug** parameters, use the **/p /disable** parameters to turn off the page heap verification (not the **/i -hpa** parameters). Otherwise, entries read by the debugger are not deleted from the registry.

**Example 12: Use page heap verification to find a bug**
This series of commands demonstrates how to use the page heap verification features of Gflags and the Windows NT Symbolic Debugger (NTSD) to detect an error in heap memory use. In this example, the programmer suspects that a fictitious application, Pheap-buggy.exe, has a heap error, and proceeds through a series of tests to identify the error.

**Step 1: Enable standard page heap verification**
The following command enables standard page heap verification for Pheap-buggy.exe:

```
gflags /p /enable pheap-buggy.exe
```

**Step 2: Verify that page heap is enabled**
The following command lists the programs on the system for which page heap verification is enabled:

```
gflags /p
```

In response, Gflags displays the following list of programs. In this display, **traces** indicates standard page heap verification and **full traces** indicates full page heap verification. In this case, Pheap-buggy.exe is listed with **traces**, indicating that standard page heap verification is enabled, as intended.

```
pheap-buggy.exe: page heap enabled with flags (traces )
```

**Step 3: Run the debugger**
The following command runs the CorruptAfterEnd function of Pheap-buggy.exe in NTSD with the **-g** (ignore initial breakpoint) and **-x** (set second-chance break on access violation exceptions) parameters set:

```
ntsd -g -x pheap-buggy /CorruptAfterEnd
```

When the application fails, NTSD generates the following display, which indicates that it detected an error in Pheap-buggy.exe:

```
============================================================
VERIFIER STOP 00000008: pid 0xAA0: corrupted suffix pattern

        00C81000 : Heap handle
        00D81EB0 : Heap block
        00000100 : Block size
        00000000 :
============================================================

Break instruction exception - code 80000003 (first chance)
eax=00000000 ebx=00d81eb0 ecx=77f7e257 edx=0006fa18 esi=00000008 edi=00c81000
eip=77f7e098 esp=0006fc48 ebp=0006fc5c iopl=0         nv up ei pl zr na po nc
cs=001b  ss=0023  ds=0023  es=0023  fs=0038  gs=0000             efl=00000246
ntdll!DbgBreakPoint:
77f7e098 cc              int     3
```

The header information includes the address of the heap with the corrupted block (00C81000 : Heap handle), the address of the corrupted block (00D81EB0 : Heap block) and the size of the allocation (00000100 : Block size).

The "corrupted suffix pattern" message indicates that the application violated the data integrity pattern that Gflags inserted after the end of the Pheap-buggy.exe heap allocation.

**Step 4: Display the call stack**
The next step is to use the addresses detected to locate the function that caused the error. The next two commands turn on line number dumping in the debugger and display the call stack with line numbers.

```
C:\>.linesLine number information will be loaded

C:\>kb
```

```
ChildEBP RetAddr  Args to Child
WARNING: Stack unwind information not available. Following frames may be wrong.

0006ffc0 77de43fe 00000000 00000001 7ffdf000 pheap-buggy!mainCRTStartup+0xe3 [crtexe.c
@ 349]
0006fff0 00000000 0100149c 00000000 78746341 kernel32!DosPathToSessionPathA+0x204
```

The debugger displays the call stack for Pheap-buggy.exe with line numbers. The call stack display shows that the error occurred when the TestCorruptAfterEnd function in Pheap-buggy.exe tried to free an allocation at 0x00c80000 by calling HeapFree, a redirect to RtlFreeHeap.

The most likely cause of this error is that the program wrote past the end of the buffer that it allocated in this function.

**Step 5: Enable full page heap verification**
Unlike standard mode, full page heap verification can catch the misuse of this heap buffer as soon as it occurs. The following command enables full page heap verification for Pheap-buggy.exe:

```
gflags /p /enable pheap-buggy.exe /full
```

**Step 6: Verify that full page heap is enabled**
The following command lists the programs on the system for which page heap verification is enabled:

```
gflags /p
```

In response, Gflags displays the following list of programs. In this display, **traces** indicates standard page heap verification and **full traces** indicates full page heap verification. In this case, Pheap-buggy.exe is listed with **full traces**, indicating that full page heap verification is enabled, as intended.

```
pheap-buggy.exe: page heap enabled with flags (full traces )
```

**Step 7: Run the debugger again**

The following command runs the CorruptAfterEnd function of Pheap-buggy.exe in the NTSD debugger with the **-g** (ignore initial breakpoint) and **-x** (set second-chance break on access violation exceptions) parameters set:

```
ntsd -g -x pheap-buggy /CorruptAfterEnd
```

When the application fails, NTSD generates the following display, which indicates that it detected an error in Pheap-buggy.exe:

```
Page heap: process 0x5BC created heap @ 00880000 (00980000, flags 0x3)
ModLoad: 77db0000 77e8c000   kernel32.dll
ModLoad: 78000000 78046000   MSVCRT.dll
Page heap: process 0x5BC created heap @ 00B60000 (00C60000, flags 0x3)
Page heap: process 0x5BC created heap @ 00C80000 (00D80000, flags 0x3)
Access violation - code c0000005 (first chance)
Access violation - code c0000005 (!!! second chance !!!)
eax=00c86f00 ebx=00000000 ecx=77fbd80f edx=00c85000 esi=00c80000 edi=00c16fd0
eip=01001398 esp=0006ff2c ebp=0006ff4c iopl=0         nv up ei pl nz na po nc
cs=001b  ss=0023  ds=0023  es=0023  fs=0038  gs=0000             efl=00000206
pheap-buggy!TestCorruptAfterEnd+1f:
01001398 889801010000     mov     [eax+0x101],bl          ds:0023:00c87001=??
```

With full page heap verification enabled, the debugger breaks at an access violation. To find the precise location of the access violation, turn on line number dumping and display the call stack trace.

The numbered call stack trace appears as follows:

```
ChildEBP RetAddr  Args to Child
0006ff3c 01001450 00000000 00000001 0006ffc0 pheap-buggy!TestCorruptAfterEnd+0x1f
[d:\nttest\base\testsrc\kernel\rtl\pageheap\pheap-buggy.cxx @ 184]
0006ff4c 0100157f 00000002 00c16fd0 00b70eb0 pheap-buggy!main+0xa9
[d:\nttest\base\testsrc\kernel\rtl\pageheap\pheap-buggy.cxx @ 69]
0006ffc0 77de43fe 00000000 00000001 7ffdf000 pheap-buggy!mainCRTStartup+0xe3 [crtexe.c
@ 349]
WARNING: Stack unwind information not available. Following frames may be wrong.
0006fff0 00000000 0100149c 00000000 78746341 kernel32!DosPathToSessionPathA+0x204
```

The stack trace shows that the problem occurs in line 184 of Pheap-buggy.exe ([d:\nttest\base\testsrc\kernel\rtl\pageheap\pheap-buggy.cxx @ 184]). Because full page heap verification is enabled, the call stack ends in the program code, not in a system DLL. As a result, the violation was caught where it happened, instead of when the heap block was freed.

**Step 8: Locate the error in the code**

A quick inspection reveals the source of the problem: The program tries to write to the 101st byte of a 100-byte buffer, a common off-by-one error.

```
*((PCHAR)Block + 0x100 + 1) = 0;
```

# Gflags Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gflags Syntax**

- **gflags**[**/r** [*Flag* [*Flag*...]] | **/k** [*Flag* [*Flag*...]] | **/i** *ImageFile* [*Flag* [*Flag*...]] | **/i** *ImageFile* **/tracedb** *SizeInMB* | **/?**]
- **gflags /p** [**/disable** *ImageFile*] [**/?**]
- **gflags /p /enable** *ImageFile* [**/full** [**/backwards**] | [**/random** *Probability*] | [**/size** *SizeStartSizeEnd*] | [**/address** *AddressStart AddressEnd*] | [**/dlls** *DLL* [*DLL*...]] [**/debug** | **/kdebug**] [**/unaligned**] [**/decommit**] [**/notraces**] [**/fault** *Rate* [*TimeOut*]] [**/leaks**] [**/protect**] [**/no_sync**] [**/no_lock_checks**]

**Parameters**

- Typing **gflags** without parameters opens the Gflags dialog box.
- Typing **gflags /p** without additional parameters displays a list of programs that have page heap verification enabled.
- The **/full**, **/random**, **/size**, **/address**, and **/dlls** parameters for the page heap **/enable** operation determine which allocations are subject to page heap verification and the verification method used. You can use only one of these parameters in each command. The default is standard page heap verification of all allocations of the process. The remaining parameters set options for page heap verification.

***Flag***

A three-letter abbreviation (*FlagAbbr*) or hexadecimal value (*FlagHex*) that represents a debugging feature. The abbreviations and hexadecimal values are listed in the Global Flags Table.

Use one of the following flag formats:

| Format | Description |
|---|---|
| {**+** \| **-**}*FlagAbbr* | Sets (**+**) or clears (**-**) the flag represented by the flag abbreviation. Without a plus (**+**) or minus (**-**) symbol, the command has no effect. |
| [**+** \| **-**]*FlagHex* | Adds (**+**) or subtracts (**-**) the hexadecimal value of a flag. A flag is set when its value is included in the sum. Add (**+**) is the default. Enter a hexadecimal value (without **0x**) that represents a single flag or enter the sum of hexadecimal values for multiple flags. |

***ImageFile***

The name of an executable file (.exe or .dll), including the file name extension. For example, Notepad.exe or Mydll.dll.

**Note**

- The ImageFile name is case insensitive.

**/r[ *Flag*[ *Flag*...]]**

Registry. View and change systemwide debugging flags stored in the registry. These settings take effect when you restart the system and remain effective until you change them.

Without flags, **gflags /r** displays the systemwide flags set in the registry.

**/k[ *Flag*[ *Flag*...]**

Kernel mode settings. View and change systemwide debugging flags for this session. These settings are effective immediately, but are lost when the system stops. The settings affect processes started after this command completes.

Without flags, **gflags /k** displays systemwide flags set for the current session.

**/i *ImageFile*[ *Flag*[ *Flag*...]]**

Image file settings. View and change debugging flags for a particular process. These settings are stored in the registry. They

are effective for all new instances of this process and they remain effective until you change them.

Without flags, **gflags /i***ImageFile* displays the flags set for the specified process.

**/tracedb *SizeInMb***

Sets the maximum size of the user mode stack trace database for the process. To use this parameter, the Gflags Flag Reference (ust) flag must be set for the process.

*SizeInMB* is a whole number representing the number of MB in decimal units. The default value is the minimum size, 8 MB; there is no maximum size. To revert to the default size, set *SizeInMB* to 0 or 8.

**/p**

Sets page heap verification options for a process. Without additional parameters, **gflags /p** displays a list of programs for which page heap verification is enabled.

Page heap verification monitors dynamic heap memory operations, including allocations and frees, and causes a debugger break when it detects a heap error.

**Note**

- The page heap features in Gflags only monitor heap memory allocations that use the standard Windows heap manager functions (HeapAlloc, GlobalAlloc, LocalAlloc, malloc, operator new, operator new[], or their corresponding deallocation functions) or those that use custom operations that call the standard heap manager functions.

**/disable *ImageFile***

Turns off page heap verification (standard or full) for the process.

This command is equivalent to turning off the Gflags Flag Reference flag for a process (**gflags /i***ImageFile*-**hpa**). You can use the commands interchangeably.

**/enable *ImageFile***

Turns on standard page heap verification for the process. Standard page heap verification examines fill patterns when a heap block is freed.

This parameter sets the Gflags Flag Reference flag for the process in the registry. However, the **/enable** parameter sets standard heap verification for the process, unlike the **/i** parameter, which sets full heap verification for a process.

**/full**

Turns on full page heap verification for the process. Full page heap verification places an inaccessible page at the end of each allocation. The default is standard page heap verification, which places fill patterns at the end of an allocation and examines the patterns when a heap block is freed.

Using this parameter is equivalent to turning on the Gflags Flag Reference flag for a process (**gflags /i***ImageFile*+**hpa**). You can use the commands interchangeably.

**Caution**

- Because full page heap verification uses at least one page of committed memory for each allocation, system resources can be quickly exhausted. For memory intensive processes, use the **/size** or **/dlls** parameter.

**/backwards**

Places the inaccessible page at the beginning of an allocation, rather than the end. As a result, the debugger traps overruns at the beginning of the buffer, instead of those at the end of the buffer. Valid only with the **/full** parameter.

**/random *Probability***

Chooses full or standard page heap verification for each allocation based on the specified probability. *Probability* is a decimal integer from 0 through 100 representing the probability of full page heap verification. A probability of 100 is the same as using the **/full** parameter. A probability of 0 is the same as using standard page heap.

**/size *SizeStart SizeEnd***

Enables full page heap verification for allocations within the specified size range and enables standard page heap verification for all other allocations by the program. *SizeStart* and *SizeEnd* are decimal integers. The default is standard page heap verification for all allocations.

**/address *AddressStart AddressEnd***

Enables full page heap verification for memory allocated while a return address in the specified address range is on the runtime call stack. It enables standard page heap verification for all other allocations by the process. To use this feature, specify the address of a function that calls the function with the suspect allocation. The address of the calling function will be on the call stack when the suspect allocation occurs.

*AddressStart* and *AddressEnd* specify the address range searched in allocation stack traces. The addresses are specified in hexadecimal "C" format, such as, 0xAABBCCDD.

The **/address** parameter is valid only on *x*86 architectures. It is not reliable and is rarely used.

**/dlls *DLL*[ ,*DLL*...]**

Enables full page heap verification for allocations requested by the specified DLLs and standard page heap verification for all other allocations by the process.

*DLL* is the name of a binary file, including its file name extension. The specified file must be a function library that the process loads during execution.

**/debug**

Automatically launches the process specified by the **/enable** parameter under the NTSD debugger with page heap enabled and with the following options: **ntsd -g -G -x**.

- **-g** ignores initial breakpoint in debugger
- **-G** ignores final breakpoint at process termination
- **-x** sets second-chance break on AV exceptions

This option is used for programs that are difficult to start from a command prompt and those that are started by other processes.

**Note**

- When using the **/debug** or **/kdebug** parameters, use the **/p /disable** parameters to turn off the page heap functions (not the **/i -hpa** parameters). Otherwise, entries read by the debugger are not deleted from the registry.

**/kdebug**

Automatically launches the process specified by the **/enable** parameter under the NTSD debugger with page heap enabled and the following options: **ntsd -g -G -d -x**. It also redirects the debugger output to the kernel debugger if one is attached.

- **-g** ignores initial breakpoint in debugger
- **-G** ignores final breakpoint at process termination
- **-d** sends all debugger output to kernel debugger via DbgPrint
- **-x** sets second-chance break on AV exceptions

This parameter is not commonly used.

**Note**

- When using the **/debug** or **/kdebug** parameters, use the **/p /disable** parameters to turn off the page heap functions (not the **/i -hpa** parameters). Otherwise, entries read by the debugger are not deleted from the registry.

**/unaligned**

Aligns the end of each allocation at an end-of-page boundary, even if doing so means that the starting address is not aligned on an 8-byte block. By default, the heap manager guarantees that the starting address of an allocation is aligned on an 8-byte block, but cannot always end at a page boundary.

This option is used to to detect off-by-one-byte errors. When this parameter is used with the **/full** parameter, the inaccessible page begins at the last byte of the allocation and an immediate fault occurs when a process tries to read or write

even one byte beyond the allocation.

Note

- Some programs, including Microsoft Internet Explorer, assume 8-byte alignment and do not operate correctly with the **/unaligned** parameter.

**/decommit**

This option is no longer valid. It is accepted, but ignored. In previous versions of page heap, the **/decommit** parameter placed a zone of reserved virtual space after an allocation instead of an inaccessible page. In this version, the **/decommit** optimization is always implemented in full page heap verification.

**/notraces**

Specifies that runtime stack traces are not saved.

This option improves performance slightly, but it makes debugging much more difficult. This parameter is valid, but its use is not recommended.

**/fault *Rate*[ *TimeOut*]**

Forces the program's memory allocations to fail at the specified rate and after the specified timeout.

This parameter inserts heap allocation errors into the image file being tested (a practice known as "fault injection") so that some memory allocations fail, as might occur when the program runs in low memory conditions. This test helps to detect errors in handling allocation failure, such as failing to release resources.

*Rate* is a decimal integer from 1 through 10000 representing the probability that an allocation will fail. *TimeOut* is the number of seconds of delay between the start of the program and the start of the fault injection routines. The default is 5 (five seconds).

**/leaks**

Checks for heap leaks when a process ends.

**Caution**

- The **/leaks** parameter disables full page heap. When **/leaks** is used, the **/full** parameter and parameters that modify the **/full** parameter, such as **/backwards**, are ignored, and Gflags performs standard page heap verification with a leak check.

**/protect**

Protects heap internal structures. This test is used to detect random heap corruptions. It can make execution significantly slower.

**/no_sync**

Checks for unsynchronized access. This parameter causes a break if it detects that a heap created with the HEAP_NO_SERIALIZE flag is accessed by different threads.

Do not use this flag to debug a program that includes a customized heap manager. Functions that synchronize heap access cause the page heap verifier to report synchronization faults that do not exist.

**/no_lock_checks**

Disables the critical section verifier.

**/?**

Displays help for Gflags.

**/p /?**

Displays help for page heap verification options in Gflags.

**Global Flags Table**

The following table lists the flags that Gflags changes, the hexadecimal value and abbreviation for each flag, and the destination (R for registry, K for kernel, I for image file) in which the flag is valid.

For a detailed description of each flag, see the Gflags Flag Reference.

**Caution**

- The symbolic name of each flag is provided for reference only. Because symbolic names change, they are not a reliable identifier of a global flag.

**Important**

- Pool tagging is permanently enabled in all versions of Windows Server 2003. On these systems, the **Enable pool tagging** check box on the Gflags dialog box is dimmed and commands to enable or disable pool tagging fail.

| Description | Symbolic name | Hexadecimal Value | Abbreviation | Destination |
|---|---|---|---|---|
| Gflags Flag Reference | FLG_DISABLE_DBGPRINT | 0x08000000 | ddp | R,K |
| Gflags Flag Reference | FLG_KERNEL_STACK_TRACE_DB | 0x2000 | kst | R |
| Gflags Flag Reference | FLG_USER_STACK_TRACE_DB | 0x1000 | ust | R,K,I |
| Gflags Flag Reference | FLG_DEBUG_INITIAL_COMMAND | 0x4 | dic | R,K |
| Gflags Flag Reference | FLG_DEBUG_INITIAL_COMMAND_EX | 0x04000000 | dwl | R, K |
| Gflags Flag Reference | FLG_HEAP_DISABLE_COALESCING | 0x00200000 | dhc | R,K,I |
| Gflags Flag Reference | FLG_DISABLE_PAGE_KERNEL_STACKS | 0x80000 | dps | R,K |
| Gflags Flag Reference | FLG_DISABLE_PROTDLLS | 0x80000000 | dpd | R,K,I |
| Gflags Flag Reference | FLG_DISABLE_STACK_EXTENSION | 0x10000 | dse | I |
| Gflags Flag Reference | FLG_CRITSEC_EVENT_CREATION | 0x10000000 | cse | R,K,I |
| Gflags Flag Reference | FLG_APPLICATION_VERIFIER | 0x100 | vrf | R,K,I |
| Gflags Flag Reference | FLG_ENABLE_HANDLE_EXCEPTIONS | 0x40000000 | bhd | R,K |
| Gflags Flag Reference | FLG_ENABLE_CLOSE_EXCEPTIONS | 0x00400000 | ece | R,K |
| Gflags Flag Reference | FLG_ENABLE_CSRDEBUG | 0x20000 | d32 | R,K |
| Gflags Flag Reference | FLG_ENABLE_EXCEPTION_LOGGING | 0x00800000 | eel | R,K |
| Gflags Flag Reference | FLG_HEAP_ENABLE_FREE_CHECK | 0x20 | hfc | R,K,I |

# Gflags UI

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gflags UI**
By using the Gflags dialog box, you can set and clear global flags from a user interface that lists all flags by name. There is no need to look up flag abbreviations or hexadecimal values.

Also, the dialog box provides access to the following features that are not available from the command line:

- Debugger. Specify that a particular program always runs in a debugger.
- Launch. Run a program with the specified debugging settings.
- Kernel Special Pool Tag. Detects kernel pool errors.

**Important**

- Pool tagging is permanently enabled on all versions of Windows Server 2003. On these systems, the **Enable pool tagging** check box on the Gflags dialog box is dimmed and commands to enable or disable pool tagging fail.

This section includes the following topics.

**Gflags dialog box**
The Gflags dialog box in System Registry mode.

**To open the dialog box**
Use one of the following methods:

- At the command line, type `gflags` (without parameters).

- In the **Run** dialog box, type `gflags` (without parameters).

**To set and clear systemwide registry flags**
Systemwide registry settings affect the entire system. They are saved in the registry and remain effective until you change them.

1. In the **Destination** area, click **System Registry**.
2. Set or clear a flag by selecting or clearing the check box associated with the flag.
3. When you have selected or cleared all the flags you want, click **Apply**.
4. Restart the system to make the changes effective.

**To set and clear kernel mode flags**
Kernel mode settings affect the entire system, but are effective only for the current session.

1. In the **Destination** area, click **Kernel Mode**.
2. Set or clear a flag by selecting or clearing the check box associated with the flag.
3. When you have selected or cleared all the flags you want, click **Apply**.

**To set and clear image file registry flags**
Image file settings affect instances of the specified program that start after the command completes. They are saved in the registry and remain effective until you change them.

1. In the **Destination** area, in the **Image File Name** box, type the name of the executable file or DLL, including the file name extension.
2. Click **Image File Options**.
3. Set or clear a flag by selecting or clearing the check box associated with the flag.
4. When you have selected or cleared all the flags you want, click **Apply**.

**To launch a program with flags**
This feature runs a program once with the specified flags. These settings affect only the instance of the program launched by the instruction in the **Command Line** box. They are not saved in the registry.

1. In the **Destination** area, in the **Command Line** box, type a command to start a program, including program parameters.
2. Set or clear a flag by selecting or clearing the check box associated with the flag.
3. When you have selected or cleared all the flags you want, click the **Launch** button.

### Notes

- Flags set in the registry do not affect the instance of the program that is launched.
- Flags set in the dialog box are used for the launched instance even when they are not image file flags.

**To run a program in a debugger**
This feature configures the program so that it always runs in a debugger with the specified options. This setting is saved in the registry. It affects all new instances of the program and remains effective until you change it.

The flags settings in the dialog box do not affect the debugger run.

1. In the **Destination** area, in the **Image File Name** box, type the name of the executable file, including the file name extension.

2. Click **Image File Options**.

3. In the **Image Debugger Options** area, click the **Debugger** check box.

4. In the **Debugger** box, type the command to run the debugger, including the program name and parameters. For example, **ntsd -d**.

5. Click **Apply**.

**To configure kernel special pool**

The kernel special pool feature uses the special pool for all allocations that have a specified tag or are within a specified size range. This feature helps you to detect and identify the source of errors in kernel pool use, such as writing beyond the allocated memory space, or referring to memory that has already been freed.

For information on using the special pool, see the *Windows Driver Development Kit*.

Kernel special pool settings are saved in the registry. They become effective when you restart the system and remain effective until you change them.

1. In the **Destination** area, click **System Registry**.

2. Choose one of the following methods:

   - To specify a pool tag in text format, click **Text**.

     Type a four-character pattern for the tag. The tag can include the **?** (substitute for any single character) and ***** (substitute for multiple characters) wildcard characters. For example, Fat* or Av?4.

     Gflags converts the ASCII characters to their hexadecimal format, placing the leftmost character in the lowest order position. For example, if you type **Tag1**, Gflags sets the tag to 0x31676154.

   - To specify a pool tag in hexadecimal format, click **Hex**.

     Type a hexadecimal value for the tag.

     Gflags sets the tag to the same numeric value. For example, if you type 12345678, Gflags stores pool tag 0x12345678.

     **Note**

Enter a hexadecimal value that is greater than the page size of the system. Otherwise, the value is interpreted as indicating a size range.

- To track kernel pool allocations of a specified size, click **Hex**.

  Allocations are organized into a range of pool block sizes. In 32-bit systems, pool blocks are divided into 8-byte ranges. In 64-bit systems, the range is 16 bytes.

  To indicate a range, type a hexadecimal number equal to the upper limit of the range plus 8 bytes for the pool header. For example, on a 32-bit system, to specify a pool block of between 9 and 16 bytes, type **18** to indicate 0x18.

  The following table shows the pattern of pool block ranges and the value you type to select that range for 32-bit systems.

| Size range (in bytes) | Value |
|---|---|
| 0 - 8 | 0x10 (16) |
| 9 - 16 | 0x18 (24) |
| 17 - 24 | 0x20 (32) |
| 25 - 32 | 0x28 (40) |
| ... | |

The following table shows the pattern of pool block ranges and the value you type to select that range for 64-bit systems.

| Size range (in bytes) | Value |
|---|---|
| 0 - 16 | 0x18 (24) |
| 17 - 32 | 0x28 (40) |
| 33 - 48 | 0x38 (56) |
| 49 - 64 | 0x46 (70) |
| ... | |

**Note**

The value for a size range must be equal to a multiple of 8 plus 8 (8x + 8) on 32-bit systems, or a multiple of 16 + 8 (16x + 8) on 64-bit systems. Also, the value must be smaller than the page size for the system. Otherwise, the value is interpreted as a hexadecimal tag.

1. Click **Verify Start** or **Verify End**.

   - **Verify Start** causes a system stop when a program tries to access tagged memory preceding its memory allocation.

   - **Verify End** causes a system stop when a program tries to access tagged memory beyond its memory allocation.

2. Click **Apply**.

3. To disable kernel special pool, delete the text or hexadecimal value from the **Kernel Special Pool Tag** box, and then click **Apply**.

**Note**

- The special pool can also be used for the memory pool allocations requested by a specific driver. This feature is activated by Driver Verifier (Verifier.exe), a tool included in the Windows\System32 directory in Windows 2000, Windows XP, and Windows Server 2003. For details, see the Driver Verifier documentation in the *Windows Driver Development Kit* (DDK).

# Gflags Flag Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Gflags Flag Reference**

**Caution**

- The symbolic name of each flag is provided for reference only. Because symbolic names change, they are not a reliable identifier of a global flag.

**Buffer DbgPrint output**

| **Abbreviation** | **ddp** |
|---|---|
| **Hexadecimal value** | 0x08000000 |
| **Symbolic Name** | FLG_DISABLE_DBGPRINT |
| **Destination** | Systemwide registry entry, kernel mode. |

Suppresses debugger output from DbgPrint(), DbgPrintEx(), KdPrint(), and KdPrintEx() calls. When this output is suppressed, it does not automatically appear in the kernel debugger. However, it can still be accessed by using the !dbgprint debugger extension.

**Create kernel mode stack trace database**

| **Abbreviation** | **kst** |
|---|---|
| **Hexadecimal value** | 0x2000 |
| **Symbolic Name** | FLG_KERNEL_STACK_TRACE_DB |
| **Destination** | Systemwide registry entry. |

Creates a run-time stack trace database of kernel operations, such as resource objects and object management operations. This feature works only when using a "checked build," that is, an internal debugging build of the operating system.

**Note**

- This flag is available as a kernel mode setting, but it is not effective in kernel mode because the kernel is already started.

**Create user mode stack trace database**

| **Abbreviation** | **ust** |
|---|---|
| **Hexadecimal value** | 0x1000 |
| **Symbolic Name** | FLG_USER_STACK_TRACE_DB |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Creates a run-time stack trace database in the address space of a particular process (image file mode) or all processes (systemwide).

**Debug initial command**

| **Abbreviation** | **dic** |
|---|---|
| **Hexadecimal value** | 0x4 |
| **Symbolic Name** | FLG_DEBUG_INITIAL_COMMAND |
| **Destination** | Systemwide registry entry, kernel mode. |

Runs Winlogon in the Windows Symbolic Debugger (Ntsd.exe) with the **-d** parameter, which directs its output to the kernel debugger console.

This flag is used for debugging the Client Server Run-time Subsystem (CSRSS), Winlogon.exe, and the Winlogon child processes.

See also: Debug Winlogon, Enable debugging of Win32 subsystem.

**Debug Winlogon**

| **Abbreviation** | **dwl** |
|---|---|
| **Hexadecimal value** | 0x04000000 |
| **Symbolic Name** | FLG_DEBUG_INITIAL_COMMAND_EX |
| **Destination** | Systemwide registry entry, kernel mode. |

Runs Winlogon in the Windows Symbolic Debugger (Ntsd.exe) with the following options:

- **-d** Send output to kernel debugger console.
- **-g** Ignore first breakpoint.
- **-x** Ignore first chance access violations.

See also: Debug Initial Command, Enable debugging of Win32 subsystem.

**Disable heap coalesce on free**

| **Abbreviation** | **dhc** |
|---|---|
| **Hexadecimal value** | 0x00200000 |
| **Symbolic Name** | FLG_HEAP_DISABLE_COALESCING |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Leaves adjacent blocks of heap memory separate when they are freed. By default, the system combines ("coalesces") newly freed adjacent blocks into a single block. Combining the blocks takes time, but reduces fragmentation that might force the heap to allocate additional memory when it can't find contiguous memory.

This flag is used to test optimizing strategies. It is not used for debugging.

**Disable paging of kernel stacks**

| **Abbreviation** | **dps** |
|---|---|
| **Hexadecimal value** | 0x80000 |
| **Symbolic Name** | FLG_DISABLE_PAGE_KERNEL_STACKS |
| **Destination** | Systemwide registry entry, kernel mode. |

Prevents paging of the kernel mode stacks of inactive threads. Generally, the kernel mode stack cannot be paged; it is guaranteed to be resident in memory. However, the system occasionally pages the kernel stacks of inactive threads. This flag prevents these occurrences.

The kernel debugger can provide information about a thread only when its stack is in physical memory. This flag is particularly important when debugging deadlocks and in other cases when every thread must be tracked.

**Disable protected DLL verification**

| **Abbreviation** | **dpd** |
|---|---|
| **Hexadecimal value** | 0x80000000 |

| | |
|---|---|
| **Symbolic Name** | FLG_DISABLE_PROTDLLS |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

This flag appears in Gflags, but it has no effect on the operating system.

**Disable stack extension**

| **Abbreviation** | **dse** |
|---|---|
| **Hexadecimal value** | 0x10000 |
| **Symbolic Name** | FLG_DISABLE_STACK_EXTENSION |
| **Destination** | Image file registry entry. |

Prevents the kernel from extending the stacks of the threads in the process beyond the initial memory committed. This is used to simulate low memory conditions (where stack extensions fail) and to test the strategic system processes that are expected to run well even with low memory.

**Early critical section event creation**

| **Abbreviation** | **cse** |
|---|---|
| **Hexadecimal value** | 0x10000000 |
| **Symbolic Name** | FLG_CRITSEC_EVENT_CREATION |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Creates event handles when a critical section is initialized, rather than waiting until the event is needed. When the system cannot create an event, it generates the exception during initialization and the calls to enter and leave the critical section do not fail.

Because this flag uses a significant amount of nonpaged pool memory, use it only on very reliable systems that have sufficient memory.

**Enable application verifier**

| **Abbreviation** | **vrf** |
|---|---|
| **Hexadecimal value** | 0x100 |
| **Symbolic Name** | FLG_APPLICATION_VERIFIER |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

**Enable bad handles detection**

| **Abbreviation** | **bhd** |
|---|---|
| **Hexadecimal value** | 0x40000000 |
| **Symbolic Name** | FLG_ENABLE_HANDLE_EXCEPTIONS |
| **Destination** | Systemwide registry entry, kernel mode. |

Raises a user mode exception (STATUS_INVALID_HANDLE) whenever a user mode process passes an invalid handle to the Object Manager.

**Enable close exception**

| **Abbreviation** | **ece** |
|---|---|
| **Hexadecimal value** | 0x00400000 |
| **Symbolic Name** | FLG_ENABLE_CLOSE_EXCEPTIONS |

| | |
|---|---|
| **Destination** | Systemwide registry entry, kernel mode. |

Raises a user mode exception whenever an invalid handle is passed to the CloseHandle() interface or related interfaces, such as SetEvent(), that take handles as arguments.

**Note**

- This flag is still supported, but it has been replaced by Enable bad handles detection, which performs a more comprehensive check of handle use.

#### Enable debugging of Win32 subsystem

| | |
|---|---|
| **Abbreviation** | **d32** |
| **Hexadecimal value** | 0x20000 |
| **Symbolic Name** | FLG_ENABLE_CSRDEBUG |
| **Destination** | Systemwide registry entry, kernel mode. |

Runs the Client Server Run-time Subsystem (Csrss.exe) in the Windows Symbolic Debugger (Ntsd.exe) with the following parameters:

- **-d** Send output to kernel debugger console.
- **-p 1** Attach the debugger to already running Csrss process, as identified by its process ID, 1.

This flag is effective only when the Debug Initial Command (dic) or Debug Winlogon (dwl) flag is also set.

#### Enable exception logging

| | |
|---|---|
| **Abbreviation** | **eel** |
| **Hexadecimal value** | 0x00800000 |
| **Symbolic Name** | FLG_ENABLE_EXCEPTION_LOGGING |
| **Destination** | Systemwide registry entry, kernel mode. |

Creates a log of exception records in the kernel run-time library. You can access the log from the kernel debugger.

#### Enable heap free checking

| | |
|---|---|
| **Abbreviation** | **hfc** |
| **Hexadecimal value** | 0x20 |
| **Symbolic Name** | FLG_HEAP_ENABLE_FREE_CHECK |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Validates the heap when it is freed.

See also: Enable heap tail checking, Enable heap parameter checking.

#### Enable heap parameter checking

| | |
|---|---|
| **Abbreviation** | **hpc** |
| **Hexadecimal value** | 0x40 |
| **Symbolic Name** | FLG_HEAP_VALIDATE_PARAMETERS |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Verifies some aspects of the heap whenever a heap API is called.

See also: Enable heap validation on call.

**Enable heap tagging**

| **Abbreviation** | **htg** |
|---|---|
| **Hexadecimal value** | 0x800 |
| **Symbolic Name** | FLG_HEAP_ENABLE_TAGGING |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Assigns unique tags to heap allocations. You can display the tag by using the !heap debugger extension with the **-t** parameter.

For information about the !heap extension, see the Microsoft Windows 2000 Debugging Tools Kit, which is available from the Microsoft Windows Driver Development Kits (DDK) Web site.

See also: Enable heap tagging by DLL.

**Enable heap tagging by DLL**

| **Abbreviation** | **htd** |
|---|---|
| **Hexadecimal value** | 0x8000 |
| **Symbolic Name** | FLG_HEAP_ENABLE_TAG_BY_DLL |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Assigns a unique tag to heap allocations created by the same DLL. You can display the tag by using the !heap debugger extension with the -t parameter.

For information about the !heap extension, see the Microsoft Windows 2000 Debugging Tools Kit, which is available from the Microsoft Windows Driver Development Kits (DDK) Web site.

See also: Enable heap tagging.

**Enable heap tail checking**

| **Abbreviation** | **htc** |
|---|---|
| **Hexadecimal value** | 0x10 |
| **Symbolic Name** | FLG_HEAP_ENABLE_TAIL_CHECK |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Checks for buffer overruns when the heap is freed. This flag adds a short pattern to the end of each allocation. The Windows heap manager detects the pattern when the block is freed and, if the block was modified, the heap manager breaks into the debugger.

See also: Enable heap free checking, Enable heap parameter checking.

**Enable heap validation on call**

| **Abbreviation** | **hvc** |
|---|---|
| **Hexadecimal value** | 0x80 |
| **Symbolic Name** | FLG_HEAP_VALIDATE_ALL |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Validates the entire heap each time a heap API is called.

To avoid the high overhead resulting from this flag, use the HeapValidate() API at critical junctures, such as when the heap is destroyed. However, this flag is useful for detecting random corruption in a pool.

See also: Enable heap parameter checking.

#### Enable loading of kernel debugger symbols

| Abbreviation | ksl |
|---|---|
| Hexadecimal value | 0x40000 |
| Symbolic Name | FLG_ENABLE_KDEBUG_SYMBOL_LOAD |
| Destination | Systemwide registry entry, kernel mode. |

Loads kernel symbols into the kernel memory space the next time the system starts. The kernel symbols are used in kernel profiling and by advanced kernel debugging tools.

#### Enable object handle type tagging

| Abbreviation | eot |
|---|---|
| Hexadecimal value | 0x01000000 |
| Symbolic Name | FLG_ENABLE_HANDLE_TYPE_TAGGING |
| Destination | Systemwide registry entry, kernel mode. |

This flag appears in Gflags, but it has no effect on the operating system.

#### Enable page heap

| Abbreviation | hpa |
|---|---|
| Hexadecimal value | 0x02000000 |
| Symbolic Name | FLG_HEAP_PAGE_ALLOCS |
| Destination | Systemwide registry entry, kernel mode, image file registry entry. |

Turns on page heap debugging, which verifies dynamic heap memory operations, including allocations and frees, and causes a debugger break when it detects a heap error.

This option enables full page heap debugging when set for image files and standard page heap debugging when set in system registry or kernel mode.

- *Full page heap debugging* (for **/i**) places an inaccessible page at the end of an allocation.
- *Standard page heap debugging* (for **/r** or **/k**) examines allocations as they are freed.

Setting this flag for an image file is the same as typing **gflags /p enable /full** for the image file at the command line.

#### Enable pool tagging

| Abbreviation | ptg |
|---|---|
| Hexadecimal value | 0x400 |
| Symbolic Name | FLG_POOL_ENABLE_TAGGING |
| Destination | Systemwide registry entry. |

**Important**

- This flag is permanently set in Windows Server 2003. On these systems, the **Enable pool tagging** check box on the Gflags dialog box is dimmed and commands to enable or disable pool tagging fail.

Collects data and calculates statistics about pool memory allocations. The data is grouped by pool tag value. Several tools that diagnose memory leaks and other kernel pool errors use the resulting data.

Use ExAllocatePoolWithTag or ExAllocatePoolWithQuotaTag to set the tag value. When no tag value is specified (ExAllocatePool, ExAllocatePoolWithQuota), the system creates a tag with the default value of "None." Because data for all

allocations with a "None" tag is combined, you cannot distinguish the data for a specific allocation.

In Windows XP and earlier systems, this flag also directs the system to attach a pool tag even when the pool memory is allocated by using ExAllocatePoolWithQuotaTag. Otherwise, the tag bytes are used to store the quota values. In Windows Server 2003, tag values and quota values are stored in separate fields that are attached to every pool memory allocation.

The **Enable pool tagging** flag is permanently set on all versions of Windows Server 2003. As a result, the system always collects data about pool memory allocations.

**Notes**

- For information on allocating pool memory, see the Windows Driver Development Kit.
- To display the data that the system collects about a tagged allocation, use Poolmon.exe, a tool in the Support Tools folder on Windows XP and Windows Server 2003.
- The description of the **Enable Pool Tagging** flag in Windows XP Support Tools is incomplete. This flag directs the system to collect and process data by tag value.

**Enable system critical breaks**

| **Abbreviation** | **scb** |
|---|---|
| **Hexadecimal value** | 0x100000 |
| **Symbolic Name** | FLG_ENABLE_SYSTEM_CRIT_BREAKS |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

- For per-process (image file) only: Forces a system breakpoint into the debugger whenever the specified process stops abnormally. This flag is effective only when the process calls the RtlSetProcessBreakOnExit() and RtlSetThreadBreakOnExit() interfaces.
- For systemwide (registry or kernel mode): Forces a system breakpoint to the debugger whenever processes that have called the RtlSetProcessBreakOnExit() and RtlSetThreadBreakOnExit() interfaces stop abnormally.

**Load DLLs top-down**

| **Abbreviation** | **ltd** |
|---|---|
| **Hexadecimal value** | 0x20000000 |
| **Symbolic Name** | FLG_LDR_TOP_DOWN |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Loads DLLs at the highest possible address. This flag is used to test 64-bit code for pointer truncation errors, because the most significant 32 bits of the pointers are not zeroes. It is designed for code running on the 64-bit versions of the Windows Server 2003.

**Maintain a list of objects for each type**

| **Abbreviation** | **otl** |
|---|---|
| **Hexadecimal value** | 0x4000 |
| **Symbolic Name** | FLG_MAINTAIN_OBJECT_TYPELIST |
| **Destination** | Systemwide registry entry, kernel mode. |

Collects and maintains a list of active objects by object type (for example, event, mutex, and semaphore). You can use Open Handles (Oh.exe), a tool included in the Windows 2000 Resource Kit, to display the object type lists. Because Oh.exe automatically sets the OTL flag, but does not clear it, you should use Gflags (-otl) to clear the flag.

**Notes**

- The linked lists created when you set this flag use eight bytes of overhead for each object. Remember to clear this flag when your analysis is complete.
- This flag is available as a kernel mode setting, but it is not effective in kernel mode because the kernel is already started.

**Show loader snaps**

| **Abbreviation** | **sls** |
|---|---|
| **Hexadecimal value** | 0x2 |
| **Symbolic Name** | FLG_SHOW_LDR_SNAPS |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

Captures detailed information about the loading and unloading of executable images and their supporting library modules.

- For systemwide (registry or kernel mode): Whenever a driver is loaded, this flag writes the kernel contents to the kernel debugger console. This feature works only when using a "checked build," that is, an internal debugging build of the operating system.
- For per-process (image file): Whenever a DLL is loaded, this flag writes the loader contents (and data related to DLL loading) to the program debugger console.

**Stop on exception**

| **Abbreviation** | **soe** |
|---|---|
| **Hexadecimal value** | 0x1 |
| **Symbolic Name** | FLG_STOP_ON_EXCEPTION |
| **Destination** | Systemwide registry entry, kernel mode, image file registry entry. |

The kernel breaks into the kernel debugger whenever a kernel mode exception occurs. The system passes all first chance exceptions (except for STATUS_PORT_DISCONNECT) with a severity of Warning or Error to the debugger before passing them to a local exception handler.

**Stop on hung GUI**

| **Abbreviation** | **shg** |
|---|---|
| **Hexadecimal value** | 0x8 |
| **Symbolic Name** | FLG_STOP_ON_HUNG_GUI |
| **Destination** | Kernel mode |

This flag appears in Gflags, but it has no effect on the operating system.

# Pviewer Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Pviewer.exe: Process Viewer**
This GUI tool displays information about a running process and allows you to stop processes and change process priority.

### Note

- Process Viewer is similar to Pview.exe, but it can view processes on remote computers.

**Corresponding UI**
Process Viewer provides its own user interface.

**Concepts**
A process is a running instance of an application or executable file, along with all the system resources that have been allocated to that instance. In general, a process is equivalent to a single application or service; for example, Microsoft Word runs in the Winword.exe process.

Each process is composed of a set of threads. A thread is a unit of work that runs simultaneously with other units of work on the computer; each process must have at least one thread.

Threads represent the basic unit of execution in Windows Server 2003. When a thread starts, the Windows Server 2003 Memory Manager allocates enough physical memory and page file space to allow the thread to run. While a thread is running, it can request additional memory to enable it to complete its task. When a thread ends, it releases the memory it was using back to the Memory Manager for reallocation.

Memory is also allocated based on the number of threads spawned by each process. For example, consider a computer running two processes. Process A has 5 threads and Process B has 15 threads. Assuming the two processes have equal priority, Process A is allocated 25 percent (5 / 20) of the memory being used and Process B is allocated 75 percent (15 / 20) of the memory being used.

This method of thread allocation helps ensure that applications receive the memory they need. However, this same method can also result in memory leaks. A memory leak occurs when an application receives an increasing amount of memory but does not relinquish that memory back to the Memory Manager. This typically happens when a process creates threads but does not destroy those threads when they have finished their work.

**System Requirements**
The following are the system requirements for Process Viewer:

- Windows XP Professional or Windows Server 2003

### File required

- Pviewer.exe

# Pviewer Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**PViewer Remarks**

The **Process Viewer** dialog box contains the following elements:

**Memory Detail**

Click this button to see details about memory use for the selected process.

**Kill Process**

Click this button to stop the selected process.

**Caution**

- Do not attempt to stop processes required for running Windows 2000 or Windows NT. Make sure you understand which program owns a process before attempting to stop it.

**Computer**

Shows the name of the computer whose processes are currently displayed (default=local computer). To view the processes on a remote machine, type the UNC path to the computer in the space provided and then click the **Connect** button.

**Process**

The name of the process followed, in parentheses, by the process ID number in hexadecimal format.

**Privileged Time**

Privileged Time is the percentage of elapsed time that the threads of the process have been executing code in Privileged Mode, a processing mode that allows direct access to hardware and all memory. Privileged Mode is designed for operating system components, but Windows system services often run in Privileged Mode to gain access to data that is not accessible to User Mode threads. This value does not include Privileged Time that Windows components spend on behalf of the process.

**User Time**

User Time is the percentage of elapsed time that the threads of the process execute code in User Mode. User Mode is a restrictive processing mode designed for applications and environment subsystems. Application and system service threads spend most of their time executing in User Mode, but the operating system switches threads to Privileged Mode to gain access to operating system services.

**Process Memory Used**

The current number of bytes in the Working Set of this process. The Working Set is the set of memory pages touched recently by the threads in the process. If free memory in the computer is above a certain threshold, pages are left in the Working Set of a process even if they are not in use. When free memory falls below the threshold, pages are trimmed from Working Sets. If they are needed, they will then be soft-faulted back into the Working Set before they leave main memory.

**Process Priority**

The current base priority of this process. Threads within a process can raise and lower their own base priority relative to the base priority of the process.

**Threads**

Thread State is the current state of the thread. It is 0 for Initialized, 1 for Ready, 2 for Running, 3 for Standby, 4 for Terminated, 5 for Wait, 6 for Transition, 7 for Unknown. A Running thread is using a processor; a Standby thread is about to use one. A Ready thread is waiting for a processor because none are free. A thread in Transition is waiting for a resource in order to execute, such as waiting for its execution stack to be paged in from disk. A Waiting thread has no use for the processor because it is waiting for a peripheral operation to complete, or a resource to become free.

**Thread Priority**

The current base priority of this thread. The system might raise the thread's dynamic priority above the base priority if the thread is handling user input, the priority can be lowered agian when a user is no longer interacting with the thread. Windows will never lower the thread below the base priority level.

**Thread Information**

**Context Switches** is the rate of switches from one thread to another in a second. Thread switches can occur either inside of a single process or across processes. A thread switch can be caused either by one thread asking another for information, or by a thread being preempted by another, higher-priority thread becoming ready to run.

# Printer and Fax Management Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Printer and Fax Management Tools**
Tools in this category are used to manage the following Windows features:

- Printers
- Print Services

### Notes

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Process and Service Management Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Process and Service Management Tools**
Tools in this category are used to manage the following Windows features:

- System or Network Monitoring
- Performance Counters
- Event Logs

**Notes**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Memsnap Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Memsnap.exe: Memory Profiling Tool**
This command-line tool takes a snapshot of the memory resources being consumed by all running processes and writes this information to a log file.

MemSnap logs system memory usage to a log file with the default name of Memsnap.log. However, any file name can be chosen by specifying it at the command line when starting the tool.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Memory leaks occur when programs allocate memory but neglect to free it when the memory is no longer being used.

For more information about memory management and memory leaks, search the Microsoft Developer Network.

**System Requirements**
The following are the system requirements for MemSnap:

- Windows XP Professional or Windows Server 2003

**File Required**

- Memsnap.exe

# Memsnap Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MemSnap Examples**

**Example 1: Generate snapshot of memory resources**

To generate a snapshot of memory resources being consumed, type the following at the command line:

```
memsnap /m memsnap.log
```

This command sends the memory data to the memsnap.log file in the in the current directory.

**A sample memsnap log**

```
Process ID         Proc.Name Wrkng.Set PagedPool  NonPgdPl  Pagefile    Commit

**Example 3: Analyzing memsnap logs**

The /a parameter generate an analysis of memsnap logs created with the /m parameter.

```
memsnap /a memsnap.log
```

This command sends the memory data to the Memsnap.txt file in the C:\Data directory.

**Sample memsnap /t output**

```

# Memsnap Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MemSnap Syntax**

MemSnap uses the following syntax:

- **memsnap** [**/m**] [**/p**] [**/a**] [**/ah**] *logfile* [**/?**]

**Parameters**

***/m logfile***

This parameter displays a snapshot of process information in the form of a log file. The default file name for the log file is memsnap.log in the current directory. If the file does not exist, it is created; if the file exists, the information is appended to it.

***/p logfile***

This parameter displays a snapshot kernel pool memory information. If the file does not exist, it is created; if the file exists, the information is appended to it.

***/a logfile***

This parameter analyzes a *logfile* for leaks and prints the output on the screen. The logfile to analyze is required with this parameter.

**/ah**

Same as '**/a**' but generates HTML tables.

**/?**

Displays command-line help.

# Poolmon Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Poolmon.exe**
This command-line tool displays data that the operating system collects about memory allocations from the system paged and non-paged kernel pools, and the memory pools used for Terminal Services sessions. The data is grouped by pool allocation tag. Poolmon is most often used to detect memory leaks.

Poolmon displays the following data for allocations grouped by tag.

- The number of allocations and frees (and allocations minus frees).
- The change in the number of allocations and frees between updates.
- The total size of allocations by tag, in bytes used, and the average allocation size.
- The change in bytes used between updates.
- The drivers that assign the tag value.

Poolmon also displays general memory information, including total and available memory, page faults, kernel physical memory, committed memory and the commit limit, peak memory, and the size of the paged and non-paged pools.

Using Poolmon, you can also:

- Sort and reconfigure the Poolmon display while it is running.
- Save configured data to a file.
- Generate a file of the tags used by drivers on the local system (32-bit system only).

### Note

- To use Poolmon on Windows XP and earlier systems, you must enable *pool tagging*, the feature that collects and processes data about memory allocations. On Windows Server 2003, pool tagging is permanently enabled. For more information, see "About Pool Tagging" in Poolmon Remarks.

**Corresponding UI**
This tool does not have a corresponding user interface.

**Concepts**
Memory leaks occur when programs allocate memory but do not free it when the memory is no longer being used.

To track kernel pool memory, the system attaches a label called a *tag* to each allocation and lets the allocating driver set the value of the tag. When pool tagging is enabled, the system collects data about the allocations, sorted by the tag value. You can use Poolmon to display the data that the system collected for all allocations, or for allocations with a particular tag.

In addition to the system memory pools, there is a paged pool for each Terminal Services session on the system. When a system is configured as a Terminal Server, (formerly known as Terminal Services in Application Server mode), the kernel-mode portion of the Win32 subsystem allocates memory from the session pool for data structures used in the session. Poolmon also displays those allocations from the Terminal Services session pools, individually and collectively, sorted by tag value.

For more information about memory management and memory leaks, search the Microsoft Developer Network.

**System Requirements**

- Windows XP Professional or Windows Server 2003

## Notes

- The system allocates memory from Terminal Services session pools only when the system is configured as a Terminal Server. Terminal Server is available on all Windows Server 2003 operating systems, except for Windows Server 2003, Web Edition.

- Poolmon cannot generate a Localtag.txt file on 64-bit versions of Windows Server 2003. As a result, the **/c** parameter and its functionality are available only on 32-bit versions of Windows.

### Files required

- Poolmon.exe

- msdis130.dll

- msvcp70.dll

- msvcr70.dll

# Poolmon Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Poolmon Remarks**
**Enabling Pool Tagging**
Before running Poolmon on Windows XP and earlier systems, you must use Gflags.exe to enable pool tagging.

### Important

- Pool tagging is permanently enabled on Windows Server 2003.

**To enable pool tagging by using a dialog box:**

1. At the command line, or in the Run dialog box, type **Gflags**.
2. Check the **Enable Pool Tagging** check box.
3. Restart the computer.

**To enable pool tagging by using the command line:**

1. Type the following at the command line: `gflags /r +ptg`
2. Restart the computer.

**About Pool Tagging**
The pool tagging feature collects and calculates statistics about pool memory sorted by the tag value of the allocation.

To set a tag value, use **ExAllocatePoolWithTag** or **ExAllocatePoolWithQuotaTag** to allocate pool memory. If you do not assign a tag value (**ExAllocatePool**, **ExAllocatePoolWithQuota**), the system still creates a tag, but it assigns the default tag value, "None". As a result, you cannot distinguish the statistics for your allocation from that of other pool memory allocations.

For more information on pool tagging, see Gflags Flag Reference. For more information about pool tags, see the Windows Driver Development Kit.

**About Poolmon**
### Command-line Syntax and Running Syntax

You can configure the Poolmon display at the command line when you start Poolmon or while Poolmon is running. The command line parameters are described in the "Command-line Syntax" section of Poolmon Syntax. The keys that you press to configure the Poolmon display while it is running are described in the "Running Syntax" section of Poolmon Syntax.

### Accumulated Values

The data that Poolmon displays is collected and calculated by the system whenever pool tagging is enabled. The values for allocations, frees, and bytes used accumulate from the time that the system starts, and increase monotonically until the system is restarted. If a driver or component is started independently of the system, the values are accumulated from the last time that the driver or component started and reset only when the driver or system are restarted.

### Update Rate

Poolmon updates its display every five seconds. You cannot change the update rate.

### Saving Poolmon Output

You can add the **/n** parameter to a command to save a snapshot of the Poolmon output to a file. Because the data saved to the file is static, the columns that show the change in values between updates are not included in the file.

### Terminal Server Session Support

Poolmon can display allocations from the Terminal Services session pools, as well as the system pools. When the computer is configured as a Terminal Server, the kernel-mode portions of the Win32 subsystem allocate memory from the session pools. Otherwise, the system allocates pool memory for Terminal Services from the system pool.

Terminal Server, previously known as Terminal Services in Application Server mode, is available on all Windows Server 2003 operating systems, except for Windows Server 2003, Web Edition.

Poolmon can display allocations from a particular session pool, or from all session pools collectively. To display only the pool for a particular session, you specify the session ID. To find a Terminal Server session ID, use Task Manager. After Task Manager opens, click the Users tab to see the session IDs.

To display session IDs in Task Manager:

- From the **View** menu, click **Select Column**, and then select the **Session ID** check box.

### Viewing Driver Names

Poolmon has two features that display the names of drivers that assign each pool tag.

- **Local drivers**. The **/c** parameter displays the names of drivers on the local computer that assign the pool tag. The data for this feature comes from Localtag.txt, a file that Poolmon generates automatically when you use the **/c** parameter. Poolmon generates a new Localtag.txt file when it cannot find a Localtag.txt file in the current directory and you do not specify an alternate file.

- **Windows components and other drivers**. The **/g** parameter displays the names of Windows components and commonly used drivers that assign the pool tag. The data for this feature comes from Pooltag.txt, a file provided by Microsoft that is installed in the Support Tools folder with Poolmon.exe.

To display the driver name, Poolmon adds a column called "Mapped_Driver" to the right edge of the display and populates the column with data from Localtag.txt (for **/c**) or Pooltag.txt (for **/g**). The "Mapped_Driver" column appears only when you use the **/c** or **/g** parameters. You can use both the **/c** and **/g** parameters in a single command. In response, Poolmon displays the data from both files in the "Mapped_Driver" column.

You can also use **/c** and **/g** to display data from alternate files in the "Mapped_Driver" column by specifying a file name and location with either parameter (**poolmon /c***filename* | **poolmon /c***filename*). In that case, the **/c** and **/g** parameters behave identically and can be used interchangeably.

### Note

- Poolmon cannot generate a Localtag.txt file on 64-bit versions of Windows Server 2003.

### Updating Pooltag.txt

Poolmon can display the name of the Windows component or commonly used driver that assigns each pool tag. This feature uses data from Pooltag.txt, a file installed with Poolmon and with Windows debuggers. Occasionally, Microsoft updates this file. To check for updates, go to the Microsoft Product Support Services Web page, http://support.microsoft.com and search for "Pooltag.txt."

#### About the Poolmon Display

Poolmon displays columns of data about pool memory allocations in a command window. Use the arrow keys, page up and page down keys to scroll through the data. Poolmon updates the display every five seconds. You cannot change the update rate.

### Note

- To see the entire Poolmon display, the command window screen must be at least 80 characters wide (width=80) and at least 53 rows high (height=53); and the command window screen buffer must be at least 500 characters wide (width=500) and at least 2000 rows high (height=2000). Otherwise, the display might be truncated.

The following table describes the columns in the Poolmon display

| Column name | Description |
|---|---|
| Tag | The 4-byte tag assigned to the pool allocation. |
| Type | Whether the memory allocations are in paged or non-paged bytes. |
| Allocs | The number of allocations. |
| ( ) | The change in the number of allocations since the last update. |
| Frees | The number of frees. |
| ( ) | The change in the number of allocations since the last update. |
| Diff | The number of allocations minus the number of frees. |
| Bytes | The size of the allocations, in bytes used. |
| ( ) | The change in the allocation size since the last update. |
| Per Alloc | The value of Bytes divided by the value of Allocs. |
| Mapped_Driver | The local drivers (**/c**) and other commonly used drivers and system components (**/g**) that assign the pool tag value. This column appears only when you use the **/c** or **/g** parameters. |

The following sample Poolmon output is sorted by number of allocations. (To sort your display this way, start Poolmon with the /a parameter.)

# Poolmon Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Poolmon Examples**
Before running any of these examples on Windows XP and earlier systems, use Gflags.exe to enable pool tagging and then restart the system to make the change effective.

**Example 1: Display and Sort Poolmon Output**
This example describes various ways to configure the Poolmon display. By default, Poolmon displays all kernel memory allocations in alphabetical order by tag value. You can modify the sort order of the display at the command line or while Poolmon is running.

The following command starts Poolmon.

**poolmon**

The following command starts poolmon and sorts the display by number of frees.

**poolmon /f**

While poolmon is running, you can use the parameters in the running syntax to change the display. For example, to sort the display by number of bytes used, press **b** or **u**. To sort by bytes per allocation, press **m**.

The following command starts Poolmon and displays only allocations from the non-paged pool.

**poolmon /p**

While Poolmon is running, you can use press **p** to toggle between allocations from the paged pool, the non-paged pool, or both.

To display data for allocations with a particular tag, use the **/i** parameter. The following command displays allocations with the AfdB tag (the tag used by Afd.sys for data buffers).

**poolmon /iAfdB**

To exclude allocations with a particular tag, use the **/x** parameter. The following command displays all allocations that do not have the AfdB tag.

**poolmon /xAfdB**

You can use the wildcard character (*) and question mark (?) to specify groups of tags. The following command lists all allocations with tags beginning with Afd, the tag used by Afd.sys.

**poolmon /iAfd***

You can also sort the Poolmon display by the change in a value between updates. The **/(** parameter places Poolmon in "sort-by-change" mode.

The following command displays allocations with tags beginning with Afd, and sorts by the change (**/)**) in allocations (**/a**).

**poolmon /iAfd* /( /a**

The **/(** parameter is a toggle. When Poolmon is in sort-by-change mode, it continues to interpret all sort commands as commands to sort by the change in the value, until you press **(** again. If, for example, after using the previous command to start Poolmon, you then pressed **f**, Poolmon would sort the display by the *change in* the number of frees. To revert to sorting by the primary value while Poolmon is running, press **(** again.

**Example 2: Display Driver Names**
You can use the /g parameter when starting Poolmon to display the names of Windows components and commonly used drivers that assign each tag. If you find a problem in allocations with a particular tag, this feature helps you identify the offending component or driver. The components and drivers are listed in the Mapped_Driver column, on the right-most side of the display. The data for the Mapped_Driver column comes from Pooltag.txt, a file installed with Poolmon.

The following command displays memory allocated with tags that begin with NtF. (It uses the question mark character (?) as a

wildcard.) Using the **/g** parameter adds the Mapped_Driver column.

**poolmon /iNtF? /g**

The resulting display lists allocations with tags beginning in NtF. The right-most column in the display, Mapped_Driver, shows that the memory was allocated by Ntfs.sys, the driver for the NTFS file system. In this case, the display is even more specific, because Pooltag.txt includes the source files for Ntfs allocations.

```

-  ViewSup.c]
```

Pooltag.txt is extensive, but it is not a complete list of all tags that can be used on the system. When a tag used in the system is not included in Pooltag.txt, Poolmon displays "Unknown driver" in the Mapped_Driver column for the tag. When this occurs, you can use the **/c** parameter to search the drivers on the local system and determine whether they use assign the tag.

The following examples demonstrate this method.

The following command uses the **/i** tag to list allocations with tags that end in MEM. The **/g** parameter adds the driver name to the display from the Pooltag.txt file.

**poolmon /i?MEM /g**

The resulting display lists the allocations with tags ending in MEM. However, because the MEM tags are not included in Pooltag.txt, "Unknown Driver" appears in the Mapped_Driver column in place of the driver name.

```
 Tag  Type        Allocs          Frees      Diff   Bytes      Per Alloc
Mapped_Driver

 1MEM Nonp       1 (   0)         0 (   0)     1    3344 (     0)   3344   Unknown
Driver
 2MEM Nonp       1 (   0)         0 (   0)     1    3944 (     0)   3944   Unknown
Driver
 3MEM Nonp       3 (   0)         0 (   0)     3     248 (     0)     82   Unknown
Driver
```

In this case, you can use the **/c** parameter to compile a list of local drivers and the tags they assign and then display the names of local drivers in the Mapped_Driver column.

The following command starts Poolmon. It uses the **/i** parameter to list allocations with tags ending in MEM, and the **/c** parameter to display the local drivers that assign the tags.

**poolmon /i?MEM /c**

If you do not specify a local tag file and Poolmon cannot find a Localtag.txt file on a 32-bit system, it creates one, as shown in the following screen messages. (Poolmon cannot generate a local tag file on 64-bit systems.)

```
d:\tools\Poolmon>poolmon /?MEM /c
Poolmon: No localtag.txt in current directory
Poolmon: Creating localtag.txt in current directory......
```

The resulting display, which uses the content from the newly created localtag.txt file, shows the local driver names in the Mapped_Driver column.

```
 Memory:  260620K Avail:   57840K  PageFlts:   162   InRam Krnl: 2116K P:19448K
 Commit: 244580K Limit: 640916K Peak: 265416K            Pool N: 8496K P:32904K
 System pool information
 Tag  Type     Allocs            Frees            Diff   Bytes      Per Alloc
Mapped_Driver

 1MEM Nonp          1 (   0)         0 (   0)        1    3344 (     0)   3344
[el90xbc5]
 2MEM Nonp          1 (   0)         0 (   0)        1    3944 (     0)   3944
[el90xbc5]
 3MEM Nonp          3 (   0)         0 (   0)        3     248 (     0)     82
[el90xbc5]
```

For a comprehensive driver name display, you can combine the **/c** and **/g** parameters in a command. (The order of parameters does not change the output.) The following command lists allocations for tags beginning with Ip. It uses the **/c** parameter, which adds contents of the Localtag.txt file to the Mapped_Driver column, and the **/g** parameter, which adds the contents of the Pooltag.txt to the Mapped_Driver column.

**poolmon /iIp** /c /g**

In the resulting display, the Mapped_Driver column contains data from both the localtag.txt and pooltag.txt files.

```

**Example 3: Detect Memory Leakage**

This example outlines a procedure for using Poolmon to detect a memory leak.

1. Start Poolmon in default mode (no additional parameters).

2. Press P twice to display allocations from only the paged pool. (The P key toggles the display between paged, non-paged, and both.)

3. Press B to sort the Bytes column in descending order.

4. Let Poolmon run for a few hours. Because starting Poolmon changes the data, you must let it run until it reaches a steady state before the data is reliable.

5. Save the information generated by Poolmon, either as a screenshot, or by copying it from the command window and pasting it into Notepad.

6. Returning to Poolmon, press P twice again, this time to display only allocations from the non-paged pool.

Repeat steps 3, 5 and 6 approximately every half-hour for at least two hours.

When data collection is complete, examine the **Diff** (allocations minus frees) and **Bytes** (number of bytes allocated minus number of bytes freed) values for each tag, and note any that continually increase. Next, stop Poolmon, wait for a few hours, and then restart Poolmon. Examine the allocations that were increasing, and determine whether the bytes are now freed. Allocations that have still not been freed, or have continued to increase in size are the likely culprits.

**Example 4: Examine a Pool Memory Leak**
The following example demonstrates using Poolmon to investigate a pool memory leak from a suspected printer driver. In the example, Poolmon displays data that the system collects about memory allocations with the Dsrd tag, the tag that the printer drivers assign.

The Drsd tag is assigned to pool memory allocated by the **Drvalloc()** function in the Rasdd.dll and Hprasdd.dll files. Printer drivers use this function when allocating Graphical Device Interface (GDI) objects and associated memory. If a printer driver has an object leak, the memory allocated with the Drsd tag will also leak.

### Note

- Before running the steps in this example, ensure that the printer you are using will not be interrupted (if, for example, it is a network printer), until you are finished, otherwise the results may be invalid.

1. At the command line, type the following:

   ```
   poolmon /iDrsd
   ```

   This command directs Poolmon to display information for allocations with the Dsrd tag. (Pool tags are case-sensitive, so be sure to type the command exactly as shown.)

2. Record the values in the **Diff** and **Bytes** columns. In the following sample display, the value of **Diff** is 21 and the number of bytes is 17472.

   ```
   Memory:  130480K Avail:   91856K  PageFlts:  1220   InRam Krnl: 2484K P: 7988K
   Commit:  30104K Limit: 248432K Peak:  34028K            Pool N: 2224K P: 8004K
   Tag  Type        Allocs           Frees           Diff  Bytes           Per Alloc

   Drsd Paged       560 ( 177)       539 ( 171)       21   17472 (  4992)    832
   ```

3. Send a job to the printer, wait briefly for the system to return to normal, and then record the values for the **Diff** and **Bytes** columns.

   ```
   Memory:  130480K Avail:   91808K  PageFlts:  1240   InRam Krnl: 2488K P: 7996K
   Commit:  30152K Limit: 248432K Peak:  34052K            Pool N: 2224K P: 8012K
   ```

```
Tag  Type        Allocs           Frees           Diff  Bytes          Per Alloc

Drsd Paged       737 (   0)       710 (   0)       27   22464 (     0)    832
```

When the memory management for the printer driver is working properly, the value of **Diff** should return to its original value of 21 after printing. However, as the preceding output illustrates, the value of **Diff** rose to 27, and the number of bytes rose to 22464. The difference between the initial and subsequent output means that six Drsd blocks, with a total of 4992 bytes, leaked during printing.

**For More Information**

If you believe you have identified a leaking driver, you may be able to find more information by visiting the Product Support Services Web site and searching the Knowledge Base for relevant articles.

**Example 5: Monitor a Terminal Services Session**

This example shows several ways to display allocations from the Terminal Services session pools on the system. It demonstrates the use of the **/s** command-line parameter, and the **s**, TSSessionID, and **i** running parameters.

The following command displays allocations from all of the Terminal Services session pools. In this example, the local computer, which is configured as a Terminal Server, is hosting the sessions, and client computers are using the Remote Desktop feature to connect to the host.

**poolmon /s**

In response, Poolmon displays allocations from all session pools. Note the **All sessions pool information** title in the header.

To help determine which drivers and components are allocating memory from the session pool, add the **/g** parameter, as shown in the following command. The **/g** parameter adds a Mapped_Driver column listing the Windows components and drivers that assign each tag.

**poolmon /s0 /g**

```

You can also configure the Terminal Services session pool display while Poolmon is running. The following table shows a series of running commands, in the order in which they are typed, and the resulting Poolmon display.

The series begins with a command to start Poolmon. All other parameters are typed while Poolmon is running.

**poolmon**

| Key | Result | Description |
|---|---|---|

| | | |
|---|---|---|
| s | Displays all session pools. | |
| s | Displays the system pools. | The **s** parameter toggles the display between the system pools and the Terminal Services session pools. |
| 0 | Displays session 0 pool. | You can type a session ID while displaying the system pools. |
| 7 | Displays session 7 pool. | |
| a | Displays pool allocations for session 7, sorted by number of allocations | All standard running parameters are valid for session pool displays. |
| 0 | Displays allocations for session 0, sorted by number of allocations. | Session and sorting options are retained until changed. |
| s | Displays the system pools. | |
| s | Displays allocations for session 0, sorted by number of allocations. | Session option is retained. |
| 10 | Displays Session 1 allocations, and then displays Session 0 allocations. | Without **i**, you can enter only session IDs 0 - 9. |
| i | Prompts for a Terminal Services session ID. | |
| 10 | Displays Session 10 allocations. | |
| i | Prompts for a Terminal Services session ID. | To display all session pools, press **i** and then press **Enter**. |
| Enter | Displays all session pools. | |

Only systems configured as a Terminal Server allocate memory from the session pool. If you use Poolmon to display the session pool on a computer that is not a Terminal Server, or if you type a session ID that does not exist on the system, Poolmon does not display any allocations. Instead, it displays only the headings with general memory data.

The following command displays allocations from all Terminal Services session pools.

**poolmon /s**

The following figure shows the Poolmon display that would result, if the **/s** command were submitted to a computer running Windows XP Professional, that could not be configured as a Terminal Server.

```

# Poolmon Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Poolmon Syntax**
Poolmon has two separate, but related, sets of parameters. You use one parameter set at the command line when starting Poolmon; you use the other parameter set while running Poolmon.

**Command-line Syntax**
Poolmon uses the following syntax at the command line:

**poolmon**[**/i***Tag*][**/x***Tag*][**/c** [*LocalTagFile*]][**/g** [*PoolTagFile*]][**/s**[*TSSessionID*]][[**/p** [**/p**]][**/e**][**/(** | **/)**][**/t** | **/a**| **/f**| **/d** | **/b**| **/m**][**/l**] [**/n** [*File*]][**/?** | **/h**]

**Parameters**

**/i *Tag***

Displays only the allocations with the specified tag. Tags are case sensitive. Do not type a space between the **/i** and the tag.

You can use the wildcard character (*) to represent zero or more instances of any character and the question mark character (?) to represent one instance of any character. Do not begin a tag with the wildcard character.

**/x *Tag***

Displays all allocations *except* those matching the specified tag. Tags are case sensitive. Do not type a space between the **/x** and the tag.

You can use the wildcard character (*) to represent zero or more instances of any character and the question mark character (?) to represent one instance of any character. Do not begin a tag with the wildcard character.

**/c[ *LocalTagFile*]**

Adds a column to the display (Mapped_Driver) listing the drivers on the local computer that assign each tag.

*LocalTagFile* is the name and location of a formatted text file that lists the drivers on the local computer and the tag values that they assign. This file is the data source for the Mapped_Driver column when you use the **/c** parameter. The default is Localtag.txt.

Poolmon can generate a local tag file for you. If you use the **/c** parameter and do not specify an alternate local tag file, and Poolmon does not find a Localtag.txt file in the current directory, it scans the drivers on the local computer (C:\Windows\System32\Drivers*.sys) and generates a Localtag.txt file.

**Notes**

- Poolmon cannot generate a Localtag.txt file on 64-bit versions of Windows Server 2003. As a result, the **/c** parameter and its functionality are available only on 32-vit versions of Windows.
- You can use the **/c** and **/g** parameters in the same command. If you do, the Mapped_Driver column displays data from both the local tag and pool tag files.

**/g[ *PoolTagFile*]**

Adds a column to the display (Mapped_Driver) listing Windows components and commonly used drivers that assign each tag.

*PoolTagFile* is the name and location of a formatted text file that lists the names of Windows components and commonly used drivers and the tag values they assign. This file is the data source for the Mapped_Driver column that appears when you use the **/g** parameter. The default is pooltag.txt, a file provided by Microsoft. Pooltag.txt is installed when you install Support Tools or a Windows kernel debugger.

**Note**

- You can use the **/c** and **/g** parameters in the same command. If you do, the Mapped_Driver column displays data from both the local tag and pool tag files.

**/s[ *TSSessionID*]**
Displays allocations from the Terminal Services session pools. If you specify a Terminal Service session ID, Poolmon displays the allocations from the memory pool for that session. Do not type a space between the **/s** parameter and the session ID.

**Note**

- The system allocates memory from Terminal Services session pools only when the computer is configured as a terminal server. For more information, see "Terminal Services Session Support" in Poolmon Remarks.

**/p**
Displays only allocations from the non-paged pool.

**/p /p**
Displays only allocations from the paged pool.

**/e**
Displays pool totals. The totals appear at the bottom of the display.

**/(or /)**
Turns on the sort-by-change mode. With **/(** or **/)**, Poolmon sorts by the change in a value (allocations, frees, bytes), instead of the value. The change in each value is displayed in a parentheses after the value.

Use with **/a**, **/f**, **/b** or **/m**. For example, **poolmon /a** sorts the display by number of allocations, while **poolmon /( /a** sorts the display by the change in the number of allocations.

**/t**
Sorts alphabetically by tag name. **/t** is the default.

**/a**
Sorts tags by the number of allocations.

**/f**
Sorts tags by the number of frees.

**/d**
Sorts tags by size difference between allocations and frees.

**/b**
Sorts tags by bytes used.

**/m**
Sorts tags by bytes per allocation.

**/l**
Turns highlighting off. By default, Poolmon highlights values that have changed since the last update.

**/n[ *File*]**
Saves a snapshot of the Poolmon output to a file, instead of displaying it in a command window. You can include other command-line parameters to configure the output.

*File* specifies the name and location of the snapshot file. The default is poolsnap.log.

**/?or /?**
Displays command-line syntax.

**Running Syntax**
While Poolmon runs, you can use the following keys to change the display:

▸[**p**][**(** | **)**][**s**][*TSSessionID*][**i**][**l**][**e**][**t**][**a**][**f**][**d**][**b** | **u**][**m**][**h** | **?**]

**p**
Toggles the display between paged allocations, non-paged allocations, and both.

**(or )**
Toggles display between sorting by value (allocations, frees, bytes) and sorting by change in value.

**s**

Toggles the display between the system pools and the Terminal Services session pools.

***TSSessionID***
Displays allocations from the specified Terminal Services session pool. *TSSessionID* represents the session ID of a Terminal Services session. It must be an integer from 0 - 9. To display all session pools or to enter session IDs greater than 9, use the **i** parameter.

**i**
Prompts you for the session ID of a Terminal Server session.

To respond to the prompt:

- To display allocations from all Terminal Services session pools, press Enter.
- To display allocations from a particular Terminal Services session pool, type a session ID.

**l**
Toggles highlighting of changed lines on and off.

**e**
Toggles pool totals on and off. Totals appear at the bottom of the display.

**t**
Sorts by tag name. **t** is the default.

**a**
Sorts by number of allocations. When used with **(**, **a** sorts by the change in allocations.

**f**
Sorts by number of frees. When used with **(**, **f** sorts by the change in frees.

**d**
Sorts by difference between allocations and frees.

**bor u**
Sorts by bytes used. When used with **(**, **b** and **u** sort by the change in bytes used.

**m**
Sorts by bytes per allocation. When used with **(**, **m** sorts by the change in bytes per allocations.

**hor ?**
Displays help including command line syntax, running syntax, and a description of the output. To close help, press the ESC key.

# Remote Administration Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Remote Administration Tools**
Tools in this category are used to manage the following Windows features:

- Emergency Management Services
- Remote Desktop
- Telnet
- Terminal Services

**Note**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Remote Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote.exe: Remote Command Line**
This command-line tool allows you to run command-line programs on remote computers. You can also use Remote to distribute the processing requirements for a specified task across several computers.

Remote.exe provides remote network access by means of named pipes to applications that use STDIN and STDOUT for input and output. Users at other computers on a network or users connected by a direct-dial modem connection can either view the remote session or enter commands themselves.

### Notes

- You must run Remote from the command window.
- Remote cannot be used to control graphical Windows-based applications.

### Security Remark

- Remote performs no security authorization. It permits anyone running Remote.exe Client to connect to your remote server. Because of this, the account under which the remote server was run is open to anyone who connects.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Remote administration is a method of managing one or more remote computers from a single location. In a large organization, you can use remote administration to centrally manage hundreds or even thousands of computers located in other buildings or even in other cities. In a small organization, you can use remote administration to manage a single server located in an adjacent office.

**System Requirements**
The following are the system requirements for Remote:

- Windows XP Professional or Windows Server 2003

**File Required**

- Remote.exe

# Remote Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Remarks**
Remote Limitations

In addition to exposing your server to unauthorized users, Remote has the following limitations:

- Only non–MS-DOS-based programs that use STDIN/STDOUT/STDERR for input/output will function when redirected across the network.
- Programs that use the Win32 Console API do not work correctly.
- MS-DOS-based programs do not work.
- Generally, any programs that use on-screen character mode windows or cursor manipulation (such as screen-mode editors) do not work.

Using Remote

**To use Remote**

1. Start the server by running **remote /s** on the computer where you want to run the selected program.
2. Connect to the server from another computer by running **remote /c**.

# Remote Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Examples**

**Example 1: Interact with a batch program running on a remote server**

In this example, you must first create a batch program on the server (Remoteserver3 in this case). To create the batch program, you can use any text editor, such as Notepad, or the `copy con` command at the command prompt as follows:

```
copy con testprog.bat
pause
schtasks /?
pause
^Z
```

Press CTRL+Z (`^Z`) to end the `copy con` session and save the Testprog.bat file in the default directory.

**On the server**

To start the remote session at the server, type the following on the server at the command line:

```
remote /s "testprog.bat" testsession1
```

You will see output similar to the following, confirming that the remote server received the command to continue executing the batch file Testprog.bat:

```
C:\Program Files\Support Tools>remote /s "testprog.bat" "testsession1"
****************************************
************     REMOTE    ************
************     SERVER    ************
****************************************
To Connect: Remote /C REMOTESERVER3 "testsession1"

C:\Program Files\Support Tools>pause
Press any key to continue . . .
```

This indicates that Testprog.bat started, then paused, waiting for any key to be pressed before continuing as instructed in the batch program.

**On the client**

On the client computer, open a command window and type the following at the command prompt:

```
remote /c remoteserver3 "testsession1"
```

On the client computer, you will see output confirming that the remote server received the command to continue executing the batch file Testprog.bat, as follows:

```
C:\Program Files\Support Tools>remote /c remoteserver3 "testsession1"
****************************************
************     REMOTE    ************
************     CLIENT    ************
****************************************
Connected...

C:\Program Files\Support Tools>pause
Press any key to continue . . .
**Remote: Connected to REMOTESERVER3 administrator1 [Sun 3:27 PM]
```

**Client-server interaction**

After establishing the client-server interactive session, you can press any key to continue running the program, (in this case we

use the Enter key). When Testprog.bat continues on the server, you will see output similar to that shown below.

Server output looks like this:

```
**Remote: Connected to REMOTESERVER3 administrator1 [Sun 3:27 PM]
^M                      [CLIENTCOMPUTER7 3:27 PM]

C:\Program Files\Support Tools>schtasks /?

SCHTASKS /parameter [arguments]

Description:
    Enables an administrator to create, delete, query CHange, run and
    end scheduled tasks on a local or remote system. Replaces AT.exe.

Parameter List:
    /Create         Creates a new scheduled task.

    /Delete         Deletes the scheduled task(s).

    /Query          Displays all scheduled tasks.

    /Change         Changes the properties of scheduled task.

    /Run            Runs the scheduled task immediately.

    /End            Stops the currently running scheduled task.

    /?              Displays this help/usage.

Examples:
    SCHTASKS
    SCHTASKS /?
    SCHTASKS /Run /?
    SCHTASKS /End /?
    SCHTASKS /Create /?
    SCHTASKS /Delete /?
    SCHTASKS /Query  /?
    SCHTASKS /Change /?

Remote exiting. Child (testprog.bat) exit code was 0.
```

Client output (Clientcomputer7 in this case) is similar to output from the server Remoteserver3, as shown here:

```
C:\Program Files\Support Tools>schtasks /?

SCHTASKS /parameter [arguments]

Description:
    Enables an administrator to create, delete, query CHange, run and
    end scheduled tasks on a local or remote system. Replaces AT.exe.

Parameter List:
    /Create         Creates a new scheduled task.

    /Delete         Deletes the scheduled task(s).

    /Query          Displays all scheduled tasks.

    /Change         Changes the properties of scheduled task.

    /Run            Runs the scheduled task immediately.

    /End            Stops the currently running scheduled task.

    /?              Displays this help/usage.
```

```
*** SESSION OVER ***
```

### Note

- The session on both the client and the server computers ends the moment the **remote** command completes. In some cases, the output to the client computer might be truncated if the remote command terminates before all the output is sent to the client. In this example, the remote command (`schtasks /?`) is delayed from terminating by the `Pause` statement that occurs after the `schtsks /?` command.

**Example 2: Example of a keyword/color file**
The following command creates a keyword-highlighting scheme on the client command console using the text file Colorscheme.txt:

```
remote /c server3 remotesession2 /k colorscheme.txt
```

In this example, the format of the Colorscheme.txt text file is as follows:

```
Error
red
Continue
lblue, white
WaRnInG
white, purple
```

When used in conjunction with the **/K** parameter, this file causes all instances of the word "error" to be highlighted in red, "continue" to be highlighted in light blue with a white background, and "warning" to be highlighted in white with a purple background. Keywords are case-insensitive.

# Remote Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Syntax**
Remote uses the following general syntax:

**remote** *Operation*

**Operations**
Server

Client

Query

**Server**
Starts the remote service on the server where the command is to be run.

**Syntax**
**remote /s** *Command UniqueID*[**/U**[*DomainName*****]*UserName*] [**/UD** *Name*] [**/F** *Color*] [**/B** *Color*] [**/V**][**/-V**] [**@K**]

**Parameters**
***Command***
Specifies the command to be run on the server, with concurrent input from and output to a client that will connect later.

***UniqueID***
Specifies a unique name to distinguish this instance of the remote session from others running on the server. If the session name contains spaces it must be enclosed with quotation marks.

**/U[*DomainName*\]*UserName***
Specifies the user name or group names that are permitted to connect to a specified session running on the server. The use of *DomainName* is optional. This parameter can be specified more than once to enable permissions for a broader set of users or groups.

**Security Remark**

- Users and groups are not authenticated when connecting to remote sessions on servers. This can create potential security vulnerability on the server.

**/UD *Name***
Specifies the user name or group names that are to be denied access to a specified session running on the server.

**/F *Color***
Specifies the foreground color for the session on the server. Acceptable values are: **yellow**, **black**, **blue**, **lblue**, **white**, **red**, **green**, **cyan**, and **purple**. Remote does not discern color conflicts between background and foreground. If the same color is specified for both background and foreground, text in the command console will not be visible.

**/B *Color***
Specifies the background color for the session on the server. Acceptable values are: **yellow**, **black**, **blue**, **lblue**, **white**, **red**, **green**, **cyan**, and **purple**. Remote does not discern color conflicts between background and foreground. If the same color is specified for both background and foreground, text in the command console will not be visible.

**/V**
Makes the specified session visible to remote users logging in with **/q** parameter.

**/-V**
Makes the specified session invisible to remote users logging in with **/q** parameter. By default, if the *command* looks like a debugger, the session is visible to the remote client.

**@K**
Causes the server session to terminate.

**Client**
Starts the remote service on the client and connects to a specified server session based on a server name and unique identifier.

**Syntax**
**remote /c** *ServerName UniqueID*[**/F** *Color*] [**/B** *Color*] [**/L** *Number*] [**/K**][**@Q**]

**Parameters**
***ServerName***
Specifies the server name to connect to from the client.

***UniqueID***
Specifies a unique name to connect to on a specified server. If the session name contains spaces it must be enclosed in quotation marks.

**/F *Color***
Specifies the foreground color for the session on the server. Acceptable values are: **yellow**, **black**, **blue**, **lblue**, **white**, **red**, **green**, **cyan**, and **purple**. Remote does not discern color conflicts between background and foreground. If the same color is specified for both background and foreground, text in the command console will not be visible.

**/B *Color***
Specifies the background color for the session on the server. Acceptable values are: **yellow**, **black**, **blue**, **lblue**, **white**, **red**, **green**, **cyan**, and **purple**. Remote does not discern color conflicts between background and foreground. If the same color is specified for both background and foreground, text in the command console will not be visible.

**/L *Number***
Specifies the number of lines of output to obtain from a specified session running on a remote server.

**Note**

- Setting a small number of lines can truncate output from the session running on the server.

**/K**
Assigns colors to highlight keywords based on information in a text file of the following format:

*Keyword ForegroundColor*[**,** *BackgroundColor*]

See "Example 2: Example of a keyword/color file" in Remote Examples.

Acceptable values for *ForegroundColor* and *BackgroundColor* are: **yellow**, **black**, **blue**, **lblue**, **white**, **red**, **green**, **cyan**, and **purple**. Remote does not discern color conflicts between background and foreground. If the same color is specified for both background and foreground, text in the command console will not be visible.

**@Q**
Terminates the client session, leaving the remote server session running.

**Query**
Queries and retrieves the available unique identifiers of visible sessions on the specified computer.

**Syntax**
**remote /Q** *ServerName*

**Parameters**
***ServerName***
Specifies the server name to query.

# Security Management Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Security Management Tools**
Tools in this category are used to manage the following Windows features:

- Access control
- Authentication
- Encrypting File System
- Public Key Infrastructure
- Software restriction policies
- Windows Time service

**Notes**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Ksetup Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Ksetup.exe: Kerberos Setup**
This command-line tool configures a client connected to a server running Windows Server 2003 to use a server running Kerberos V5. The client then uses a Kerberos V5 realm instead of a Windows Server 2003 domain. This provides a single sign-on to the Key Distribution Center (KDC) and a local client account connected to a computer running Windows Server 2003.

KSetup is part of a group of tools, including Ktpass Overview, that is used to configure Windows for Kerberos V5 interoperability.

Administrators can use KSetup to:

- Set up a realm entry for a Kerberos V5 realm.
    - Set up a list of KDCs for that realm.
    - Set up a kpasswd server for that realm.
- Set up local account to Kerberos V5 account mappings. This is necessary to inform the operating system how to authorize a specific security principal. This links authorization data to an identity. Windows domains do not need this data because they get it through other means.
- Set the computer's password in the Kerberos realm. A Kerberos realm (and Windows domain) tracks computers joined to them using a shared secret in the form of the computer's password. When joining a Kerberos realm, a host principal must be created. The password used by the realm to create the host key must be entered using this command so that Windows can decode host tickets presented to it.
- Change a user's password in a Kerberos V5 realm.

Note

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Kerberos is an authentication system designed to enable two parties to exchange private information across an otherwise open network. It assigns a unique key, called a ticket, to each user who logs on to the network. The ticket is used to secure messages and identify the sender of the message.

**System Requirements**
The following are the system requirements for KSetup:

- Windows Server 2003
- User's membership in the Administrators or Server Operators group on the target computer. Also, both the user account and the server computer must be members of the same domain or reside within trusted domains.

**File Required**

- KSetup.exe

# Ksetup Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**KSetup Remarks**
**Understanding KSetup**
KSetup is used to change the computer settings for locating non-Microsoft Kerberos realms. In non-Microsoft Kerberos–based implementations, this information is usually kept in the Krb5.conf file. In Windows Server 2003 systems, it is kept in the registry. You can use this tool to modify these settings. These settings are used by workstations to locate non-Windows Kerberos realms and by domain controllers to locate non-Microsoft Kerberos realms for cross-realm trust relationships.

KSetup initializes registry keys that the Kerberos Security Provider uses to locate an non-Microsoft Kerberos Key Distribution Center (KDC) if the computer running a Windows Server 2003 operating system is not a member of a Windows domain. After configuration, the user of a computer running Windows XP Professional can log on to accounts in the Kerberos realm.

The Kerberos V5 authentication protocol is the default for network authentication on computers running Windows XP Professional. Computers running Windows XP Professional can participate in Kerberos realms that are not Windows Server 2003 domains. In this case, the KDC will not be on a domain controller running Windows Server 2003, so the DNS names for KDC servers must be stored in the registry of the client computer. The Kerberos Security Support Provider (SSP) looks in the registry for the DNS domain name of the user's realm, and then resolves the name to an IP address by querying a DNS server. Kerberos can use DNS to locate KDCs, using only the realm name but must be specially configured to do so.

# Ksetup Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**KSetup Examples**

**Example 1: Configure a UNIX KDC server and workstation realm**

Run the KSetup tool on a Windows XP Professional–based workstation to configure the UNIX KDC server and the realm that the workstation should use. Type the following at the command line to set the UNIX realm:

```
ksetup /addkdc DOMAIN.MICROSOFT.COM mitkdc.microsoft.com
```

Finally, type the following at the command line to set the local computer account password:

```
ksetup /setcomputerpassword p@ssword1!
```

Restart the computer for the changes to take effect.

**Example 2: Authenticate a realm's principals**

Type the following at the command line to authenticate the principals of the given realm if they present valid Kerberos tickets:

```
ksetup /mapuser user@DOMAIN.MICROSOFT.COM guest
```

### Note

- The computer will authenticate the principals of the given realm if they present valid Kerberos tickets. Any principal from the given Kerberos realm will be treated as Guest for local authorization purposes.

**Example 3: Configure a single sign-on to local workstation accounts**

Type the following at the command line to authenticate the principals of the given realm if they present valid Kerberos tickets:

```
ksetup /mapuser user@DOMAIN.MICROSOFT.COM guest
```

### Note

- In this case, any principal from the given Kerberos realm will be treated as Guest for local authorization purposes. For example, accessing a file or registry key will be granted or denied as though the Guest had attempted to access the file or registry key.

**Example 4: List the available realm flags that ksetup knows**

Type the following at the command line to map clients to local accounts of the same name:

```
ksetup /ListRealmFlags
```

```
Ksetup knows the following realm flags:
0x00 None         No Realm Flags
0x01 SendAddress  Include IP numbers within tickets.
                  Useful for solving SOME compatibility issues.
0x02 TcpSupported Indicates that this realm supports TCP.
                  (as opposed to just UDP)
0x04 Delegate     Everyone in this realm is trusted for delegation
0x08 NcSupported  This realm supports Name Canonicalization...
```

### Note

- To list the available realm flags that KSetup does not know, type either of the following commands at the command line:
    - /SetRealmFlags REALM SendAddress TcpSupported Delegate NcSupported
    - /SetRealmFlags REALM 0xF

# Ksetup Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**KSetup Syntax**

KSetup uses the following syntax:

**ksetup** [**/SetRealm***DnsDomainName*] [**/MapUser***PrincipalAccount*] [**/Addkdc***RealmNameKdcName*] [**/Delkdc***RealmNameKdcName*] [**/Addkpasswd***RealmNameKpasswdName*] [**/Delkpasswd***Realm*
*[flag][...]*] [**/AddRealmFlags***Realmflag[flag][flag][...]*] [**/DelRealmFlags***Realmflag[flag][flag][...]*] [**/DumpState***No Arguments*] [**/?**] [**/help**]

**Parameters**

**/SetRealm *DnsDomainName***
Sets the name of an RFC1510 Kerberos realm.

**/MapUser *Principal Account***
Maps the name of a Kerberos principal to an account (* = any/all). If account name is omitted, mapping is deleted for the specified principal.

**/AddKdc *RealmName KdcName***
Adds an additional KDC address for the given realm. If KdcName is omitted, DNS may be used to locate KDCs.

**/DelKdc *RealmName KdcName***
Deletes instance(s) of KDC address for the realm.

**/AddKpasswd *RealmName KpasswdName***
Adds Kpasswd server address for a realm.

**/DelKpasswd *RealmName KpasswdName***
Deletes Kpasswd server address for a realm.

**/Server *ServerName***
Specifies the name of a Windows 2000 computer to target the changes.

**/SetComputerPassword *Password***
Sets the password for the local computer.

**/RemoveRealm *RealmName***
Deletes all information for this realm from the registry.

**/Domain *DomainName***
Uses this domain (if DomainName is unspecified, detects it).

**/ChangePassword *OldPasswd NewPasswd***
Uses Kpasswd to change the password of the logged-on user. Uses '*' to be prompted for passwords.

**/ListRealmFlags *No arguments***
Lists the available realm flags that ksetup knows.

**/SetRealmFlags *realm flag [flag] [flag] [...]***
Sets RealmFlags for a specific realm. /SetRealmFlags requires one or more arguments that are either numerical (0x5) or labels (from the /ListRealmFlags call).

**/AddRealmFlags *realm flag[flag][flag][...]***
Adds additional RealmFlags to a realm.

**/DelRealmFlags *realm flag [flag] [flag] [...]***
Deletes RealmFlags from a realm.

**/DumpState *No arguments***
Analyzes the kerberos configuration on the given machine.

**/? or /help**
Displays the usage screen.

**Note**

- The arguments for KSetup are evaluated in the order entered. This is irrelevant for most commands except /Server.

**Examples**

See Ksetup Examples, Ksetup Examples or Ksetup Examples.

# Ktpass Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Ktpass.exe: Kerberos Keytab Setup**
This command-line tool enables an administrator to configure a non-Windows Server 2003 Kerberos service as a security principal in the Windows Server 2003 Active Directory. KtPass configures the server principal name for the host or service in Active Directory and generates an MIT-style Kerberos "keytab" file containing the shared secret key of the service. The tool allows UNIX-based services that support Kerberos authentication to use the interoperability features provided by the Windows Server 2003 Kerberos KDC service.

### Note

- The keytab output file is used to replace or merge with the MIT Kerberos /Etc/Krb5.keytab file. MIT Kerberos-based services (noninteractive) use the keytab to log on and use Kerberos services.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Kerberos is an authentication system designed to enable two parties to exchange private information across an otherwise open network. It assigns a unique key, called a ticket, to each user that logs on to the network. The ticket is embedded in messages to identify the sender of the message.

**System Requirements**
The following are the system requirements for KtPass:

- Windows Server 2003
- User's membership in the Administrators or Server Operators group on the target computer. Also, both the user account and the server computer must be members of the same domain or reside within trusted domains.

**File Required**

- Ktpass.exe

# Ktpass Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**KtPass Remarks**
**Using KtPass**
Services running on UNIX systems can be configured with service instance accounts in Active Directory. This allows full interoperability. MIT Kerberos clients and servers on UNIX systems can authenticate by using the Windows Server 2003 Kerberos server, and clients connected to servers running Windows Server 2003 can authenticate to Kerberos services that support GSS API.

Unlike Kerberos principal names, Windows Server 2003 account names do not have multiple parts. For this reason, it is not possible to directly create an account of the name Sample/Unix1.microsoft.com. Such a principal instance is created by using the service principal name mappings.

To generate a UNIX host keytab file, map the principal to the account, and set the host principal password:

1. Use the Active Directory User and Computers snap-in to create a user account for the UNIX service. For example, create an account with the name SampleUnix1.

2. Set up an identity mapping for the user account using KtPass by typing a command line that uses this syntax:

   **ktpass /princ *ServiceInstance@REALM* /mapuser *AccountName* /pass *Password* /out *Unixmachine.Keytab***

   **Note**

   - You cannot map multiple service instances to the same user account.

3. Merge the keytab file with the /Etc/Krb5.keytab file on the UNIX host.

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**KtPass Syntax**

**ktpass** [**/out***FileName*] [**/princ***UserName*] [**/pass** {*Password*|*}] [**/mapuser***LocalUserName*] [**/mapop** {**add**|**set**}] [{-|+}**desonly**] [**/in***FileName*] [**/crpyto** {**DES-CBC-CRC**|**DES-CBC-MD5**}] [**/ptype** {**KRB5_NT_PRINCIPAL**|**KRB5_NT_SRV_INST**|**KRB5_NT_SRV_HST**}] [**/kvno***KeyVersionNum*] [**/ktvno***KeyTabVersion*] [**/rawsalt**] [{-|+}**dumpsalt**] [{-|+}**setupn**] [{-|+}**setpass***Password*] [**/**

**Parameters**

**/out *FileName***
Specifies the name of the Kerberos 5 keytable file to generate.

**Note**

- This is the keytable you transfer to the UNIX computer and replace or merge with your existing keytable file, /Etc/Krb5.keytab.

**/princ *UserName***
Specifies the principal name in the form *user@REALM*.

**/pass{ *Password*| *}**
Specifies a password for the principal user name specified in the **/princ** parameter. Use "*" to prompt for a password.

**/mapuser *LocalUserName***
Maps the name of the Kerberos principal specified by the **/princ** parameter to the specified local user name. By default, Kerberos principals are not mapped to local user names.

**/mapop{ add| set}**
Specifies how the mapping attribute is set.

| Value | Description |
|---|---|
| **add** | Adds value. This is the default. |
| **set** | Sets value. |

**{ -| +} desonly**
Sets (+) or unsets (-) an account for des-only encryption. Des-only encryption is set by default.

**/in *FileName***
Specifies the keytab to read or digest.

**/crypto{ DES-CBC-CRC| DES-CBC-MD5]**
Sets the encryption type to use.

| Value | Description |
|---|---|
| **DES-CBC-CRC** | Default |
| **DES-CBC-MD5** | More MIT-like |

**/ptype{ KRB5_NT_PRINCIPAL| KRB5_NT_SRV_INST| KRB5_NT_SRV_HST}**
Specifies the principal type.

| Value | Description |
|---|---|
| **KRB5_NT_PRINCIPAL** | General ptype (recommended). |
| **KRB5_NT_SRV_INST** | User service instance. |
| **KRB5_NT_SRV_HST** | Host service instance. |

**/kvno *KeyVersionNum***
Specifies the Key version number. The default value is 1.

**/?| /h| /help**
Displays command-line help for KtPass.

# Sidwalk Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sidwalk.exe: Security ID Administration**
This command-line tool takes a mapping file as input and scans all the Access Control Lists (ACLs) in the registry, file system, file and print shares, and local group membership. SIDWalk uses the mapping information in the mapping file to either delete or replace every occurrence of an old security identifier (SID) with the corresponding new SID. The same mapping file can be used for SIDWalk conversion on multiple computers.

### Note

- This tool is part of the Sidwalker Security Administration Tools.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
Access control is implemented by access control lists (ACLs). Every file in the NTFS file system and every registry key has a unique ACL, granting access rights to file resources to users and groups, and defining what specific access rights each is granted. Each user and group is identified in the ACL by a security identifier (SID).

**System Requirements**
SIDWalk can be run as scheduled batch jobs. It must be run locally on the computer where the access permissions are to be changed. SIDWalk uses Windows NT security APIs (supported on Windows NT 4.0, Windows 2000, and Windows XP) to examine every ACL on every object on the system. It is a CPU and I/O intensive program; plan to run it when system use is otherwise very light and expect significant resource use.

**Files Required**

- Sidwalk.exe
- Msvcrt50.dll (found in the \System32 directory)

# Sidwalk Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SIDWalk Syntax**

SIDWalk uses the following syntax:

**sidwalk** *ProfileFile*[*ProfileFile* ...][**/t**][**/f** [*Path*]][**/r**][**/s**][**/p**][**/g**][**/l***File*][**/?**]

**Parameters**

***ProfileFile***

Specifies the path and file name of one or more .csv mapping files to be used for input.

**/t**

Conducts a test/dry run.

**/f[ *Path*]**

Scans all NTFS file system files or, optionally, only those on the directory tree of the specified path.

**/r**

Scans the registry.

**/s**

Scans file shares.

**/p**

Scans printer shares.

**/g**

Scans local groups.

**/l *File***

Generates a Converter log file with *File* as the file name and path.

**/?**

Displays help on SIDwalk.

**Remarks**

- When run without parameters, SIDWalk displays help.

# Sidwalker Security Administration Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SIDWalker Security Administration Tools**
This set of programs helps system administrators manage access-control policies on systems running Windows Server 2003, Windows XP, Windows 2000, and Windows NT. The SIDWalker tools are designed to support a three-phase approach to modifying access control. Each phase of changing access control can take a day or longer to complete and verify, and requires significant amounts of system resources and administrator time. The phases are:

- **Planning.** The administrator needs to determine what users have been granted access to resources (file shares, print shares, NTFS files, registry keys, and local group membership) on a particular computer.
- **Mapping Accounts.** Based on who has access to what resources on the system, the administrator can choose to delete old, unused security identifiers (SIDs), or replace them with corresponding new SIDs, such as new security groups.
- **Converting ACLs.** Using the information from the planning and mapping phases, the third phase is the conversion of security identifiers found anywhere on a system to corresponding new SIDs.

**SIDWalker Components**

- Showaccs Overview
- Sidwalk Overview
- Sidwkr.dll

**Usage Scenario**
The following example is a scenario requiring migration of access control policies:

All of the files for a project on a file server have an access control list (ACL) that grants the group ProjectTeam Read/Write access to the project files.

ProjectTeam is a security group that has a unique security identity in the Windows XP account directory. If the project changes and ProjectTeam merges into a larger project team, the administrator might want to change the access permissions on the project files. The Read/Write access-control rights granted to the original ProjectTeam can be replaced by access rights granted to a NewProjectTeam group. NewProjectTeam can be defined in a different domain and project file server. The computer on which the project file server runs can move from the current domain to a new domain for the larger project. In changing situations like this, SIDWalker can facilitate managing and updating security access policies on the servers involved.

# Sidwkr.dll

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sidwkr.dll: Security Migration Editor Snap-In**
The Security Migration Editor is a Microsoft Management Console (MMC) snap-in that provides a graphical user interface (GUI) for mapping old security identifiers (SIDs) (listed in a mapping file created by ShowAccs), to new security identifiers. The "migration" referred to is from old SIDs to corresponding new SIDs, which are mapped by selecting from the list of user and group accounts in target domains or computers. The snap-in also gives options to ignore or delete these SIDs as they show up in access-control lists (ACLs). The Security Migration Editor updates the mapping file, which is then used as input to SIDWalk.

### Note

- This tool is part of the Sidwalker Security Administration Tools.

**Corresponding UI**
Security Migration Editor provides its own user interface. See the MMC snap-in for more information.

**Concepts**
Access control is implemented by access control lists (ACLs). Every file in the NTFS file system and every registry key has a unique ACL, granting access rights to file resources to users and groups, and defining what specific access rights each is granted. Each user and group is identified in the ACL by a security identifier (SID).

**System Requirements**
Security Migration Editor does not have to run on the same computer on which ShowAccs or SIDWalk runs. An administrator can schedule ShowAccs to run remotely on one server in the network, can transfer the resulting files to a local workstation for analysis and update using Security Migration Editor, and then can copy the mapping file back to one or more target systems and run SIDWalk on them.

**Files Required**

- Sidwalk.msc
- Msvcrt50.dll (found in the \System32 directory)
- Sidwkr.dll (the snap-in file for Security Migration Editor)

# Sidwkr Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security Migration Editor Remarks**

**Installing Security Migration Editor**

Before running the Security Migration Editor snap-in, it must be initialized from the command prompt with the command:

```
regsvr32 sidwkr.dll
```

This initializes the class libraries used by the snap-in.

**Using Security Migration Editor**

To use the snap-in, add it to the MMC. Security Migration Editor can also be started from the command prompt with the command:

```
sidwalk.msc
```

Further instructions on using snap-ins can be found in Help for the MMC.

# Xcacls Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Xcacls.exe**
This command-line tool sets all file-system security options that are accessible in Windows Explorer. XcAcls does this by displaying and modifying the access control lists (ACLs) of files.

XcAcls is especially useful in unattended installations of Microsoft Windows XP. Using this tool, you can set the initial access rights for folders in which the operating system resides. When you distribute software to servers or workstations, XcAcls also offers one-step protection against deletion of directories or files by users.

**Corresponding UI**
File-system security options can be set manually from Windows Explorer.

**To set file-security options from Windows Explorer:**

1. Right-click the file or folder for which you want to set security.
2. Select **Sharing** or **Properties**.
3. Select the **Security** tab.
4. Click **Advanced**.

**Concepts**
For more information on ACLs, see "Access control overview" or "Understanding Access Control" in Help for Windows Server 2003.

**System Requirements**
The following are the system requirements for XcAcls:

- Windows XP Professional or Windows Server 2003

**File required**

- Xcacls.exe

  To download the Xcacls tool, see Free Tool Downloads on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=18748).

# Xcacls Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**XcAcls Examples**

**Example 1: Replace ACLs of All Files and Directories in the Current Directory**

You want to replace the existing ACLs of all files and directories in the current directory with Read and Write access for the administrator, suppressing confirmation. Type the following at the command line:

```
xcacls *.* /g administrator:rw /y
```

Notice that you are not asked to confirm the change. You see output similar to the following:

```
processed file:  C:\data\compressed.txt
processed file:  C:\data\deptdata.txt
processed file:  C:\data\dirafter.txt
processed file:  C:\data\temp.txt
processed file:  C:\data\uncompressed.txt
processed file:  C:\data\userdata.txt
```

You can check to see that the command was executed by typing the following at the command line:

```
xcacls *.*
```

You see output similar to the following, confirming that the access rights have been set for the administrator:

```
C:\data\compressed.txt MYCOMPUTER\Administrator:(special access:)

                                          READ_CONTROL
                                          SYNCHRONIZE
                                          FILE_GENERIC_READ
                                          FILE_GENERIC_WRITE
                                          FILE_GENERIC_EXECUTE
                                          FILE_READ_DATA
                                          FILE_WRITE_DATA
                                          FILE_APPEND_DATA
                                          FILE_READ_EA
                                          FILE_WRITE_EA
                                          FILE_EXECUTE
                                          FILE_READ_ATTRIBUTES
                                          FILE_WRITE_ATTRIBUTES

C:\data\deptdata.txt MYCOMPUTER\Administrator:(special access:)

                                         READ_CONTROL
                                         SYNCHRONIZE
                                         FILE_GENERIC_READ
                                         FILE_GENERIC_WRITE
                                         FILE_GENERIC_EXECUTE
                                         FILE_READ_DATA
                                         FILE_WRITE_DATA
                                         FILE_APPEND_DATA
                                         FILE_READ_EA
                                         FILE_WRITE_EA
                                         FILE_EXECUTE
                                         FILE_READ_ATTRIBUTES
                                         FILE_WRITE_ATTRIBUTES

C:\data\dirafter.txt MYCOMPUTER\Administrator:(special access:)

                                         READ_CONTROL
                                         SYNCHRONIZE
                                         FILE_GENERIC_READ
                                         FILE_GENERIC_WRITE
                                         FILE_GENERIC_EXECUTE
                                         FILE_READ_DATA
```

```
                                        FILE_WRITE_DATA
                                        FILE_APPEND_DATA
                                        FILE_READ_EA
                                        FILE_WRITE_EA
                                        FILE_EXECUTE
                                        FILE_READ_ATTRIBUTES

                                    READ_CONTROL
                                    SYNCHRONIZE
                                    FILE_GENERIC_READ
                                    FILE_GENERIC_WRITE
                                    FILE_GENERIC_EXECUTE
                                    FILE_READ_DATA
                                    FILE_WRITE_DATA
                                    FILE_APPEND_DATA
                                    FILE_READ_EA
                                    FILE_WRITE_EA
                                    FILE_EXECUTE
                                    FILE_READ_ATTRIBUTES
                                    FILE_WRITE_ATTRIBUTES

C:\data\uncompressed.txt MYCOMPUTER\Administrator:(special access:)

                                        READ_CONTROL
                                        SYNCHRONIZE
                                        FILE_GENERIC_READ
                                        FILE_GENERIC_WRITE
                                        FILE_GENERIC_EXECUTE
                                        FILE_READ_DATA
                                        FILE_WRITE_DATA
                                        FILE_APPEND_DATA
                                        FILE_READ_EA
                                        FILE_WRITE_EA
                                        FILE_EXECUTE
                                        FILE_READ_ATTRIBUTES
                                        FILE_WRITE_ATTRIBUTES

C:\data\userdata.txt MYCOMPUTER\Administrator:(special access:)

                                        READ_CONTROL
                                        SYNCHRONIZE
                                        FILE_GENERIC_READ
                                        FILE_GENERIC_WRITE
                                        FILE_GENERIC_EXECUTE
                                        FILE_READ_DATA
                                        FILE_WRITE_DATA
                                        FILE_APPEND_DATA
                                        FILE_READ_EA
                                        FILE_WRITE_EA
                                        FILE_EXECUTE
                                        FILE_READ_ATTRIBUTES
                                        FILE_WRITE_ATTRIBUTES
```

**Example 2: Edit the ACLs of the Current Directory**

You want to give TestUser Read, Write, Run, and Delete rights on all new files created in this directory, but only Read and Write permissions on the directory itself. Type the following at the command line:

**xcacls *.* /g TestUser:rwed;rw /e**

You see output similar to the following:

```
processed file:  C:\test\compressed.txt
processed file:  C:\test\deptdata.txt
processed file:  C:\test\dirafter.txt
processed file:  C:\test\temp.txt
processed file:  C:\test\uncompressed.txt
processed file:  C:\test\userdata.txt
```

```
C:\data\compressed.txt Everyone:(special access:)
                               READ_CONTROL
                               SYNCHRONIZE
                               FILE_GENERIC_READ
                               FILE_GENERIC_WRITE
                               FILE_GENERIC_EXECUTE
                               FILE_READ_DATA
                               FILE_WRITE_DATA

```

```
                                    FILE_GENERIC_WRITE
                                    FILE_GENERIC_EXECUTE
                                    FILE_READ_DATA
                                    FILE_WRITE_DATA
                                    FILE_APPEND_DATA
                                    FILE_READ_EA
                                    FILE_WRITE_EA
                                    FILE_EXECUTE
                                    FILE_READ_ATTRIBUTES
                                    FILE_WRITE_ATTRIBUTES

                           MYCOMPUTER\TestUser:C

C:\data\userdata.txt Everyone:(special access:)
                                READ_CONTROL
                                SYNCHRONIZE
                                FILE_GENERIC_READ
                                FILE_GENERIC_WRITE
                                FILE_GENERIC_EXECUTE
                                FILE_READ_DATA
                                FILE_WRITE_DATA
                                FILE_APPEND_DATA
                                FILE_READ_EA
                                FILE_WRITE_EA
                                FILE_EXECUTE
                                FILE_READ_ATTRIBUTES
                                FILE_WRITE_ATTRIBUTES

                       MYCOMPUTER\TestUser:C
```

The command edited the ACL of a file or a directory, but its effect on a directory was different. The ACE added to the directory is also an inherit ACE for new files created in this directory.

**Example 3: Edit Permissions on a Directory Without Creating an Inherit for New Files**

You want to grant Read and Write permissions on a directory for TestUser. You do not want to create an inherit entry for new files, but grant only Read access to existing files. Type the following at the command line:

**xcacls *.* /g TestUser:r;trw /e**

You see output similar to the following:

```
C:\data\compressed.txt Everyone:(special access:)
                                 READ_CONTROL
                                 SYNCHRONIZE
                                 FILE_GENERIC_READ
                                 FILE_GENERIC_WRITE
                                 FILE_GENERIC_EXECUTE
                                 FILE_READ_DATA
                                 FILE_WRITE_DATA
                                 FILE_APPEND_DATA
                                 FILE_READ_EA
                                 FILE_WRITE_EA
                                 FILE_EXECUTE

# Xcacls Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**XcAcls Syntax**

XcAcls uses the following syntax:

**xcacls** *FileName*[**/t**][**/e**][**/x**][**/c**][**/g***User*:*Permissions*;*Spec*][**/r***User*][**/p***User*:*Permissions*;*Spec*] [...]][**/d***User* [...]][**/y**][**/?**|**/h**]

**Parameters**

***FileName***

Indicates the name of the file or directory to which the access control list (ACL) or access control entry (ACE) is typically applied. All standard wildcard characters can be used.

**/t**

Recursively walks through the current directory and all of its subdirectories, applying the chosen access rights to the matching files or directories.

**/e**

Edits the ACL instead of replacing it.

**/x**

Edits the ACL instead of replacing it; affects only the ACEs that the specified users already own.

**/c**

Causes XcAcls to continue if an "access denied" error occurs. If **/c** is omitted, XcAcls stops on this error.

**/g *User*: *Permissions*; *Spec***

Grants *User* access to the matching file or directory. *Permissions* apply the specified access right to files. *Spec* can be the same as *Permissions* and only applies to a directory. In this case, *Permissions* is used for file inheritance in this directory. *Permissions* and *Spec* accept the following values:

| Value | Description |
|---|---|
| **R** | Read |
| **C** | Change (write) |
| **F** | Full Control |
| **P** | Change Permissions (special access) |
| **O** | Take Ownership (special access) |
| **X** | Execute (special access) |
| **E** | Read (Special access) |
| **W** | Write (Special access) |
| **D** | Delete (Special access) |
| **T** | Used only by *Spec*. ACE not specified. Sets an ACE for the directory itself without specifying an ACE that is applied to new files created in that directory. At least one access right must follow. *Spec* entries that precede T (in other words, those between the semicolon and the T) are ignored. (Special value) |

**Notes**

- The access options for files (special file and directory access options for directories) are identical. For detailed explanations of these options, see Permissions for files and folders on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48679) or Share permissions on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48680).

- All other options, which can also be set in Windows Explorer, are subsets of all possible combinations of the basic access rights. Therefore, there are no special options for directory access rights, such as LIST or READ.

***/r User***
Revokes all access rights for the specified user.

***/p User: Permissions; Spec***
Replaces access rights for *User*. *Permissions* applies the specified access right to files. *Spec* can be the same as *Permissions* and only applies to a directory. In this case, *Permissions* is used for file inheritance in this directory. *Permissions* and *Spec* accept the following values:

| Value | Description |
|---|---|
| **R** | Read |
| **C** | Change (write) |
| **F** | Full Control |
| **P** | Change Permissions (special access) |
| **O** | Take Ownership (special access) |
| **X** | Execute (special access) |
| **E** | Read (special access) |
| **W** | Write (special access) |
| **D** | Delete (special access) |
| **T** | Used only by *Spec*. ACE not specified. Sets an ACE for the directory itself without specifying an ACE that is applied to new files created in that directory. At least one access right must follow. *Spec* entries that precede T (in other words, those between the semicolon and the T) are ignored. (Special value.) |

**Notes**

- The access options for files (special file and directory access options for directories) are identical. For detailed explanations of these options, see Permissions for files and folders on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48679) or Share permissions on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48680).

- All other options, which can also be set in Windows Explorer, are subsets of all possible combinations of the basic access rights. Therefore, there are no special options for directory access rights, such as LIST or READ.

***/d User***
Denies the specified user access to the file or directory.

***/y***
Disables the confirmation when replacing user access rights. By default, XcAcls asks for confirmation. Because of this feature, when XcAcls is used in a batch routine, the routine stops responding until the right answer is entered. Use the **/y** parameter when you use XcAcls in batch mode.

# Software and System Deployment Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: Software and System Deployment Tools**
Tools in this category are used to manage the following Windows features:

- RIS
- Terminal Services

**Notes**

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Addiag.exe

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Addiag.exe: Application Deployment Diagnosis**
This command-line tool provides information on the current state of software either installed or available for installation on a computer managed by IntelliMirror Software Installation and Maintenance.

AdDiag provides the following information about software on a computer:

- The current user, including logon credentials and security identifier (SID), and the platform (processor, locale) that could affect the managed software.
- Whether or not Terminal Server is running on the computer.
- Installed or advertised information about software, derived from the registry.
- Advertised information about available software stored in Active Directory.
- Windows Installer information.

**Corresponding UI**
There is no corresponding user interface for this tool.

**Concepts**
IntelliMirror is a set of features that enable desktop change and configuration management technology. These features include: user data management, software installation and maintenance, user settings management, and remote installation services. For more information, see IntelliMirror.

**System Requirements**
The following are the system requirements for AdDiag:

- Windows XP Professional or Windows Server 2003

**Files Required**

- Addiag.exe

# Addiag Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**AdDiag Remarks**

**Understanding AdDiag Report Output**
AdDiag can generate a report containing the following sections of information.

**General Info**
Provides user configuration details.

**TS Info**
Provides information about whether or not Microsoft Terminal Server is running.

**Managed Apps (Local List)**
Lists all applications with information stored in the registry. The applications are listed by GUID. The GUID is set from the Software Installation snap-in, so in a case where the friendly name does not appear correct, the GUID is the information of most use in troubleshooting.

Assign count is the count of full advertisements executed for the application. This should make a difference only in Roaming User Profile (RUP) cases, the only cases when additional full advertisements are made for the same user.

The following table lists values returned for UI level and their descriptions.

| Level | Description |
|---|---|
| 0x0 | UI level is unchanged. |
| 0x1 | Default UI. |
| 0x2 | Completely silent installation. |
| 0x3 | Progress bars and error handling. |
| 0x4 | Authored UI (wizard dialog boxes suppressed). |
| 0x5 | Authored UI (wizards, progress bars, and error handling). |
| 0x40 | Display only progress bars. |
| 0x80 | Display success or failure dialog box on completion. |

The following table lists values returned for Application State and their descriptions.

| State | Description |
|---|---|
| 0x1 | Assigned. |
| 0x2 | Published. |
| 0x4 | Remove unmanaged version before assignment. |
| 0x8 | Leave application unmanaged when Group Policy no longer applies. |
| 0x10 | Remove application when Group Policy no longer applies. |
| 0x20 | Leave application unmanaged. |
| 0x40 | Remove application. |
| 0x18 | Assigned, and leave application unmanaged when Group Policy no longer applies. |

**Deployed Apps (Server)**

Deployed Apps (Server) is a full list of applications from the Group Policy objects applied to the given user (or computer). In the case of upgrade relationships, the base application is still listed, even if there is an upgrade for it. This feature has not yet been implemented.

**MSI Apps**
MSI Apps lists all applications for which there is Windows Installer information. Managed applications come from Software Installation and Maintenance, unmanaged applications come from alternative distribution, such as Microsoft Systems Management Server.

# Addiag Examples

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**AdDiag Examples**

**Example: Display diagnostic information for the local computer**

If you want to display diagnostic information for the local computer, type the following at the command line:

```
addiag
```

**Sample AdDiag output**

```
Microsoft (R) Software Distribution Diagnostics. Version 2.00

*********************************************************************
This check compares the local App Management data with the data found
on the domain controller.
Please note that inconsistency between them is common when the policy
has not been recently applied.
To ensure good results please reapply the policy before this test.
Last refresh: 9:34:55 on 3/13/2001.

# Addiag Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**AdDiag Syntax**

AdDiag uses the following syntax:

**addiag** [**/verbose:**{**TRUE**|**FALSE**}] [**/user:**{**TRUE**|**FALSE**}] [**/trace:***String*] [**/test:** *StringList*] [**/debug:** *Ulong*] [**/?:**{**TRUE**|**FALSE**}]

**Parameters**

**/verbose: {TRUE|FALSE}**

Specifies the level of detail returned.

| Value | Description |
|---|---|
| **TRUE** | Runs diagnostics in verbose mode. |
| **FALSE** | Runs diagnostics in concise mode. This is the default. |

**/user: {TRUE|FALSE}**

Specifies which diagnostics to run.

| Value | Description |
|---|---|
| **TRUE** | Runs diagnostics for the user. This is the default. |
| **FALSE** | Runs diagnostics for the computer. |

**/trace: *String***

Specifies in a string what system tracing to turn on or off. The string must be between 1 and 260 characters in length.

| Value | Description |
|---|---|
| **AppMgmtOn** | Turns on verbose logging for AppMgmt. The log file is generated at %WINDIR%\debug\usermode\appmgmt.log. |
| **AppMgmtOff** | Turns off verbose logging for AppMgmt. |
| **MSIOn** | Turns on verbose logging for Windows Installer. The log file is generated either at %WINDIR%\temp\msi*.log or %temp%\msi*.log. |
| **MSIOff** | Turns off verbose logging for Windows Installer. |
| **UserEnvOff** | Turns on verbose logging for the policy engine. The log file is generated at %WINDIR%\debug\usermode\userenv.log. |
| **UserEnvOn** | Turns off verbose logging for the policy engine. |

**/test: *StringList***

Specifies the list of diagnostics to be run. The string must be between 1 and 260 characters, and multiple diagnostics must be separated by comma (,) or semicolon (;). The default *StringList* is "**Info**,**TS**,**LocalApps**,**ServerApps**,**MSIApps**,**ADHistory**,**EventDump**,**All**".

| Value | Description |
|---|---|
| **Info** | Dumps Addiag Remarks information. |
| **TS** | Dumps Addiag Remarks information. |
| **LocalApps** | Dump Addiag Remarks List. |

| | |
|---|---|
| **ServerApps** | Dumps Addiag Remarks List. |
| **MSIApps** | Dumps Addiag Remarks List. |
| **GPOList** | Dumps Local Group Policy Object List. |
| **ScriptList** | Dumps Local Script Application List. |
| **ADHistory** | Dumps Local Active Directory policy history. |
| **MSIFeatures** | Dumps Local MSI Features List. |
| **MSILinks** | Dumps MSI shortcuts in the profile. |
| **EventDump** | Dumps Application log related events. |
| **Check** | Performs Active Directory Integrity check. |
| **all** | Performs all tests. |

**/debug: *Ulong***

Specifies a debug level of *Ulong* where *Ulong* is an unsigned long (debug only).

**/?:{TRUE|FALSE}**

Specifies whether command-line help is displayed.

| Value | Description |
|---|---|
| **TRUE** | Displays command-line usage. |
| **FALSE** | Does not display command-line usage. This is the default. |

# System Management Support Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Category: System Management Tools**
Tools in this category are used to manage the following Windows features:

- Automation tools
- Group Policy
- Logon scripts
- Message Queuing (MSMQ)
- Task Scheduler

### Notes

- There may not be a tool for every Windows feature listed here.
- Some tools may appear in more than one category.

# Apmstat Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Apmstat.exe: Advanced Power Management Status**
This command-line tool provides status information on Advanced Power Management (APM) features.

The output of ApmStat can be helpful in troubleshooting APM problems. The tool reports on APM-related registry entries and on APM BIOS problems.

ApmStat tells you whether a computer has multiple processors and whether it is running in ACPI mode.

**Corresponding UI**

- The control panel includes a Power Options program. If APM is installed (enabled or disabled) there will be an **APM** tab in this program. You can turn APM on and off by selecting the box in this tab. This is the only recommended and supported way to turn APM off. Turning APM on is Plug and Play and on the fly, turning it off requires a reboot. If the tab is absent, the computer is either an ACPI computer or an APM-disabled computer.

- If APM is turned on, there is a **Stand by** option under **Shutdown** in the logon dialog box invoked with CTRL-ALT-DELETE. There might also be a hibernate entry, but that is not related. (Hibernate can work even if neither APM nor ACPI are present.) Standby under APM has the same use as under ACPI.

- If the battery display is turned on in the Power Options program of Control Panel, a battery status icon appears, and it works similarly to ACPI. Note that APM computers always report a single composite battery, regardless of how many are present. (The unified/composite number is used because this is thought to be more reliable on a wide range of APM BIOSs, and it is simpler.)

- On most APM computers, pressing the power button or sleep button can put the computer on standby (suspend). Most computers require pressing the power button to resume, although some resume with a keyboard touch. Windows 2000 APM does not support custom power buttons.

**Concepts**
Advanced Power Management (APM) is an older power management scheme based on an SMI/SMM (hidden hardware) BIOS approach. In APM, most of the functionality is in a computer-specific BIOS that is hidden from the operating system. APM was first widely supported on Windows 95.

Advanced Configuration and Power Interface (ACPI) is the new scheme for power management supported on Windows 98 and Windows 2000. Many computers support both APM and ACPI.

APM on Windows 2000 is intended primarily to support older notebook computers, although it can run on desktop computers. In general, it is preferable to disable APM on desktop computers.

On Windows 2000, APM supports only battery status, suspend, resume, and hibernate. Timer wakeup, wake on LAN, wake on ring, and other APM features are not supported.

ACPI should always be used if a computer has a working ACPI BIOS. Some useful features (timed wakeups, for example) are only available through ACPI on Windows 2000.

If no ACPI BIOS is available or if it does not work well, it might be better to use APM.

ACPI should always be used if a computer has a working ACPI BIOS. Some useful features (timed wakeups, for example) are only available through ACPI on Windows 2000.

If no ACPI BIOS is available or if it does not work well, it might be better to use APM.

**System Requirements**

- Windows Server 2003

- In Windows 2000 Server, APM is disabled.
- If Windows 2000 does not find a battery installed at startup, as is generally the case with desktop computers, stand-by status is not available. Only power-off status is enabled.

**File Required**

- Apmstat.exe

# Apmstat Remarks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**APMstat Remarks**
**APM on desktop computers**
In general, APM should be avoided on desktop computers because third-party video cards or other add-in cards might cause problems. There are some computers on which the APM BIOS causes instability all by itself. Both APM support (Ntapm.sys) in the Windows 2000 operating system and the APM BIOS itself should be turned off on such computers. Other computers, though, may be more reliable under Windows 2000 with APM support turned on, for example, those that have an APM BIOS that cannot be disabled.

### Caution

- APM should not be run on any computer that could be made unstable by it, because an unstable APM BIOS might cause loss of data.

**Key components of APM**

- **APM BIOS:** Placed in ROM or flash by the OEM. Does most of the work of powering things on and off, but is invisible to the operating system. The APM BIOS must be turned on for APM to work. If it is unstable, it might be necessary to turn the APM BIOS off in a hardware configuration screen, in addition to turning off Windows 2000 APM support. Timeouts in the APM BIOS should be off, or set as long as possible, so that the operating system rather than the APM BIOS can time things out. The APM BIOS is replaced by ACPI.

- **NtLdr:** Does a restart of APM on resume from hibernate, if APM was active before the hibernate.

- **Ntapm.sys:** The device driver that hooks the system and the APM BIOS together. Some system operations end up here for dispatch to the APM BIOS. APM BIOS events and status are polled from here. Note that when the APM BIOS presents an event (for example to suspend or power off) Ntapm.sys catches this, and then does an NtInitiatePowerAction call, which tells the operating system to perform an operation. At the very end, the power manager calls into the Hardware Abstraction Layer (HAL) which calls back into Ntapm.sys which, in turn, calls the APM BIOS. So, almost all the power code in the operating system and driver stacks is the same between APM and ACPI.

- **Hal.dll**

- **Apmbatt.sys:** Simulates a battery unit so the system battery status code can work.

- **Power Options control panel program:** Allows the user to enable or disable APM support on his or her computer. This is the preferred way (and the only supported way) to turn operating system APM support on or off.

- **Biosinfo.inf:** Lists computers on the auto-enable list and the disable list, and the BIOS detection sequences used to match them.

**Troubleshooting APM**

1. If the computer is a desktop computer, it is unlikely that it will run APM well. But you can get most of the value of APM by using hibernate, which requires neither APM nor ACPI to work.

2. If the computer is a laptop or a desktop that must run APM, make sure the user has APM turned on, hibernate turned on, and the battery icon turned on.

3. Make sure that the APM BIOS screen blanking is off. This will often make the system seem to behave badly when all that is wrong is that the screen is black. (Use a screen saver of BLANK to get the right effect.)

4. Run Apmstat.exe. Its output will often reveal a common problem, such as trying to run APM on an multi-processor

computer, for example.

5. If Windows 2000 APM has been turned off, and the computer is still unstable, try turning off the APM BIOS itself in the computer's setup screen. Some computers work better with Windows 2000 APM turned on, since this puts them more in sync with their APM BIOSs.

While troubleshooting, keep in mind the following considerations:

- Virtually all APM computers have some sort of computer setup/configuration screen, usually invoked at boot by pressing ESC, DEL, F1, F2, or F10. If you can get access to these screens, you can often improve system behavior by changing or disabling APM options.

- Some APM BIOSs turn themselves off if you disable all their timers; in this case, it is best to set them all to some long timeout value.

- Some APM BIOSs refuse to suspend if the kernel debugger is active on one of their COM ports.

- Event Log If an APM_SETPOWER call fails (that is, a standby/suspend fails at the APM BIOS interface), Ntapm.sys writes a record into the system event log, and produces data that reports what happened in addition to the error code the APM BIOS returned. This information is sometimes helpful in determining if the computer refused to suspend due to activity (that the user is not aware of) on a port.

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**APMstat Examples**

**Example 1: Provide status information on Advanced Power Management (APM)**

To provide status information on Advanced Power Management (APM) features, type:

**apmstat**

Your results will look similar to the following output:

```
This machine has an APM bios present that looks OK, and it is
not on the list of machines known to have APM problems.
Check the power applet in the control panel to see if APM is enabled.
```

**Example 2: Display a verbose report**

To display a verbose report, type:

**apmstat /v**

Your results will look similar to the following output:

```
This computer appears to have an APM legal HAL.
This machine has an APM bios present that looks OK, and it is
not on the list of machines known to have APM problems.
Check the power applet in the control panel to see if APM is enabled.
APM Registry Data Dump
Major = 0001  Minor = 0002
InstallFlags = 0003
Code16Segment = f000  Code16Offset = f10c  DataSeg = f000
Signature = APM
Valid = 0001
Detection Log Data:
44 45 54 4c 4f 47 31 00 00 00 00 00 00 00 00 00
 D  E  T  L  O  G  1

# Apmstat Syntax

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**APMstat Syntax**

**apmstat** [**-v**] [**-?**]

**Parameters**

**apmstat**

Without arguments, displays a basic report on Advanced Power Management status on the local computer.

**-v**

Displays a verbose report with more data about APM versions, address, and setup codes from the system description of the hardware tree in the registry.

**-?**

Displays this syntax listing.

# Support Tools Glossary

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Glossary**

A B C D E F G H I J K L M N O P Q R S T U V W X Y Z

**A**

**access control**
A security mechanism that determines which operations a user, group, service, or computer is authorized to perform on a computer or on a particular object, such as a file, printer, registry subkey, or directory service object.

See also: permission; registry; service

**access control entry (ACE)**
An entry in an object's discretionary access control list (DACL) that grants permissions to a user or group. An ACE is also an entry in an object's system access control list (SACL) that specifies the security events to be audited for a user or group.

See also: access control; access control list (ACL); permission; security descriptor

**access control list (ACL)**
A list of security protections that apply to an entire object, a set of the object's properties, or an individual property of an object. There are two types of access control lists: discretionary and system.

See also: access control entry (ACE); security descriptor

**ACL**
See definition for: access control list (ACL)

**Active Directory**
The Windows-based directory service. Active Directory stores information about objects on a network and makes this information available to users and network administrators. Active Directory gives network users access to permitted resources anywhere on the network using a single logon process. It provides network administrators with an intuitive, hierarchical view of the network and a single point of administration for all network objects.

See also: directory service; domain; forest; replication

**active volume**
The volume from which the computer starts up. The active volume must be a simple volume on a dynamic disk. You cannot mark an existing dynamic volume as the active volume, but you can upgrade a basic disk containing the active partition to a dynamic disk. After the disk is upgraded to dynamic, the partition becomes a simple volume that is active.

See also: basic disk; dynamic disk; simple volume

**ActiveX**
A set of technologies that allows software components to interact with one another in a networked environment, regardless of the language in which the components were created.

**American Standard Code for Information Interchange (ASCII)**
A standard single-byte character encoding scheme used for text-based data. ASCII uses designated 7-bit or 8-bit number combinations to represent either 128 or 256 possible characters. Standard ASCII uses 7 bits to represent all uppercase and lowercase letters, the numbers 0 through 9, punctuation marks, and special control characters used in U.S. English. Most current x86-based systems support the use of extended (or "high") ASCII. Extended ASCII allows the eighth bit of each character to identify an additional 128 special symbol characters, foreign-language letters, and graphic symbols.

See also: Unicode

**application programming interface (API)**
A set of routines that an application uses to request and carry out lower-level services performed by a computer's operating system. These routines usually carry out maintenance tasks such as managing files and displaying information.

**ASCII (American Standard Code for Information Interchange)**

See definition for: American Standard Code for Information Interchange (ASCII)

**B**

**base priority**
A precedence ranking that determines the order in which the threads of a process are scheduled for the processor. Use Task Manager to view and change base priorities.

For Message Queuing, a property that specifies the queue's priority in a public queue. You can set the base priority from -32,768 to 32,767; the default priority is 0. Private queues do not support base priority. Message Queuing routes and delivers messages first by base priority, then by message priority.

**basic disk**
A physical disk that can be accessed by MS-DOS and all Windows-based operating systems. Basic disks can contain up to four primary partitions, or three primary partitions and an extended partition with multiple logical drives. If you want to create partitions that span multiple disks, you must first convert the basic disk to a dynamic disk by using Disk Management or the Diskpart.exe command-line tool.

See also: dynamic disk

**basic input/output system (BIOS)**
On x86-based computers, the set of essential software routines that test hardware at startup, start the operating system, and support the transfer of data among hardware devices. The BIOS is stored in read-only memory (ROM) so that it can be executed when you turn on the computer. Although critical to performance, the BIOS is usually invisible to computer users.

See also: Extensible Firmware Interface (EFI)

**batch program**
An ASCII (unformatted text) file that contains one or more operating system commands. A batch program's file name has a .cmd or .bat extension. When you type the file name at the command prompt, or when the batch program is run from another program, its commands are processed sequentially. Also called *batch files*.

See also: American Standard Code for Information Interchange (ASCII)

**BIOS**
See definition for: basic input/output system (BIOS)

**broadcast**
The transmission of packets by an Internet Protocol version 4 (IPv4) host to all computers on the subnet.

See also: packet

**browser**
Software that interprets the markup of files in HTML, formats them into Web pages, and displays them to the end user. Some browsers also permit end users to send and receive e-mail, read newsgroups, and play sound or video files embedded in Web documents.

**C**

**capture**
To assign a port to a printer. Documents that you print are sent to the printer through the captured port.

For Network Monitor, the process by which frames are copied.

See also: frame

**capture trigger**
A set of conditions that, when met, stop the capture or execute a program or command file to perform another type of action related to the capture.

**CCP**
See definition for: Compression Control Protocol (CCP)

**certification authority (CA)**
An entity responsible for establishing and vouching for the authenticity of public keys belonging to subjects (usually users or computers) or other certification authorities. Activities of a certification authority can include binding public keys to distinguished names through signed certificates, managing certificate serial numbers, and certificate revocation.

**CGI**
See definition for: common gateway interface (CGI)

**checked build**
A version of Windows that consists of binaries that provide additional error checking, argument verification, and system debugging code. Much of the extra code in the checked binaries is in the form of ASSERT macros that test an expression. If the expression evaluates to FALSE, the macro generates a kernel debugger error message and breaks into the debugger. This lets you immediately determine the cause and location of the error. Because of the additional error checking code and debugging information, the checked binaries are larger and run slower than the free binaries. This can conceal synchronization or other timing-related problems, such as race conditions, that become apparent only in the free build. If you run the checked build of Windows NT without having enabled kernel debugging, unexpected system shutdowns can occur. This is because the additional checks in the checked build increase the likelihood of encountering a breakpoint.

**cluster**
In data storage, the smallest amount of disk space that can be allocated to hold a file. All file systems used by Windows organize hard disks based on clusters, which consist of one or more contiguous sectors. The smaller the cluster size, the more efficiently a disk stores information. If no cluster size is specified during formatting, Windows picks defaults based on the size of the volume. These defaults are selected to reduce the amount of space that is lost and the amount of fragmentation on the volume. Also called an *allocation unit*.

In computer networking, a group of independent computers that work together to provide a common set of services and present a single-system image to clients. The use of a cluster enhances the availability of the services and the scalability and manageability of the operating system that provides the services.

See also: volume

**cluster storage**
Storage where one or more attached disks hold data used either by server applications running on the cluster or by applications for managing the cluster. Each disk on the cluster storage is owned by only one node of the cluster. The ownership of disks moves from one node to another when the disk group fails over or moves to the other node.

See also: cluster

**code page**
A means of providing support for character sets and keyboard layouts for different countries or regions. A code page is a table that relates the binary character codes used by a program to keys on the keyboard or to characters on the display.

**COM**
See definition for: Component Object Model (COM)

**common gateway interface (CGI)**
A server-side interface for initiating software services. For example a set of interfaces that describe how a Web server communicates with software on the same computer. Any software can be a CGI program if it handles input and output according to the CGI standard.

**Component Object Model (COM)**
An object-based programming model designed to promote software interoperability; it allows two or more applications or components to easily cooperate with one another, even if they were written by different vendors, at different times, in different programming languages, or if they are running on different computers running different operating systems. OLE technology and ActiveX are both built on top of COM.

See also: ActiveX

**Compression Control Protocol (CCP)**
A protocol used in the negotiation process in a Point-to-Point Protocol (PPP) connection. CCP is one type of Network Control Protocol. Network Control Protocols are used to establish and configure different network protocol parameters for Internet Protocol (IP), Internetwork Packet Exchange (IPX), and NetBIOS Extended User Interface (NetBEUI).

See also: NetBIOS Extended User Interface (NetBEUI)

**console tree**
The left pane in Microsoft Management Console (MMC) that displays the items contained in the console. The items in the console tree and their hierarchical organization determine the capabilities of a console.

See also: Microsoft Management Console (MMC)

**credentials**
A set of information that includes identification and proof of identification that is used to gain access to local and network resources. Examples of credentials are user names and passwords, smart cards, and certificates.

**cyclic redundancy check (CRC)**
A procedure used in checking for errors in data transmission. CRC error checking uses a complex calculation to generate a number based on the data transmitted. The sending device performs the calculation before transmission and sends its result to the receiving device. The receiving device repeats the same calculation after transmission. If both devices obtain the same result, it is assumed that the transmission was error-free. The procedure is known as a redundancy check because each transmission includes not only data but extra (redundant) error-checking values. Communications protocols such as XMODEM and Kermit use cyclical redundancy checking.

**D**

**daemon**
A networking program, usually associated with UNIX systems, that runs in the background performing tool functions such as housekeeping or maintenance without user intervention or awareness. Pronounced "demon."

**DFS**
See definition for: Distributed File System (DFS)

**DHCP**
See definition for: Dynamic Host Configuration Protocol (DHCP)

**DHCP client**
Any network-enabled device that supports the ability to communicate with a DHCP server for the purpose of obtaining dynamic leased IP configuration and related optional parameters information.

See also: DHCP server; Dynamic Host Configuration Protocol (DHCP)

**DHCP server**
A computer running the Microsoft DHCP service that offers dynamic configuration of IP addresses and related information to DHCP-enabled clients.

See also: Dynamic Host Configuration Protocol (DHCP); IP address

**dial-up connection**
The connection to your network if you use a device that uses the telephone network. This includes modems with a standard telephone line, ISDN cards with high-speed ISDN lines, or X.25 networks.

If you are a typical user, you might have one or two dial-up connections, for example, to the Internet and to your corporate network. In a more complex server situation, multiple network modem connections might be used to implement advanced routing.

**directory service**
Both the directory information source and the service that makes the information available and usable. A directory service enables the user to find an object when given any one of its attributes.

See also: Active Directory

**disk mirroring**
A set of software processes that maintains a backup copy of a volume at all times. Each mirror of a volume resides on a different disk; ideally, each disk has its own controller. If one mirror becomes unavailable (due to a disk failure, for example), you can use the other mirror to gain access to the volume's data.

See also: mirror; volume

**distinguished name**
A name that uniquely identifies an object by using the relative distinguished name for the object, plus the names of container objects and domains that contain the object. The distinguished name identifies the object as well as its location in a tree. Every object in Active Directory has a distinguished name. A typical distinguished name might be

CN=MyName,CN=Users,DC=Microsoft,DC=Com

This identifies the MyName user object in the microsoft.com domain.

See also: Active Directory; domain

**Distributed File System (DFS)**
A service that allows system administrators to organize distributed network shares into a logical namespace, enabling users to access files without specifying their physical location and providing load sharing across network shares.

See also: service

**DLL**
See definition for: dynamic-link library (DLL)

**DNS**
See definition for: Domain Name System (DNS)

**DNS server**
A server that maintains information about a portion of the DNS database and that responds to and resolves DNS queries.

See also: Domain Name System (DNS)

**domain**
In Active Directory, a collection of computer, user, and group objects defined by the administrator. These objects share a common directory database, security policies, and security relationships with other domains.

In DNS, any tree or subtree within the DNS namespace. Although the names for DNS domains often correspond to Active Directory domains, DNS domains should not be confused with Active Directory domains.

See also: Active Directory; Domain Name System (DNS)

**domain controller**
In an Active Directory forest, a server that contains a writable copy of the Active Directory database, participates in Active Directory replication, and controls access to network resources. Administrators can manage user accounts, network access, shared resources, site topology, and other directory objects from any domain controller in the forest.

See also: Active Directory; forest; shared resource

**domain DFS**
An implementation of Distributed File System (DFS) in which DFS topological information is stored in Active Directory. Because this information is made available on multiple domain controllers in the domain, domain DFS provides fault tolerance for any distributed file system in the domain.

See also: Active Directory; Distributed File System (DFS); fault tolerance

**Domain Name System (DNS)**
A hierarchical, distributed database that contains mappings of DNS domain names to various types of data, such as IP addresses. DNS enables the location of computers and services by user-friendly names, and it also enables the discovery of other information stored in the database.

See also: IP address; service; Transmission Control Protocol/Internet Protocol (TCP/IP)

**dynamic disk**
A physical disk that provides features that basic disks do not, such as support for volumes that span multiple disks. Dynamic disks use a hidden database to track information about dynamic volumes on the disk and other dynamic disks in the computer. You convert basic disks to dynamic by using the Disk Management snap-in or the DiskPart command-line tool. When you convert a basic disk to dynamic, all existing basic volumes become dynamic volumes.

See also: active volume; basic disk; partition; volume

**Dynamic Host Configuration Protocol (DHCP)**
A TCP/IP service protocol that offers dynamic leased configuration of host IP addresses and distributes other configuration parameters to eligible network clients. DHCP provides safe, reliable, and simple TCP/IP network configuration, prevents address conflicts, and helps conserve the use of client IP addresses on the network.

DHCP uses a client/server model where the DHCP server maintains centralized management of IP addresses that are used on the network. DHCP-supporting clients can then request and obtain lease of an IP address from a DHCP server as part of their network boot process.

See also: DHCP client; DHCP server; IP address; service; Transmission Control Protocol/Internet Protocol (TCP/IP)

**dynamic-link library (DLL)**

An operating system feature that allows executable routines (generally serving a specific function or set of functions) to be stored separately as files with .dll extensions. These routines are loaded only when needed by the program that calls them.

See also: Resource DLL

**E**

**EFI**
See definition for: Extensible Firmware Interface (EFI)

**Encrypting File System (EFS)**
A feature in this version of Windows that enables users to encrypt files and folders on an NTFS volume disk to keep them safe from access by intruders.

See also: NTFS file system

**environment variable**
A string consisting of environment information, such as a drive, path, or file name, associated with a symbolic name that can be used by Windows. You use System in Control Panel or the **set** command from the command prompt to define environment variables.

See also: variable

**Extensible Firmware Interface (EFI)**
In computers with the Intel Itanium processor, the interface between a computer's firmware, hardware, and the operating system. EFI defines a new partition style called GUID partition table (GPT). EFI serves the same purpose for Itanium-based computers as the basic input/output system (BIOS) found in x86-based computers. However, it has expanded capabilities that provide a consistent way to start any compatible operating system and an easy way to add EFI drivers for new bootable devices without the need to update the computer's firmware.

See also: basic input/output system (BIOS)

**F**

**FAT**
See definition for: file allocation table (FAT)

**FAT32**
A derivative of the file allocation table (FAT) file system. FAT32 supports smaller cluster sizes and larger volumes than FAT, which results in more efficient space allocation on FAT32 volumes.

See also: file allocation table (FAT)

**fault tolerance**
The ability of computer hardware or software to ensure data integrity when hardware failures occur. Fault-tolerant features appear in many server operating systems and include mirrored volumes, RAID-5 volumes, and server clusters.

See also: cluster; RAID-5 volume

**file allocation table (FAT)**
A file system used by MS-DOS and other Windows operating systems to organize and manage files. The file allocation table is a data structure that Windows creates when you format a volume by using FAT or FAT32 file systems. Windows stores information about each file in the file allocation table so that it can retrieve the file later.

See also: FAT32; NTFS file system

**File Share resource**
A file share accessible by a network path that is supported as a cluster resource by a Resource DLL.

See also: Resource DLL

**File Transfer Protocol (FTP)**
A member of the TCP/IP suite of protocols, used to copy files between two computers on the Internet. Both computers must support their respective FTP roles: one must be an FTP client and the other an FTP server.

See also: Transmission Control Protocol/Internet Protocol (TCP/IP)

**filter**
For Indexing Service, software that extracts content and property values from a document to index them.

For Internet Protocol security (IPSec), a specification of Internet Protocol (IP) traffic that provides the ability to trigger security negotiations for a communication based on the source, destination, and type of IP traffic.

For Internet Information Services (IIS), a feature of Internet Server Application Programming Interface (ISAPI) that allows preprocessing of requests and postprocessing of responses, permitting site-specific handling of Hypertext Transfer Protocol (HTTP) requests and responses.

In IP and Internetwork Packet Exchange (IPX) packet filtering, a definition in a series of definitions that indicates to the router the type of traffic allowed or disallowed on each interface.

See also: Internet Server Application Programming Interface (ISAPI)

**flexible single-master operations (FSMO)**
See definition for: operations master

**flow**
A stream of data sent or received by a host. Also known as *network traffic*.

**forest**
One or more Active Directory domains that share the same class and attribute definitions (schema), site and replication information (configuration), and forest-wide search capabilities (global catalog). Domains in the same forest are linked with two-way, transitive trust relationships.

See also: Active Directory; domain; global catalog; schema; two-way trust

**frame**
In synchronous communication, a package of information transmitted as a single unit from one device to another.

See also: capture

**FSMO**
See definition for: operations master

**FTP**
See definition for: File Transfer Protocol (FTP)

**G**

**gateway**
A dedicated device (or a set of services running on a dedicated computer) that routes network traffic and enables communication between different networking protocols. A gateway is a multiprotocol Internet Protocol (IP) router that translates between different transport protocols or data formats.

**global catalog**
A directory database that applications and clients can query to locate any object in a forest. The global catalog is hosted on one or more domain controllers in the forest. It contains a partial replica of every domain directory partition in the forest. These partial replicas include replicas of every object in the forest, as follows: the attributes most frequently used in search operations and the attributes required to locate a full replica of the object.

In Microsoft Provisioning System, the Exchange server maintains a list of global catalogs, and it maintains a load balance across global catalogs.

See also: Active Directory; domain controller; forest; replication

**globally unique identifier (GUID)**
A 16-byte value generated from the unique identifier on a device, the current date and time, and a sequence number. A GUID is used to identify a particular device or component.

**GPO**
See definition for: Group Policy object (GPO)

**graphical user interface (GUI)**
A display format, like that of Windows, that represents a program's functions with graphic images such as buttons and icons. GUIs enable a user to perform operations and make choices by pointing and clicking with a mouse.

**Group Policy**
The infrastructure within Active Directory directory service that enables directory-based change and configuration management of user and computer settings, including security and user data. You use Group Policy to define configurations for groups of users and computers. With Group Policy, you can specify policy settings for registry-based policies, security, software installation, scripts, folder redirection, remote installation services, and Internet Explorer maintenance. The Group Policy settings that you create are contained in a Group Policy object (GPO). By associating a GPO with selected Active Directory system containers—sites, domains, and organizational units—you can apply the GPO's policy settings to the users and computers in those Active Directory containers. To create an individual GPO, use the Group Policy Object Editor. To manage Group Policy objects across an enterprise, you can use the Group Policy Management console.

See also: Active Directory; Group Policy object (GPO)

**Group Policy object (GPO)**
A collection of Group Policy settings. GPOs are essentially the documents created by the Group Policy Object Editor. GPOs are stored at the domain level, and they affect users and computers that are contained in sites, domains, and organizational units. In addition, each computer has exactly one group of policy settings stored locally, called the *local Group Policy object*.

See also: Group Policy

**GUID**
See definition for: globally unique identifier (GUID)

**H**

**handle**
In the user interface, an interface added to an object that facilitates moving, sizing, reshaping, or other functions pertaining to an object. In programming, a pointer to a pointer, that is, a token that lets a program access an identified resource.

**hardware abstraction layer (HAL)**
A thin layer of software provided by the hardware manufacturer that hides, or abstracts, hardware differences from higher layers of the operating system. By means of the filter provided by the HAL, different types of hardware look alike to the rest of the operating system. This enables the operating system to be portable from one hardware platform to another. The HAL also provides routines that enable a single device driver to support the same device on all platforms.

**high performance file system (HPFS)**
The file system designed for the OS/2 version 1.2 operating system.

**hive**
A file in which the system stores a portion of the registry (named for their resemblance to the cellular structure of a beehive). A hive is backed by a single file and a .log file, which are in either the *systemroot*\System32\Config folder or the *systemroot*\Profiles*username* folder.

By default, most hive files (Default, SAM, Security, and System) are stored in the *systemroot*\System32\Config folder. The *systemroot*\Profiles folder contains the user profile for each user of the computer. Because a hive is a file, it can be moved from one system to another. However, you must use the Registry Editor, Regedit.exe, to edit the file.

See also: key; registry

**Hosts file**
A local text file in the same format as the 4.3 Berkeley Software Distribution (BSD) UNIX /etc/hosts file. This file maps host names to IP addresses, and it is stored in the \%Systemroot%\System32\Drivers\Etc folder.

**HTML**
See definition for: Hypertext Markup Language (HTML)

**HTTP**
See definition for: Hypertext Transfer Protocol (HTTP)

**Hypertext Markup Language (HTML)**
A simple markup language used to create hypertext documents that are portable from one platform to another. HTML files are simple ASCII text files with codes embedded (indicated by markup tags) to denote formatting and hypertext links.

See also: American Standard Code for Information Interchange (ASCII)

**Hypertext Transfer Protocol (HTTP)**
The protocol used to transfer information on the World Wide Web. An HTTP address (one kind of Uniform Resource Locator

(URL)) takes the following form: http://www.microsoft.com.

See also: protocol; Uniform Resource Locator (URL)

**I**

**incorrect delegation**
A condition in which the resource records establishing a Domain Name System (DNS) zone delegation contain incorrect data or indicate a DNS server that does not have authority for the delegated zone. An improper delegation causes a DNS resolver to direct queries to an incorrect server and the query fails.

See also: Domain Name System (DNS)

**infrastructure master**
A domain controller that holds the infrastructure operations master role in Active Directory. The infrastructure master updates the group-to-user reference whenever group memberships change and replicates these changes across the domain. At any time, the infrastructure master role can be assigned to only one domain controller in each domain.

See also: Active Directory; domain controller; operations master

**IntelliMirror**
A set of change and configuration management features based on Active Directory that enables management of user and computer data and settings, including security data. IntelliMirror also provides limited ability to deploy software to Windows 2000 and later workstations or servers.

See also: Active Directory

**Internet Server Application Programming Interface (ISAPI)**
An application programming interface (API) that resides on a server computer for initiating software services tuned for Windows operating systems.

In Microsoft Provisioning System, ISAPI resides on the Web server.

See also: application programming interface (API)

**Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX)**
Transport protocols used in Novell NetWare networks, which together correspond to the combination of TCP and IP in the TCP/IP protocol suite. Windows implements IPX through NWLink.

See also: NWLink IPX/SPX/NetBIOS Compatible Transport Protocol (NWLink); Transmission Control Protocol/Internet Protocol (TCP/IP)

**IP address**
For Internet Protocol version 4 (IPv4), a 32-bit address used to identify a node on an IPv4 internetwork. Each node on the IP internetwork must be assigned a unique IPv4 address, which is made up of the network ID, plus a unique host ID. This address is typically represented with the decimal value of each octet separated by a period (for example, 192.168.7.27). You can configure the IP address statically or dynamically by using Dynamic Host Configuration Protocol (DHCP).

For Internet Protocol version 6 (IPv6), an identifier that is assigned at the IPv6 layer to an interface or set of interfaces and that can be used as the source or destination of IPv6 packets.

See also: Dynamic Host Configuration Protocol (DHCP)

**IPX/SPX**
See definition for: Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX)

**ISAPI**
See definition for: Internet Server Application Programming Interface (ISAPI)

**J**
There are no glossary terms that begin with this letter.

**K**

**KDC**
See definition for: Key Distribution Center (KDC)

**Kerberos V5 authentication protocol**
An authentication mechanism used to verify user or host identity. The Kerberos V5 authentication protocol is the default authentication service. Internet Protocol security (IPSec) can use the Kerberos protocol for authentication.

See also: Key Distribution Center (KDC); ticket-granting service (TGS); ticket-granting ticket (TGT)

**kernel**
The core of layered architecture that manages the most basic operations of the operating system and the computer's processor. The kernel schedules different blocks of executing code, called threads, for the processor to keep it as busy as possible and coordinates multiple processors to optimize performance. The kernel also synchronizes activities among Executive-level subcomponents, such as I/O Manager and Process Manager, and handles hardware exceptions and other hardware-dependent functions. The kernel works closely with the hardware abstraction layer.

**kernel mode**
A highly privileged mode of operation where program code has direct access to all memory, including the address spaces of all user-mode processes and applications, and to hardware. Also known as *supervisor mode*, *protected mode*, or *Ring 0*.

**key**
In Registry Editor, a folder that appears in the left pane of the Registry Editor window. A key can contain subkeys and entries. For example, Environment is a key of **HKEY_CURRENT_USER**.

In IP security (IPSec), a value used in combination with an algorithm to encrypt or decrypt data. Key settings for IPSec are configurable to provide greater security.

See also: registry

**Key Distribution Center (KDC)**
A network service that supplies session tickets and temporary session keys used in the Kerberos V5 authentication protocol.

See also: Kerberos V5 authentication protocol; ticket-granting service (TGS); ticket-granting ticket (TGT)

**Knowledge Consistency Checker (KCC)**
A built-in process that runs on all domain controllers and generates the replication topology for the Active Directory forest. At specified intervals, the KCC reviews and makes modifications to the replication topology to ensure propagation of data either directly or transitively.

See also: Active Directory; domain controller; forest; replication topology

**Korn shell (ksh)**
A command shell that provides the following functionality: file input and output redirection; command-line editing by using **vi**; command history; integer arithmetic; pattern matching and variable substitution; command name abbreviation (aliasing); and built-in commands for writing shell programs.

**ksh**
See definition for: Korn shell (ksh)

**L**

**lame delegation**
See definition for: incorrect delegation

**LAN**
See definition for: local area network (LAN)

**Layer Two Tunneling Protocol (L2TP)**
An industry-standard Internet tunneling protocol that provides encapsulation for sending Point-to-Point Protocol (PPP) frames across packet-oriented media. For IP networks, L2TP traffic is sent as User Datagram Protocol (UDP) messages. In Microsoft operating systems, L2TP is used in conjunction with Internet Protocol security (IPSec) as a virtual private network (VPN) technology to provide remote access or router-to-router VPN connections. L2TP is described in RFC 2661.

See also: frame

**LDAP**
See definition for: Lightweight Directory Access Protocol (LDAP)

**Lightweight Directory Access Protocol (LDAP)**
The primary access protocol for Active Directory. LDAP is an industry-standard protocol, established by the Internet

Engineering Task Force (IETF), that allows users to query and update information in a directory service. Active Directory supports both LDAP version 2 and LDAP version 3.

See also: Active Directory; directory service; protocol

**local area network (LAN)**
A communications network connecting a group of computers, printers, and other devices located within a relatively limited area (for example, a building). A LAN enables any connected device to interact with any other on the network.

See also: NetBIOS Extended User Interface (NetBEUI); network basic input/output system (NetBIOS); virtual local area network (VLAN)

**Local Security Authority (LSA)**
A protected subsystem that authenticates and logs users on to the local computer. In addition, the LSA maintains information about all aspects of local security on a computer (collectively known as the *local security policy*), and it provides various services for translation between names and identifiers.

**M**

**MAC**
See definition for: media access control (MAC)

**majority node set server cluster**
A cluster configuration that has two or more nodes and that is configured so that the nodes may or may not be attached to one or more cluster storage devices. The cluster configuration data is stored on multiple disks across the cluster, and the Cluster service makes sure that this data is kept consistent across the different disks. There are advantages and limitations for each cluster configuration (single node server cluster, single quorum device server cluster, and majority node set server cluster).

See also: cluster; cluster storage; single quorum device server cluster

**management information base (MIB)**
A set of objects that represent various types of information about a device, used by Simple Network Management Protocol (SNMP) to manage the device. Because different network management services are used for different types of devices and protocols, each service has its own set of objects.

See also: service; Simple Network Management Protocol (SNMP)

**master boot record (MBR)**
The first sector on a hard disk, which begins the process of starting the computer. The MBR contains the partition table for the disk and a small amount of executable code called the *master boot code*.

**MBR**
See definition for: master boot record (MBR)

**media access control (MAC)**
A sublayer of the IEEE 802 specifications that defines network access methods and framing.

**Message Authentication Code (MAC)**
An algorithm that ensures the quality of a block of data.

**MIB**
See definition for: management information base (MIB)

**Microsoft Management Console (MMC)**
A framework for hosting administrative tools called *snap-ins*. A console might contain tools, folders or other containers, World Wide Web pages, and other administrative items. These items are displayed in the left pane of the console, called a *console tree*. A console has one or more windows that can provide views of the console tree. The main MMC window provides commands and tools for authoring consoles. The authoring features of MMC and the console tree itself might be hidden when a console is in User Mode.

See also: console tree; snap-in

**mirror**
One of the two volumes that make up a mirrored volume. Each mirror of a mirrored volume resides on a different disk. If one mirror becomes unavailable (due to a disk failure, for example), Windows can use the remaining mirror to gain access to the volume's data.

See also: fault tolerance; volume

**MMC**
See definition for: Microsoft Management Console (MMC)

**multicasting**
The process of sending a message simultaneously to more than one destination on a network.

**N**

**native mode**
In Windows 2000 domains, the domain mode in which all domain controllers in a domain are running Windows 2000 and a domain administrator has switched the domain operation mode from mixed mode to native mode. Native mode supports universal groups and nesting of groups. In native mode, domain controllers running Windows NT 4.0 or earlier are not supported.

In Windows Server 2003 domains, native mode is referred to as *Windows 2000 native*, and it is one of three domain functional levels available.

See also: Active Directory

**NetBEUI**
See definition for: NetBIOS Extended User Interface (NetBEUI)

**NetBIOS**
See definition for: network basic input/output system (NetBIOS)

**NetBIOS Extended User Interface (NetBEUI)**
A network protocol native to Microsoft Networking. It is usually used in small, department-size local area networks (LANs) of 1 to 200 clients. NetBEUI can use Token Ring source routing as its only method of routing. NetBEUI is the Microsoft implementation of the NetBIOS standard.

See also: Compression Control Protocol (CCP); local area network (LAN); network basic input/output system (NetBIOS); protocol

**Netsh**
A command-line and scripting tool for networking components for local or shared computers running Windows 2000, Windows XP Professional, or Windows Server 2003.

**network basic input/output system (NetBIOS)**
An application programming interface (API) that can be used by programs on a local area network (LAN). NetBIOS provides programs with a uniform set of commands for requesting the lower-level services required to manage names, conduct sessions, and send datagrams between nodes on a network.

See also: application programming interface (API); basic input/output system (BIOS); local area network (LAN); service

**nonpaged pool**
Operating system memory that is never paged to disk. Paging is the moving of infrequently used parts of a program's working memory from RAM to another storage medium, usually the hard disk. In Task Manager, the amount of memory used by a process, in kilobytes.

**notification area**
The area on the taskbar to the right of the taskbar buttons. The notification area displays the time and can also contain shortcuts that provide quick access to programs, such as Volume Control and Power Options. Other shortcuts can appear temporarily, providing information about the status of activities. For example, the printer shortcut icon appears after a document has been sent to the printer and disappears when printing is complete.

**NTFS file system**
An advanced file system that provides performance, security, reliability, and advanced features that are not found in any version of file allocation table (FAT). For example, NTFS guarantees volume consistency by using standard transaction logging and recovery techniques. If a system fails, NTFS uses its log file and checkpoint information to restore the consistency of the file system. NTFS also provides advanced features, such as file and folder permissions, encryption, disk quotas, and compression.

See also: FAT32; file allocation table (FAT)

**NTLM authentication protocol**
A challenge/response authentication protocol. The NTLM authentication protocol is supported in Windows 2000, Windows XP, and the Windows Server 2003 family, but it is not the default. It was the default authentication protocol for earlier versions of Windows.

See also: protocol

**NWLink**
See definition for: NWLink IPX/SPX/NetBIOS Compatible Transport Protocol (NWLink)

**NWLink IPX/SPX/NetBIOS Compatible Transport Protocol (NWLink)**
The Microsoft implementation of the Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) protocol used on NetWare networks. NWLink allows connectivity between Windows-based computers and NetWare networks running IPX/SPX. NWLink also provides network basic input/output system (NetBIOS) functionality and the Routing Information Protocol (RIP).

See also: Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX); network basic input/output system (NetBIOS); Routing Information Protocol over IPX (RIPX)

**O**

**object linking and embedding (OLE)**
A method for sharing information among applications. Linking an object, such as a graphic, from one document to another inserts a reference to the object into the second document. Any changes you make in the object in the first document will also be made in the second document. Embedding an object inserts a copy of an object from one document into another document. Changes you make in the object in the first document will not be updated in the second unless the embedded object is explicitly updated.

**ODBC**
See definition for: Open Database Connectivity (ODBC)

**one-way trust**
A trust relationship between two domains in which only one of the two domains trusts the other domain. For example, domain A trusts domain B, and domain B does not trust domain A. One-way trusts are often used to enable authenticated access to resource domains.

See also: domain; trust relationship; two-way trust

**Open Database Connectivity (ODBC)**
An application programming interface (API) that enables database applications to access data from a variety of existing data sources.

See also: application programming interface (API)

**operations master**
A domain controller that has been assigned one or more special roles in an Active Directory domain. The domain controllers assigned these roles perform operations that are single-master (not permitted to occur at different places on the network at the same time). Examples of these operations include resource identifier allocation, schema modification, PDC emulation, adding and removing domains to and from the forest, and tracking changes to security principals across all domains in a forest.

See also: Active Directory; domain controller; infrastructure master

**organizational unit**
An Active Directory container object used within domains. An organizational unit is a logical container into which users, groups, computers, and other organizational units are placed. It can contain objects only from its parent domain. An organizational unit is the smallest scope to which a Group Policy object (GPO) can be linked, or over which administrative authority can be delegated.

See also: Active Directory; Group Policy object (GPO)

**orphan**
A member of a mirrored volume or a RAID-5 volume that has failed due to a severe cause, such as a loss of power or a complete hard-disk head failure. When this happens, the fault-tolerant driver determines that it can no longer use the orphaned member and directs all new reads and writes to the remaining members of the fault-tolerant volume.

See also: fault tolerance; RAID-5 volume

## P

**packet**
An Open Systems Interconnection (OSI) network layer transmission unit that consists of binary information representing both data and a header containing an identification number, source and destination addresses, and error-control data.

**packet header**
In network protocol communications, a specially reserved field of a defined bit length that is attached to the front of a packet for carry and transfer of control information. When the packet arrives at its destination, the field is then detached and discarded as the packet is processed and disassembled in a corresponding reverse order for each protocol layer.

See also: packet

**page fault**
The interrupt that occurs when software attempts to read from or write to a virtual memory location that is marked *not present*.

In Task Manager, page fault is the number of times data has to be retrieved from disk for a process because it was not found in memory. The page fault value accumulates from the time the process started.

**paged pool**
The system-allocated virtual memory that has been charged to a process and that can be paged. Paging is the moving of infrequently used parts of a program's working memory from random access memory (RAM) to another storage medium, usually the hard disk.

In Task Manager, the amount of system-allocated virtual memory, in kilobytes, used by a process.

**parity**
A calculated value that is used to reconstruct data after a failure. RAID-5 volumes stripe data and parity intermittently across a set of disks. When a disk fails, some server operating systems use the parity information together with the data on good disks to recreate the data on the failed disk.

See also: fault tolerance; RAID-5 volume; striped volume

**parity bit**
In asynchronous communications, an extra bit used in checking for errors in groups of data bits transferred within or between computer systems. In modem-to-modem communications, a parity bit is often used to check the accuracy with which each character is transmitted.

See also: parity

**partition**
A portion of a physical disk that functions as though it were a physically separate disk. After you create a partition, you must format it and assign it a drive letter before you can store data on it.

On basic disks, partitions are known as basic volumes, which include primary partitions and logical drives. On dynamic disks, partitions are known as dynamic volumes, which include simple, striped, spanned, mirrored, and RAID-5 volumes.

See also: basic disk

**partition table**
On a hard disk, the data structure that stores the offset (location) and size of each primary partition on the disk. On MBR disks, the partition table is located in the master boot record. On GPT disks, the partition table is located in the GUID partition entry array.

See also: globally unique identifier (GUID); master boot record (MBR); partition

**path**
A sequence of directory (or folder) names that specifies the location of a directory, file, or folder within the Windows directory tree. Each directory name and file name within the path must be preceded by a backslash (\). For example, to specify the path of a file named Readme.doc located in the Windows directory on drive C, type **C:\Windows\Readme.doc**.

**PCMCIA device**
A removable device, approximately the size of a credit card, that can be plugged into a PCMCIA slot in a portable computer. PCMCIA devices can include modems, network adapters, and hard disk drives.

Some PCMCIA cards can be connected to and disconnected from your computer without restarting it. Before you remove the

PCMCIA card, however, you should use the Add Hardware Wizard to notify Windows that you are doing so. Windows will then notify you when you can remove the device.

**PDC**
See definition for: primary domain controller (PDC)

**Performance Monitor**
A Windows NT administrative tool that monitors performance on local or remote computers. Performance Monitor was replaced by the Performance console in Windows 2000.

**permission**
A rule associated with an object to regulate which users can gain access to the object and in what manner. Permissions are assigned or denied by the object's owner.

**POP**
See definition for: Post Office Protocol

**Portable Operating System Interface for UNIX (POSIX)**
An Institute of Electrical and Electronics Engineers (IEEE) standard that defines a set of operating-system services. Programs that adhere to the POSIX standard can be easily ported from one system to another. POSIX was based on UNIX system services, but it was created in a way that allows it to be implemented by other operating systems.

See also: service

**POSIX**
See definition for: Portable Operating System Interface for UNIX (POSIX)

**Post Office Protocol**
A maildrop service that allows a client to retrieve mail that the server is holding for it. The most recent implementation is Version 3, or POP3.

**primary domain controller (PDC)**
In a Windows NT domain, a domain controller running Windows NT Server 4.0 or earlier that authenticates domain logon attempts and updates user, computer, and group accounts in a domain. The PDC contains the master read-write copy of the directory database for the domain. A domain has only one PDC.

In a Windows 2000 or Windows Server 2003 domain, the PDC emulator master supports compatibility with client computers that are not running Windows 2000 or Windows XP Professional.

See also: Active Directory

**printer**
A device that puts text or images on paper or other print media. Examples are laser printers or dot-matrix printers.

**process**
An operating system object that consists of an executable program, a set of virtual memory addresses, and one or more threads. When a program runs, a process is created.

**promiscuous mode**
A mode in which a network device listens to all traffic present on the local network segment. A device operating in promiscuous mode reads every frame it receives, whether the frames are broadcast, multicast, or unicast. Certain devices typically operate in promiscuous mode, such as bridges, which must listen to all traffic in order to build their media access control (MAC) address tables, and network troubleshooting devices, which capture and analyze all traffic on a particular local area network (LAN) segment.

See also: broadcast; local area network (LAN)

**protocol**
A set of rules and conventions for sending information over a network. These rules govern the content, format, timing, sequencing, and error control of messages exchanged among network devices.

See also: Transmission Control Protocol/Internet Protocol (TCP/IP)

**Q**

**QoS**
See definition for: Quality of Service (QoS)

**Quality of Service (QoS)**
A set of quality assurance standards and mechanisms for data transmission, implemented in this version of Windows.

**R**

**RAID-5 volume**
A fault-tolerant volume with data and parity striped intermittently across three or more physical disks. Parity is a calculated value that is used to reconstruct data after a failure. If a portion of a physical disk fails, Windows recreates the data that was on the failed portion from the remaining data and parity. You can create RAID-5 volumes only on dynamic disks on computers running the Windows 2000 Server or Windows Server 2003 families of operating systems. You cannot mirror or extend RAID-5 volumes. In Windows NT 4.0, a RAID-5 volume was known as a *striped set with parity*.

See also: dynamic disk; fault tolerance; parity; volume

**RAS**
See definition for: Remote Access Service (RAS)

**reduced instruction set computing**
A type of microprocessor design that focuses on rapid and efficient processing of a relatively small set of instructions. RISC architecture limits the number of instructions that are built into the microprocessor, but optimizes each so it can be carried out very rapidly{bmct emdash.bmp}usually within a single clock cycle.

**Redundant Array of Independent Disks (RAID)**
A method used to standardize and categorize fault-tolerant disk systems. RAID levels provide various mixes of performance, reliability, and cost. Some servers provide three of the RAID levels: Level 0 (striping), Level 1 (mirroring), and Level 5 (RAID-5).

See also: fault tolerance; RAID-5 volume

**registry**
A database repository for information about a computer's configuration. The registry contains information that Windows continually references during operation, such as:

- Profiles for each user
- The programs installed on the computer and the types of documents that each can create
- Property settings for folders and program icons
- What hardware exists on the system
- Which ports are being used

The registry is organized hierarchically as a tree, and it is made up of keys and their subkeys, hives, and entries.

See also: hive; key

**registry key**
An identifier for a record or group of records in the registry.

**relative ID (RID)**
The part of a security ID (SID) that uniquely identifies an account or group within a domain.

See also: domain; forest; security ID (SID)

**remote access**
Part of the integrated Routing and Remote Access service that provides remote networking for telecommuters, mobile workers, and system administrators who monitor and manage servers at multiple branch offices. Users can use Network Connections to dial in to remotely access their networks for services such as file and printer sharing, electronic mail, scheduling, and SQL database access.

See also: service

**Remote Access Service (RAS)**
A Windows NT 4.0 service that provides remote networking for telecommuters, mobile workers, and system administrators

who monitor and manage servers at multiple offices.

**remote procedure call (RPC)**
A message-passing facility that allows a distributed application to call services that are available on various computers on a network. Used during remote administration of computers.

See also: service

**reparse points**
NTFS file system objects that have a definable attribute containing user-controlled data and that are used to extend functionality in the input/output (I/O) subsystem.

See also: NTFS file system

**replication**
The process of copying updated data from a data store or file system on a source computer to a matching data store or file system on one or more destination computers to synchronize the data.

In Active Directory, replication synchronizes schema, configuration, application, and domain directory partitions between domain controllers.

In Distributed File System (DFS), replication synchronizes files and folders between DFS roots and root targets.

See also: Active Directory; Distributed File System (DFS); topology

**replication topology**
In Active Directory replication, the set of physical connections that domain controllers use to replicate directory updates among domain controllers within sites and between sites.

In the File Replication service (FRS), the interconnections between replica set members. These interconnections determine the path that data takes as it replicates to all replica set members.

See also: Active Directory; Distributed File System (DFS); domain controller; replication

**Request for Comments (RFC)**
An official document of the Internet Engineering Task Force (IETF) that specifies the details for protocols included in the TCP/IP family.

See also: protocol; Transmission Control Protocol/Internet Protocol (TCP/IP)

**resource**
Generally, any part of a computer system or network, such as a disk drive, printer, or memory, that can be allotted to a running program or a process.

For Device Manager, any of four system components that control how the devices on a computer work. These four system resources are interrupt request (IRQ) lines, direct memory access (DMA) channels, input/output (I/O) ports, and memory addresses.

For server clusters, a physical or logical entity that is capable of being managed by a cluster, brought online and taken offline, and moved between nodes. A resource can be owned only by a single node at any point in time.

**Resource DLL**
A dynamic-link library (DLL) containing an implementation of the Resource application programming interface (API) for a specific type of resource. The Resource DLL is loaded into the address space of its Resource Monitor.

See also: application programming interface (API); dynamic-link library (DLL)

**RID**
See definition for: relative ID (RID)

**ring transition**
A ring transition or kernel-mode transition occurs when user-mode processes use application program interfaces (APIs) to switch their threads from user mode to kernel mode.

**RIPX**
See definition for: Routing Information Protocol over IPX (RIPX)

**RISC**

See definition for: reduced instruction set computing

**router**
Hardware that helps local area networks (LANs) and wide area networks (WANs) achieve interoperability and connectivity and that can link LANs that have different network topologies (such as Ethernet and Token Ring). Routers match packet headers to a LAN segment and choose the best path for the packet, optimizing network performance.

See also: local area network (LAN); packet header; Routing Information Protocol over IPX (RIPX); static routes; wide area network (WAN)

**Routing Information Protocol over IPX (RIPX)**
A protocol used by routers to exchange information between routers on an Internetwork Packet Exchange (IPX) network and by hosts to determine the best router to use when forwarding IPX traffic to a remote IPX network.

See also: NWLink IPX/SPX/NetBIOS Compatible Transport Protocol (NWLink); protocol; router

**RPC**
See definition for: remote procedure call (RPC)

**S**

**SAM**
See definition for: Security Accounts Manager (SAM)

**schema**
The set of definitions for the universe of objects that can be stored in a directory. For each object class, the schema defines which attributes an instance of the class must have, which additional attributes it can have, and which other object classes can be its parent object class.

**script**
A type of program consisting of a set of instructions to an application or tool program. A script usually expresses instructions by using the application's or tool's rules and syntax, combined with simple control structures such as loops and if/then expressions. "Batch program" is often used interchangeably with "script" in the Windows environment.

**SCSI**
See definition for: small computer system interface (SCSI)

**Security Accounts Manager (SAM)**
A Windows service used during the logon process. SAM maintains user account information, including groups to which a user belongs.

See also: service

**security descriptor**
A data structure that contains security information associated with a protected object. Security descriptors include information about who owns the object, who can access it and in what way, and what types of access are audited.

See also: permission

**security ID (SID)**
A data structure of variable length that identifies user, group, and computer accounts. Every account on a network is issued a unique SID when the account is first created. Internal processes in Windows refer to an account's SID rather than the account's user or group name.

**Server Message Block (SMB)**
A file-sharing protocol designed to allow networked computers to transparently access files that reside on remote systems over a variety of networks. The SMB protocol defines a series of commands that pass information between computers. SMB uses four message types: session control, file, printer, and message.

See also: protocol

**service**
A program, routine, or process that performs a specific system function to support other programs, particularly at a low (close to the hardware) level. When services are provided over a network, they can be published in Active Directory, facilitating service-centric administration and usage. Some examples of services are the Security Accounts Manager service, File Replication service, and Routing and Remote Access service.

See also: Security Accounts Manager (SAM)

**sh**
See definition for: shell (sh)

**share**
To make resources, such as folders and printers, available to others.

See also: resource

**shared resource**
Any device, data, or program that is used by more than one program or one other device. For Windows, *shared resource* refers to any resource that is made available to network users, such as folders, files, printers, and named pipes. *Shared resource* can also refer to a resource on a server that is available to network users.

See also: resource; share

**shell (sh)**
A command-line POSIX tool that contains a large subset of Korn shell functionality (though no variable arrays).

**SID**
See definition for: security ID (SID)

**Simple Mail Transfer Protocol (SMTP)**
A member of the TCP/IP suite of protocols that governs the exchange of electronic mail between message transfer agents.

See also: protocol; Transmission Control Protocol/Internet Protocol (TCP/IP)

**Simple Network Management Protocol (SNMP)**
A network protocol used to manage TCP/IP networks. In Windows, the SNMP service is used to provide status information about a host on a TCP/IP network.

See also: protocol; service; Transmission Control Protocol/Internet Protocol (TCP/IP)

**simple volume**
A dynamic volume made up of disk space from a single dynamic disk. A simple volume can consist of a single region on a disk or multiple regions of the same disk that are linked together. If the simple volume is not a system volume or boot volume, you can extend it within the same disk or onto additional disks. If you extend a simple volume across multiple disks, it becomes a spanned volume. You can create simple volumes only on dynamic disks. Simple volumes are not fault tolerant, but you can mirror them to create mirrored volumes on computers running the Windows 2000 Server or Windows Server 2003 families of operating systems.

See also: dynamic disk; fault tolerance; spanned volume; volume

**single quorum device server cluster**
A cluster configuration that has two or more nodes and that is configured so that every node is attached to one or more cluster storage device. The cluster configuration data is stored on a single cluster storage device. There are advantages and limitations for each cluster configuration (single node server cluster, single quorum device server cluster, and majority node set server cluster).

See also: cluster; cluster storage; majority node set server cluster

**small computer system interface (SCSI)**
A standard high-speed parallel interface defined by the American National Standards Institute (ANSI). A SCSI interface is used for connecting microcomputers to peripheral devices, such as hard disks and printers, and to other computers and local area networks (LANs).

See also: local area network (LAN)

**SMB**
See definition for: Server Message Block (SMB)

**SMTP**
See definition for: Simple Mail Transfer Protocol (SMTP)

**snap-in**
A type of tool that you can add to a console supported by Microsoft Management Console (MMC). A stand-alone snap-in can

be added by itself; an extension snap-in can be added only to extend the function of another snap-in.

See also: Microsoft Management Console (MMC)

**spanned volume**
A dynamic volume consisting of disk space on more than one physical disk. You can increase the size of a spanned volume by extending it onto additional dynamic disks. You can create spanned volumes only on dynamic disks. Spanned volumes are not fault tolerant and cannot be mirrored.

See also: dynamic disk; fault tolerance; simple volume; volume

**SQL**
See definition for: structured query language (SQL)

**standard error (STDERR)**
In UNIX, the defined receiver of error messages about a process. By default, the standard error goes to the terminal.

**standard input (STDIN)**
In UNIX, the defined source of input for a process. By default, standard input comes from the terminal.

**standard output (STDOUT)**
In UNIX, the defined receiver for output from a process. By default, the standard output goes to the terminal.

**static routes**
Routes in a routing table that are permanent until changed by a network administrator or by an automatically scheduled auto-static update.

See also: router

**striped volume**
A dynamic volume that stores data in stripes on two or more physical disks. Data in a striped volume is allocated alternately and evenly (in stripes) across the disks. Striped volumes offer the best performance of all the volumes that are available in Windows, but they do not provide fault tolerance. If a disk in a striped volume fails, the data in the entire volume is lost. You can create striped volumes only on dynamic disks. Striped volumes cannot be mirrored or extended.

See also: dynamic disk; fault tolerance; volume

**structured query language (SQL)**
A widely accepted standard database sublanguage used in querying, updating, and managing relational databases.

**subnet mask**
A 32-bit value that enables the recipient of Internet Protocol version 4 (IPv4) packets to distinguish the network ID and host ID portions of the IPv4 address. Typically, subnet masks use the format 255.*x.x.x*. IPv6 uses network prefix notations rather than subnet masks.

See also: IP address

**system tray**
See definition for: notification area

**T**

**TAPI**
See definition for: Telephony API (TAPI)

**TCP**
See definition for: Transmission Control Protocol/Internet Protocol (TCP/IP)

**TCP/IP**
See definition for: Transmission Control Protocol/Internet Protocol (TCP/IP)

**TDI**
See definition for: Transport Driver Interface (TDI)

**Telephony API (TAPI)**
An application programming interface (API) used by communications programs to work with telephony and network services. Communications programs like HyperTerminal and Phone Dialer use TAPI to dial, answer, and route telephone calls on

conventional telephony devices, including PBXs, modems, and fax machines. TAPI 3.0 also provides Internet Protocol (IP) telephony support, which Phone Dialer and other programs use to transmit, route, and control real-time audio and video signals over IP-based networks such as the Internet.

See also: application programming interface (API); service

**Telnet**
A protocol that enables an Internet user to log on to and enter commands on a remote computer linked to the Internet, as if the user were using a text-based terminal directly attached to that computer. Telnet is part of the TCP/IP suite of protocols. The term *telnet* also refers to the software (client or server component) that implements this protocol.

See also: protocol; Transmission Control Protocol/Internet Protocol (TCP/IP)

**TGS**
See definition for: ticket-granting service (TGS)

**TGT**
See definition for: ticket-granting ticket (TGT)

**thread**
A type of object within a process that runs program instructions. Using multiple threads allows concurrent operations within a process and enables one process to run different parts of its program on different processors simultaneously. A thread has its own set of registers, its own kernel stack, a thread environment block, and a user stack in the address space of its process.

See also: kernel

**ticket**
A set of identification data for a security principal, issued by a domain controller for purposes of user authentication. Two forms of tickets in Windows are ticket-granting tickets (TGTs) and service tickets.

See also: domain controller; ticket-granting ticket (TGT)

**ticket-granting service (TGS)**
A Kerberos V5 service provided by the Kerberos V5 Key Distribution Center (KDC) service that issues service tickets that allow users to authenticate to services in a domain.

See also: Kerberos V5 authentication protocol; Key Distribution Center (KDC); ticket-granting ticket (TGT)

**ticket-granting ticket (TGT)**
A credential issued to a user by the Kerberos Key Distribution Center (KDC) when the user logs on. The user must present the TGT to the KDC when requesting session tickets for services. Because a TGT is normally valid for the life of the user's logon session, it is sometimes called a *user ticket*.

See also: Kerberos V5 authentication protocol; Key Distribution Center (KDC); ticket-granting service (TGS)

**topology**
The physical layout of computers, cables, switches, routers, and other components of a network. *Topology* also refers to the underlying network architecture, such as Ethernet or Token Ring.

In Active Directory replication, the set of connections that domain controllers use to replicate information among themselves.

See also: domain controller

**touch**
Command-line POSIX tool which changes the modification date of files.

**Transmission Control Protocol/Internet Protocol (TCP/IP)**
A set of networking protocols widely used on the Internet that provides communications across interconnected networks of computers with diverse hardware architectures and various operating systems. TCP/IP includes standards for how computers communicate and conventions for connecting networks and routing traffic.

See also: protocol

**Transport Driver Interface (TDI)**
A common set of routines for network layer components that communicate with the session layer of the Open Systems Interconnection (OSI) model. These routines allow software components above and below the transport layer to be mixed and matched without reprogramming.

**transport protocol**
A protocol that defines how data should be presented to the next receiving layer in the Windows NT and Windows 2000 networking model and packages the data accordingly. The transport protocol passes data to the network adapter driver through the Network Driver Interface Specification (NDIS) interface and to the redirector through the Transport Driver Interface (TDI).

**trust relationship**
A logical relationship established between domains to allow pass-through authentication, in which a trusting domain honors the logon authentications of a trusted domain. User accounts and global groups defined in a trusted domain can be given rights and permissions in a trusting domain, even though the user accounts or groups don't exist in the trusting domain's directory.

See also: domain; permission

**tunnel server**
A server or router that terminates tunnels and forwards traffic to the hosts on the target network.

See also: router

**two-way trust**
A trust relationship between two domains in which both domains trust each other. For example, domain A trusts domain B, and domain B trusts domain A. All parent-child trusts are two-way.

See also: domain; one-way trust; trust relationship

**U**

**UCS**
See definition for: Universal Character Set (UCS)

**UNC**
See definition for: Universal Naming Convention (UNC)

**UNC (Universal Naming Convention) name**
The full name of a resource on a network. It conforms to the *servername**sharename* syntax, where *servername* is the name of the server and *sharename* is the name of the shared resource. UNC names of directories or files can also include the directory path under the share name, with the following syntax:

\\servername\sharename\directory\filename

See also: resource

**Unicode**
A character encoding standard developed by the Unicode Consortium that represents almost all of the written languages of the world. The Unicode character repertoire has multiple representation forms, including UTF-8, UTF-8, and UTF-32. Most Windows interfaces use the UTF-16 form.

See also: American Standard Code for Information Interchange (ASCII); Universal Character Set (UCS)

**Uniform Resource Locator (URL)**
An address that uniquely identifies a location on the Internet. A URL for a World Wide Web site is preceded by *http://*, as in the fictitious URL *http://www.example.microsoft.com*. A URL can contain more detail, such as the name of a page of hypertext, usually identified by the file name extension .html or .htm.

**uninterruptible power supply (UPS)**
A device that connects a computer and a power source to ensure that electrical flow is not interrupted. UPS devices use batteries to keep the computer running for a period of time after a power failure. UPS devices usually provide protection against power surges and brownouts as well.

**Universal Character Set (UCS)**
An international standard character set reference that is part of the Unicode standard. The most widely held existing version of the UCS standard is UCS-2, which specifies 16-bit character values currently accepted and recognized for use to encode most of the world's languages.

See also: American Standard Code for Information Interchange (ASCII); Unicode

**Universal Naming Convention (UNC)**

A convention for naming files and other resources beginning with two backslashes (\), indicating that the resource exists on a network computer. UNC names conform to the *servername**sharename* syntax, where *servername* is the server's name and *sharename* is the name of the shared resource. The UNC name of a directory or file can also include the directory path after the share name, by using the following syntax: *servername**sharename**directory**filename*.

**universal serial bus (USB)**
An external bus that supports Plug and Play installation. Using USB, you can connect and disconnect devices without shutting down or restarting your computer. You can use a single USB port to connect up to 127 peripheral devices, including speakers, telephones, CD-ROM drives, joysticks, tape drives, keyboards, scanners, and cameras. A USB port is usually located on the back of your computer near the serial port or parallel port.

**UNIX**
A powerful, multiuser, multitasking operating system initially developed at AT&T Bell Laboratories in 1969 for use on minicomputers. UNIX is considered more portable, that is, less computer-specific, than other operating systems because it is written in C language. Newer versions of UNIX have been developed at the University of California at Berkeley and by AT&T.

**UPS**
See definition for: uninterruptible power supply (UPS)

**URL**
See definition for: Uniform Resource Locator (URL)

**USB**
See definition for: universal serial bus (USB)

**user profile**
A file that contains configuration information for a specific user, such as desktop settings, persistent network connections, and application settings. Each user's preferences are saved to a user profile that Windows uses to configure the desktop each time a user logs on.

**UUEncoding/Decoding**
A form of encoding and decoding that allows binary files to be sent as e-mail. A binary file, such as a program or image, cannot be sent directly over the Internet by e-mail. To send such a file, you must first encode it to hide the control characters. This encoding can be accomplished by converting the binary file to a text file. UUEncoding carries out this conversion, and UUDecoding regenerates the original file.

**V**

**variable**
In programming, a named storage location capable of containing a certain type of data that can be modified during program execution.

System environment variables are defined by the operating systems in the Windows Server 2003 family, and they are the same no matter who is logged on to the computer. Administrator group members can add new variables or change the values, however.

User environment variables can be different for each user of a particular computer. They include any environment variables you want to define or variables defined by your applications, such as the path where application files are located.

See also: environment variable

**virtual local area network (VLAN)**
A logical grouping of hosts on one or more local area networks (LANs) that allows communication to occur between hosts as if they were on the same physical LAN.

See also: local area network (LAN)

**VLAN**
See definition for: virtual local area network (VLAN)

**VoIP (Voice over Internet Protocol)**
A method for sending voice over a local area network (LAN), a wide area network (WAN), or the Internet using TCP/IP packets.

See also: local area network (LAN); Transmission Control Protocol/Internet Protocol (TCP/IP); wide area network (WAN)

**volume**

An area of storage on a hard disk. A volume is formatted by using a file system, such as file allocation table (FAT) or NTFS, and has a drive letter assigned to it. You can view the contents of a volume by clicking its icon in Windows Explorer or in My Computer. A single hard disk can have multiple volumes, and volumes can also span multiple disks.

See also: file allocation table (FAT); NTFS file system; simple volume; spanned volume

**volume set**
A volume that consists of disk space on one or more physical disks. A volume set is created by using basic disks and is supported only in Windows NT 4.0 or earlier. Volume sets were replaced by spanned volumes, which use dynamic disks.

See also: basic disk; dynamic disk; partition; spanned volume; volume

**voluntary tunnel**
A tunnel that is initiated by the client. A voluntary tunnel tunnels Point-to-Point Protocol (PPP) over Internet Protocol (IP) from the client to the tunnel server, and then the data is forwarded to the target host by the tunnel server.

See also: tunnel server

**W**

**WAN**
See definition for: wide area network (WAN)

**wc**
Word count. Command-line POSIX tool that returns the number of bytes, words, and lines in files.

**wide area network (WAN)**
A communications network connecting geographically separated computers, printers, and other devices. A WAN enables any connected device to interact with any other on the network.

See also: local area network (LAN)

**Windows Internet Name Service (WINS)**
A software service that dynamically maps IP addresses to computer names (network basic input/output system (NetBIOS) names). This enables users to access resources by name instead of requiring them to use IP addresses that are difficult to recognize and remember.

See also: IP address; network basic input/output system (NetBIOS); resource; service; WINS resource

**Windows Support Tools**
Tools that administrators, developers, or support personnel can use to diagnose and troubleshoot operating system configuration problems. Although Windows Support Tools are included on the operating system CD, they are not guaranteed or supported by Microsoft, and they must be installed separately from the operating system.

**WINS**
See definition for: Windows Internet Name Service (WINS)

**WINS resource**
A resource type that provides Windows Internet Name Service (WINS) from a cluster.

See also: cluster; Windows Internet Name Service (WINS)

**working set**
For a process, the amount of physical memory assigned to the process by the operating system.

**X**

**X.500**
A set of standards defining a distributed directory service, developed by the International Standards Organization (ISO).

See also: directory service

**Y**
There are no glossary terms that begin with this letter.

**Z**
There are no glossary terms that begin with this letter.

# Security Policy Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security Policy Settings**

**In this subject**

- Account Policy Settings
- Local Policy Settings
- Event Log Policy Settings
- Restricted Groups Policy Settings
- System Services
- Registry
- File System
- Wireless Network (IEEE 802.11) Policies
- Public Key Policy Settings
- Software Restriction Policy Settings
- IP Security Policies on Active Directory

Security policy settings are among the settings contained in Group Policy objects (GPOs). When you edit security settings in a local GPO, only the security policy settings on that computer are affected. When you edit security policy settings in a GPO in Active Directory directory service, the policy settings affect sites, domains, and organizational units (OUs) to which the GPO is linked. Some settings, like password policy settings, are only operative at the domain level.

This subject documents security policy settings in Microsoft Windows Server 2003.

# Account Policy Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Account Policies**

**In this section**

- Password Policy
- Account Lockout Policy
- Kerberos Policy

The policy settings under Account Policies are implemented at the domain level. A Windows Server 2003 domain must have a single password policy, account lockout policy, and Kerberos version 5 authentication protocol policy for the domain. Configuring these policy settings at any other level in Active Directory will only affect local accounts on member servers. If there are groups that require separate password policies, they should be segmented into another domain or forest, based on any additional requirements.

For domain accounts, there can be only one account policy per domain. The account policy must be defined in the Default Domain Policy or in a new policy that is linked to the root of the domain and given precedence over the Default Domain Policy, which is enforced by the domain controllers that make up the domain. A domain controller always pulls the account policy from a Group Policy object (GPO)linked to the domain, which by default is the Default Domain Policy GPO. This behavior occurs even if there is a different account policy applied to the organizational unit (OU) that contains the domain controller.

By default, workstations and servers joined to a domain — the domain member computers — also receive the same account policy for their local accounts. However, local account policies for member computers can be differentiated from the domain account policy by defining an account policy for the OU that contains the member computers.

Account Policies contains three subsets:

- **Password Policy**. These policy settings are used for domain or local user accounts. They determine settings for passwords, such as enforcement and lifetimes.
- **Account Lockout Policy**. These policy settings are used for domain or local user accounts. They determine the circumstances and length of time that an account will be locked out of the system.
- **Kerberos Policy**. These policy settings are used for domain user accounts. They determine Kerberos-related settings, such as ticket lifetimes and enforcement. Kerberos policy settings do not exist in local computer policy.

Account Policies policy settings can be configured in the following location in Group Policy Object Editor:

Computer Configuration\Windows Settings\Security Settings\Account Policies\

**Password Policy**

In Windows and many other operating systems, the most common method for authenticating a user's identity is to use a secret passphrase or password. Securing your network environment requires that strong passwords be used by all users. This helps avoid the threat of a malicious user guessing a weak password, whether through manual methods or by using tools, to acquire the credentials of a compromised user account. This is especially true for administrative accounts. When you change a complex password regularly, it reduces the likelihood of a successful password attack. Password policy settings control the complexity and lifetime of passwords. Each specific password policy account setting is discussed in this section. Password Policy settings can be configured in the following location in Group Policy Object Editor:

Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

**Enforce password history**

The **Enforce password history** policy setting determines the number of unique new passwords that must be associated with a user account before an old password can be reused.

The possible values for this Group Policy setting are:

- A user-defined number from 0 through 24.
- Not defined.

**Discussion**

Password reuse is an important concern in any organization. Many users want to reuse the same password for their account over a long period of time. The longer the same password is used for a particular account, the greater the chance that an attacker will be able to determine the password through brute force attacks. If users are required to change their password, but nothing prevents them from using the old password or continually reusing a small number of passwords, the effectiveness of a good password policy is greatly reduced.

Specifying a low number for **Enforce password history** allows users to continually use the same small number of passwords repeatedly. If you do not also set **Minimum password age**, users can change their password as many times in a row as necessary in order to reuse their original password.

If you set **Enforce password history** to a number greater than zero, users must come up with a new password every time they are required to change their old one. This improves security, but it can increase the risk that users will write down their passwords so they do not forget them.

If you set the value to the maximum of **24**, it helps to ensure that vulnerabilities caused by password reuse are kept to a minimum.

For this policy setting to be effective in your organization, configure **Minimum password age** so that you do not allow passwords to be changed immediately. **Enforce password history** should be set at the level that combines a reasonable maximum password age with a reasonable password change interval requirement for users.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 24 passwords remembered |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 0 passwords remembered |
| DC Effective Default Settings | 24 passwords remembered |
| Member Server Effective Default Settings | 24 passwords remembered |

**Maximum password age**

The **Maximum password age** policy setting determines the number of days that a password can be used before the system requires the user to change it.

The possible values for this Group Policy setting are:

- A user-defined number of days from 0 through 999.
- Not defined.

**Discussion**

If your users change their passwords frequently, it helps to reduce the risk that a valid password might be cracked, and it mitigates the risk that someone may use a password that has been wrongfully acquired. **Maximum password age** can be configured so that users are never required to change their passwords, but this results in a major security risk.

Many cautious administrators choose to set **Maximum password age** to a value between **30** and **60** days. You can set **Maximum password age** to never expire by setting the number of days to **0**.

Setting **Maximum password age** very low requires users to change their passwords too often. This might actually reduce

security in the organization, because it can increase the possibility of that users will write their passwords down to avoid forgetting them. If you set the value very high, it reduces the level of security within an organization, because it gives a potential attacker more time to guess a user's password.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 42 days |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 42 days |
| DC Effective Default Settings | 42 days |
| Member Server Effective Default Settings | 42 days |

**Minimum password age**
The **Minimum password age** policy setting determines the number of days that a password must be used before the user is allowed to change it. **Minimum password age** must be less than **Maximum password age**.

Configure this to be greater than **0** if you want the **Enforce password history** policy setting to be effective. If **Enforce password history** is set to **0**, the user does not have to choose a new password. If **Enforce password history** is set to a number greater than zero, users must enter a new unique password when they change their password.

The possible values for this Group Policy setting are:

- A user-defined number of days from 0 through 999.
- Not defined.

**Discussion**
Forcing users to change passwords regularly is ineffective if they can cycle through passwords until they get to an old favorite. Use **Minimum password age** with **Enforce password history** to prevent this. For example, if **Enforce password history** is set to 12 (which ensures that users cannot reuse any of their last 12 passwords) and **Minimum password age** is 0, users could change their password 13 times in a row to return to the password they were originally using. Therefore, **Minimum password age** must be set to a value greater than 0 for **Enforce password history** to be effective.

It is advisable to set **Minimum password age** to a value of 2 days. Setting the number of days to 0 allows immediate password changes, which is not recommended.

There is one minor issue associated with setting **Minimum password age** to a number greater than 0. If an administrator sets a password for a user, and then would like for that user to change the administrator-defined password, the administrator must select the **User must change password at next logon** check box. Otherwise, the user will not be able to change the password until the number of days specified by **Minimum password age**.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 1 day |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 0 days |
| DC Effective Default Settings | 1 day |

| | |
|---|---|
| Member Server Effective Default Settings | 1 day |

**Minimum password length**

The **Minimum password length** policy setting determines the least number of characters that can make up a password for a user account. There are many different theories about determining the best password length for an organization. One possibility is to use *pass phrases* rather than passwords. In Microsoft Windows 2000, Windows XP, and Windows Server 2003, pass phrases can be quite long and they can include spaces. A valid pass phrase such as "I want to drink a $5 milkshake" is considerably stronger than a ten-character string of random numbers and letters, yet is easier to remember.

The possible values for this Group Policy setting are:

- A user-defined number of characters from 0 through 14.
- Not defined.

**Discussion**

There are several types of password attacks that can be performed to obtain the password for a particular user account. These include dictionary attacks — which attempt to use common words and phrases — and brute-force attacks, which try every possible combination of characters. In addition, an attack can be performed by obtaining the account database and using tools to crack the accounts and passwords.

Set **Minimum password length** to at least a value of 8. If the number of characters is set to 0, no password is required. In most environments, an eight-character password is recommended because it is long enough to provide adequate security and still short enough for users to easily remember. This value will help to provide adequate defense against a brute-force attack. Adding complexity requirements will help reduce the possibility of a dictionary attack. Complexity requirements are discussed in the description of the **Passwords must meet complexity requirements** policy setting.

Permitting short passwords reduces security, because short passwords can be easily broken with tools that perform either dictionary or brute-force attacks against the passwords. Requiring very long passwords can result in mistyped passwords that might cause an account lockout and subsequently increase the volume of Help desk calls.

In addition, requiring extremely long passwords can actually decrease the security of an organization because users might be more likely to write their passwords down to avoid forgetting them. However, if users are taught they can use pass phrases as described above, they should be much more likely to remember.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 7 characters |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 0 characters |
| DC Effective Default Settings | 7 characters |
| Member Server Effective Default Settings | 7 characters |

**Passwords must meet complexity requirements**

The **Passwords must meet complexity requirements** policy setting determines whether passwords must meet a series of guidelines that are considered important for a strong password. Enabling this policy setting requires passwords to meet the following requirements:

- The password is at least six characters long.
- The password contains characters from three of the following four categories:
    - English uppercase characters (from A through Z)
    - English lowercase characters (from a through z)

    - Base 10 digits (from 0 through 9)
    - Non-alphanumeric characters (for example: !, $, #, or %)

- The password does not contain three or more characters from the user's account name. If the account name is less than three characters long, this check is not performed because the rate at which passwords would be rejected would be too high. When checking against the user's full name, several characters are treated as delimiters that separate the name into individual tokens: commas, periods, dashes, hyphens, underscores, spaces, number signs (#), and tab characters. Each token that is three or more characters long is searched for in the password, and if it is present, the password change is rejected. For example, the name "Erin M. Hagens" would be split into three tokens: "Erin," "M," and "Hagens." Because the second token is only one character long, it would be ignored. Therefore this user could not have a password that included either "erin" or "hagens" as a substring anywhere in the password. None of these checks are case-sensitive.

These complexity requirements are enforced when passwords are changed or new passwords created.

The rules that are included in the Windows Server 2003 password complexity requirements are part of Passfilt.dll and cannot be directly modified. The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Passwords that contain only alphanumeric characters are easy to crack by using publicly available tools. To prevent this, passwords should contain additional characters and meet complexity requirements.

Set **Passwords must meet complexity requirements** to **Enabled**. This policy setting, combined with a minimum password length of 8, ensures that there are at least 218,340,105,584,896 different possibilities for a single password. This makes the use of a brute-force attack difficult, but still not impossible. An attacker who had enough processing power to test 1 million passwords per second could determine such a password in about seven-and-a-half days or less.

Enabling the default Passfilt.dll may cause some additional Help desk calls for locked-out accounts because users might not be used to having passwords that contain characters other than those found in the alphabet. However, this policy setting is liberal enough that all users should be able to abide by the requirements with a minor learning curve.

Additional settings that can be included in a custom Passfilt.dll are the use of non–upper-row characters. Upper-row characters are those that are typed by holding down the SHIFT key and typing any of the digits from 1 through 10.

Also, the use of ALT key character combinations can greatly enhance the complexity of a password. However, requiring all users in an organization to adhere to such stringent password requirements can result in unhappy users and an extremely busy Help desk. Consider implementing a requirement in your organization to use ALT characters in the range from 0128 through 0159 as part of all administrator passwords. (ALT characters outside of this range can represent standard alphanumeric characters that do not add additional complexity to the password.)

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Enabled |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Enabled |

| | |
|---|---|
| Member Server Effective Default Settings | Enabled |

**Store password using reversible encryption for all users in the domain**

The **Store password using reversible encryption for all users in the domain** policy setting determines whether Windows Server 2003, Windows 2000, and Windows XP Professional store passwords by using reversible encryption.

This policy setting provides support for applications that use protocols that require knowledge of the user's password for authentication purposes. By definition, storing encrypted passwords in a way that is reversible means that the encrypted passwords can be decrypted. A knowledgeable attacker who is able to break this encryption can then log on to network resources by using the compromised account. For this reason, never enable **Store password using reversible encryption for all users in the domain** unless application requirements outweigh the need to protect password information.

If you use Challenge Handshake Authentication Protocol (CHAP) authentication through remote access or Internet Authentication Service (IAS) services, you must enable this policy setting. CHAP is an authentication protocol used by Microsoft remote access and Network Connections. Digest Authentication in Internet Information Services (IIS) also requires that you enable this policy setting.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

This policy setting determines whether Windows Server 2003 will store passwords in a weaker format that is much more susceptible to brute force attacks.

It is advisable to set the value for **Store password using reversible encryption for all users in the domain** to **Disabled**. If you use either Digest Authentication in IIS or the CHAP authentication protocol through remote access or IAS, you must set this value to **Enabled**. This is an extremely dangerous policy setting to apply by using Group Policy on a user-by-user basis, because it requires opening the appropriate user account object in Active Directory Users and Computers.

### Note

- *Never* enable this policy setting unless business requirements outweigh the need to protect password information.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Disabled |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Account Lockout Policy**

Someone who attempts to use more than a few unsuccessful passwords while trying to log on to your system might be a malicious user attempting to determine an account password by trial and error. Windows Server 2003 keeps track of logon attempts, and it can be configured to respond to this type of potential attack by disabling the account for a preset period of time. Account Lockout Policy settings control the threshold for this response and the actions to be taken after the threshold is reached. The Account Lockout Policy settings can be configured in the following location in Group Policy Object Editor:

Computer Configuration\Windows Settings\Security Settings\Account Policies\Account Lockout Policy\

**Account lockout duration**

The **Account lockout duration** policy setting determines the number of minutes a locked-out account remains locked out before automatically becoming unlocked. The available range is from 1 through 99,999 minutes. A value of 0 specifies that the account will be locked out until an administrator explicitly unlocks it. If **Account lockout threshol**d is set to a number greater than zero, **Account lockout duration** must be greater than or equal to the value of **Reset account lockout counter after**.

The possible values for this Group Policy setting are:

- A user-defined number of minutes from 0 through 99,999.
- Not defined.

**Discussion**

A denial-of-service attack can occur if an attacker abuses the **Account lockout threshold** and repeatedly attempts to log on to an account. If the **Account lockout threshold** is configured, after the specified number of failed attempts the account will be locked out. If the **Account lockout duration** is set to 0, the account will remain locked out until an administrator unlocks it manually.

It is advisable to set **Account lockout duration** to approximately 30 minutes. To specify that the account will never be locked out, set the value to 0. To configure the value for this policy setting so that it never automatically unlocks the account might seem like a good idea, doing so can increase the number of requests that your organization's Help desk receives to unlock accounts that were locked by mistake.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Password Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not applicable |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Account lockout threshold**

The **Account lockout threshold** policy setting determines the number of failed logon attempts that will cause a user account to be locked out. A locked-out account cannot be used until it is reset by an administrator or until the number of minutes specified by **Account lockout duration** expires. You can set a value from 1 through 999 failed logon attempts, or you can specify that the account will never be locked out by setting the value to 0. If **Account lockout threshold** is set to a number greater than zero, **Account lockout duration** must be greater than or equal to the value of **Reset account lockout counter after**.

Failed password attempts on workstations or member servers that have been locked by using either CTRL+ALT+DELETE or password-protected screen savers do not count as failed logon attempts unless **Interactive logon: Require Domain Controller authentication to unlock workstation** is set to **Enabled**. If **Interactive logon: Require Domain Controller authentication to unlock workstation** is enabled, repeated failed password attempts to unlock the workstation will count against the account lockout threshold.

The possible values for this Group Policy setting are:

- A user-defined number from 0 through 999.
- Not defined.

**Discussion**

Brute force password attacks can be automated to try thousands or even millions of password combinations for any or all user accounts. Limiting the number of failed logons that can be performed nearly eliminates the effectiveness of such attacks.

However, it is important to note that, in contrast, a denial-of-service attack could be performed on a domain that has an account lockout threshold configured. A malicious user could programmatically attempt a series of password attacks against all users in the organization. If the number of attempts is greater than the value of **Account lockout threshold**, the attacker could potentially lock out every account.

Because vulnerabilities can exist both when this value is configured and when it is not, any organization should weigh their identified threats and the risks that they are trying to mitigate. There are two options to consider for this policy setting:

- Set **Account lockout threshold** to 0. This ensures that accounts will not be locked out. This setting will prevent a denial-of-service attack that intentionally locks out all or some accounts. In addition, this setting helps reduce Help desk calls because users cannot accidentally lock themselves out of their accounts.

  Because it will not prevent a brute force attack, a value of 0 should only be chosen if both of the following criteria are explicitly met:

  - Password Policy settings force all users to have complex passwords made up of eight or more characters.
  - A robust auditing mechanism is in place to alert administrators when a series of failed logons are occurring in the environment.

  If these criteria cannot be met, set **Account lockout threshold** to a high enough value that users can accidentally mistype their password several times before they are locked out of their account, but ensure that a brute-force password attack would still lock out the account. It is advisable to specify a value of 50 invalid logon attempts. Keep in mind, however, that although this setting can reduce the number of Help desk calls by reducing the number of user lockouts, it cannot prevent a denial-of-service attack.

Setting **Account lockout threshold** to a number greater than zero locks out user accounts until they are reset by an administrator, or until the number of minutes specified in **Account lockout duration** expires. This setting will likely generate a number of additional Help desk calls. In fact, in many organizations, locked accounts generate the most calls to the Help desk.

By setting **Account lockout threshold** to 0, you leave your organization open to the possibility that you will not detect a brute force attack.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Account Lockout Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 0 invalid login attempts |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 0 invalid login attempts |
| DC Effective Default Settings | 0 invalid login attempts |
| Member Server Effective Default Settings | 0 invalid login attempts |

**Reset account lockout counter after**
The **Reset account lockout counter after** policy setting determines the number of minutes that must elapse from the time a user fails to log on before the failed logon attempt counter is reset to 0 bad logon attempts. If **Account lockout threshold** is set to a number greater than zero, this reset time must be less than or equal to the value of **Account lockout duration**.

The possible values for this Group Policy setting are:

- A user-defined number of minutes from 1 through 99,999.
- Not defined.

**Discussion**

A disadvantage to setting this too high is that users lock themselves out for an inconveniently long period, if they exceed the account lockout threshold through login errors. Users may make excessive help desk calls.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Account Lockout Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not applicable |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Kerberos Policy**
In Windows Server 2003, the Kerberos version 5 authentication protocol provides the default mechanism for authentication services and the authorization data necessary for a user to access a resource and perform a task on that resource. By reducing the lifetime of Kerberos tickets, you reduce the risk of a legitimate user's credentials' being stolen and successfully used by an attacker; however, you increase authorization overhead. In most environments, these settings should not need to be changed. In a default installation of a Windows 2000 or Windows Server 2003 Active Directory domain, the default values of these policy settings, which are applied at the domain level, are configured in the Default Domain Policy Group Policy object (GPO). The Kerberos Policy settings can be configured in the following location in Group Policy Object Editor:

Computer Configuration\Windows Settings\Security Settings\Account Policies\Kerberos Policy\

**Enforce user logon restrictions**
The **Enforce user logon restrictions** policy setting determines whether the Kerberos V5 Key Distribution Center (KDC) validates every request for a session ticket against the user rights policy of the user account. Validating each request for a session ticket is optional because the extra step takes time, and that can slow network access to services.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
If this policy setting is disabled, users might be granted session tickets for services they do not have the right to use.

It is advisable to set **Enforce user logon restrictions** to **Enabled**.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Kerberos Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Enabled |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not applicable |
| DC Effective Default Settings | Enabled |

| | |
|---|---|
| Member Server Effective Default Settings | Not applicable |

**Maximum lifetime for service ticket**

The **Maximum lifetime for service ticket** policy setting determines the maximum number of minutes that a granted session ticket can be used to access a particular service. The value must be 10 minutes or greater, and it must be less than or equal to the value of the **Maximum lifetime for user ticket** policy setting.

The possible values for this Group Policy setting are:

- A user-defined number of minutes from 10 through 99,999, or 0, in which case service tickets do not expire.
- Not defined.

**Discussion**

If a client presents an expired session ticket when it requests a connection to a server, the server returns an error message. The client must request a new session ticket from the Kerberos V5 KDC. After a connection is authenticated, however, it no longer matters whether the session ticket remains valid. Session tickets are used only to authenticate new connections with servers. Ongoing operations are not interrupted if the session ticket that authenticated the connection expires during the connection.

If the value for this policy setting is too high, users might be able to access network resources outside of their logon hours, or users whose accounts have been disabled might be able to continue accessing network services by using valid service tickets that were issued before their account was disabled. If the value is set to 0, service tickets never expire.

It is advisable to set **Maximum lifetime for service ticket** to **600** minutes.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Kerberos Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 600 minutes |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not applicable |
| DC Effective Default Settings | 600 minutes |
| Member Server Effective Default Settings | Not applicable |

**Maximum lifetime for user ticket**

The **Maximum lifetime for user ticket** policy setting determines the maximum amount of time (in hours) that a user's ticket-granting ticket can be used. When a user's ticket-granting ticket expires, a new one must be requested or the existing one must be renewed.

The possible values for this Group Policy setting are:

- A user-defined number of hours from 0 through 99,999.
- Not defined.

**Discussion**

If the value for this policy setting is too high, users might be able to access network resources outside of their logon hours, or users whose accounts have been disabled might be able to continue to access network services by using valid service tickets that were issued before their account was disabled. If the value is set to 0, ticket-granting tickets never expire.

It is advisable to set **Maximum lifetime for user ticket** to 10 hours.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Kerberos Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 10 hours |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not applicable |
| DC Effective Default Settings | 10 hours |
| Member Server Effective Default Settings | Not applicable |

**Maximum lifetime for user ticket renewal**

The **Maximum lifetime for user ticket renewal** policy setting determines the period of time (in days) during which a user's ticket-granting ticket can be renewed.

The possible values for this Group Policy setting are:

- A user-defined number of days from 0 through 99,999.
- Not defined.

**Discussion**

If the value for this policy setting is too high, users may be able to renew very old user ticket-granting tickets. If the value is 0, ticket-granting tickets never expire.

It is advisable to set **Maximum lifetime for user ticket renewal** to **7** days.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Kerberos Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 7 days |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not applicable |
| DC Effective Default Settings | 7 days |
| Member Server Effective Default Settings | Not applicable |

**Maximum tolerance for computer clock synchronization**

The **Maximum tolerance for computer clock synchronization** policy setting determines the maximum time difference (in minutes) that Kerberos V5 tolerates between the time on the client clock and the time on the domain controller running Windows Server 2003 that provides Kerberos authentication.

The possible values for this Group Policy setting are:

- A user-defined number of minutes from 1 through 99,999.
- Not defined.

**Discussion**

To prevent replay attacks, Kerberos V5 uses time stamps as part of its protocol definition. For time stamps to work properly, the clocks of the client and the domain controller need to be synchronized as closely as possible. Because the clocks of two computers are often out of sync, administrators can use this policy setting to establish the maximum acceptable difference to Kerberos V5 between a client clock and domain controller clock. If the difference between a client clock and the domain controller clock is less than **Maximum tolerance for computer clock synchronization**, any time stamp that is used in a session between the two computers is considered authentic.

It is advisable to set **Maximum tolerance for computer clock synchronization** to a value of 5 minutes.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Account Policies\Kerberos Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | 5 minutes |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not applicable |
| DC Effective Default Settings | 5 minutes |
| Member Server Effective Default Settings | Not applicable |

# Local Policy Settings

Updated: October 8, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Local Policies**

**In this section**

- Audit Policy
- User Rights Assignment
- Security Options

These policy settings apply to a computer and contain these subsets:

- **Audit policy**. Determines whether security events are written to the security log in Event Viewer on the computer. Also determines whether to log successful attempts, failed attempts, or both.
- **User rights assignment**. Determines which users or groups have logon rights or privileges on the computer.
- **Security options**. Enables or disables security policy settings for the computer, such as digital signing of data, Administrator and Guest account names, floppy disk drive and CD drive access, driver installation, and logon prompts.

Because a computer can have more than one policy setting applied to it, security policy settings can conflict with each other. The order of precedence from highest to lowest is: OU, domain, and local computer.

**Audit Policy**

An audit log records an entry whenever users perform certain actions that you specify. For example, the modification of a file or policy setting can trigger an audit entry. The audit entry shows the action performed, the associated user account, and the date and time of the action. You can audit both successful and failed attempts at actions.

The state of the operating system and applications on a computer is dynamic. For example, an administrator might need to change security levels temporarily to resolve an administrative or network issue, but all too often, such changes are forgotten about and never undone. In a case like this, the computer might no longer meet the requirements for enterprise security.

Regular analysis enables an administrator to track and ensure an adequate level of security on each computer as part of an enterprise risk-management program. Analysis focuses on highly specific information about all system aspects related to security. This enables an administrator to tune the security levels and—most importantly—detect any security flaws that might occur in the system over time.

Security auditing is extremely important for any enterprise system, because audit logs sometimes give the only indication that a security breach has occurred. If the breach is discovered some other way, proper audit policy settings generate an audit log that contains important information about the breach.

Often, failure logs are much more informative than success logs, because failures typically indicate an error. For example, if a user successfully logs on to the system, this is considered normal. However, if a user unsuccessfully tries to log on to the system multiple times, it can indicate that someone is trying to break into the system by using someone else's user ID.

All computers in your organization should have sensible auditing policy settings so that legitimate users can be held accountable for their actions and unauthorized activity can be detected and tracked. If no auditing is configured, or if the auditing is set too low on the computers in your organization, you will not have sufficient evidence to analyze after security incidents take place. On the other hand, if too much auditing is enabled, the security log will fill up with meaningless entries. The Audit Policy settings can be configured in the following location in Group Policy Object Editor:

Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy

**Audit account logon events**

The **Audit account logon events** policy setting determines whether to audit each instance of a user logging on to or logging off from another computer, in which the computer recording the audit event is used to validate the account. If you configure

this policy setting, you can specify whether to audit successful logons, audit failed logons, or not audit logon events at all.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**

If **Audit account logon events** is set to **Success**, an audit entry is recorded in the security log whenever an account logon attempt succeeds. This can be useful information for accounting purposes and for post-incident forensics when you want to determine who successfully logged on to which computer. If **Audit account logon events** is set to **Failure**, an audit entry is recorded whenever an account logon attempt fails. This can be useful for intrusion detection, but this setting can also leave your enterprise vulnerable to a denial-of-service condition, because a malicious user could generate millions of logon failures and fill your security log.

If the value of this policy setting on a domain controller is **Success**, an entry is recorded for each user who is validated against that domain controller, even though the user is actually logging on to a workstation that is joined to the domain.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Success |
| Stand-Alone Server Default Settings | Success |
| DC Effective Default Settings | Success |
| Member Server Effective Default Settings | Success |

**Audit account management**

The **Audit account management** policy setting determines whether to audit each event of account management on a computer.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**

Examples of account management events include the following:

- A user account or group is created, changed, or deleted.
- A user account is renamed, disabled, or enabled.
- A password is set or changed.

If you configure this policy setting, you can specify whether to audit successes, audit failures, or not audit account management events at all. When you set the value of **Audit account management** to **Success**, an audit entry is generated when any

account management event succeeds. It is advisable to set the value to **Success** on all computers in your enterprise. To respond to security incidents, it is critical that organizations be able to track who created, changed, or deleted an account. When the value is set to **Failure**, an audit entry is generated when any account management event fails.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Success |
| Stand-Alone Server Default Settings | No auditing |
| DC Effective Default Settings | Success |
| Member Server Effective Default Settings | No auditing |

**Audit directory service access**
The **Audit directory service access** policy setting determines whether to audit the event of a user accessing an Active Directory object that has specified its own system access control list (SACL). An SACL is a list of users and groups for which actions on an object are to be audited on a Windows 2000–based network. If you configure this policy setting, you can specify whether to audit successes, audit failures, or not audit directory service access at all. Success audits generate an audit entry when a user successfully accesses an Active Directory object that has an SACL specified. Failure audits generate an audit entry when a user unsuccessfully attempts to access an Active Directory object that has a SACL specified.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**
Auditing directory service access and configuring SACLs on directory objects can generate a large volume of entries in the security logs on domain controllers. You should only configure these policy settings if you actually intend to use the information.

Note that you can set an SACL on an object in Active Directory by using the **Security** tab in that object's properties. This is analogous to the **Audit object access** policy setting, except that it applies only to Active Directory objects and not to file system and registry objects.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Success |
| Stand-Alone Server Default Settings | No auditing |
| DC Effective Default Settings | Success |
| Member Server Effective Default Settings | No auditing |

**Audit logon events**
The **Audit logon events** policy setting determines whether to audit each instance of a user logging on to, logging off from, or

making a network connection to the computer that is recording the audit event.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**
If you are logging successful account logon audit events on a domain controller, workstation logon attempts do not generate logon audits. Only interactive and network logon attempts to the domain controller itself generate logon events. In short, account logon events are generated where the account is located; logon events are generated where the logon attempt occurs.

If you configure this policy setting, you can specify whether to audit successes, audit failures, or not audit the logon events at all. Success audits generate an audit entry when a logon attempt succeeds, which is useful information for accounting purposes and for post-incident forensics so that you can determine who successfully logged on to which computer. Failure audits generate an audit entry when a logon attempt fails, which is useful for intrusion detection, but this setting also creates a potential denial-of-service condition because a malicious user could generate millions of logon failures and fill your security event log.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Success |
| Stand-Alone Server Default Settings | Success |
| DC Effective Default Settings | Success |
| Member Server Effective Default Settings | Success |

**Audit object access**
The **Audit object access** policy setting determines whether to audit the event of a user accessing an object—for example, a file, folder, registry key, or printer—that has specified its own SACL.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**
If you define this policy setting, you can specify whether to audit successes, audit failures, or not audit object access at all. Success audits generate an audit entry when a user successfully accesses an object that has specified an SACL. Failure audits generate an audit entry when a user unsuccessfully attempts to access an object that has specified an SACL; some failure events are to be expected in the course of normal system operations. For example, many applications, such as Microsoft Word, always attempt to open files with both read and write user rights; if they are unable to do so, they try to open them with read-only user rights. When this happens, a failure event will be recorded if you have enabled both failure auditing and the appropriate SACL on that file.

Enabling auditing of object access and configuring SACLs on objects can generate a large volume of entries in the security logs on systems in your enterprise; therefore, you should only enable these policy settings if you actually intend to use the information.

Enabling the capability to audit an object—such as a file, folder, printer, or registry key—is a two-step process in Windows Server 2003. After enabling the **Audit object access** policy setting, you must determine the objects to which you want to monitor access, and then modify their SACLs accordingly. For example, if you want to audit any attempts by users to open a particular file, you can use Group Policy or Windows Explorer to set a **Success** or **Failure** attribute directly on the file that you want to monitor for that particular event.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No auditing |
| Stand-Alone Server Default Settings | No auditing |
| DC Effective Default Settings | No auditing |
| Member Server Effective Default Settings | No auditing |

**Audit policy change**
The **Audit policy change** policy setting determines whether to audit every incidence of a change to user rights assignment policy settings, audit policy settings, or trust policy settings.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**
If you configure this policy setting, you can specify whether to audit successes, audit failures, or not audit the policy settings changes at all. Success audits generate an audit entry when a change to user rights assignment, audit, or trust policy settings is successful, which is useful information for accounting purposes and for post-incident forensics so that you can determine who successfully modified policy settings in the domain or on individual computers. Failure audits generate an audit entry when a change to user rights assignment, audit, or trust policy settings fails.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Success |
| Stand-Alone Server Default Settings | No auditing |
| DC Effective Default Settings | Success |
| Member Server Effective Default Settings | No auditing |

**Audit privilege use**
The **Audit privilege use** policy setting determines whether to audit each instance of a user exercising a user right.

The possible values for this Group Policy setting are:

- Success.

- Failure.
- No auditing.

**Discussion**
If you configure this policy setting, you can specify whether to audit successes, audit failures, or not audit privilege use at all. Success audits generate an audit entry when the exercise of a user right succeeds. Failure audits generate an audit entry when the exercise of a user right fails. The volume of events generated by enabling these policy settings is very high and difficult to sort through. You should only enable these policy settings if you have a plan for how you will use the information that is generated.

By default, audit events are not generated for use of the following user rights, even if success audits or failure audits are specified for **Audit privilege use**:

- Bypass traverse checking
- Debug programs
- Create a token object
- Replace process level token
- Generate security audits
- Backup files and directories
- Restore files and directories

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No auditing |
| Stand-Alone Server Default Settings | No auditing |
| DC Effective Default Settings | No auditing |
| Member Server Effective Default Settings | No auditing |

**Audit process tracking**
The **Audit process tracking** policy setting determines whether to audit detailed tracking information for events such as program activation, process exit, handle duplication, and indirect object access.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**
If you configure this policy setting, you can specify whether to audit successes, audit failures, or not audit process tracking at

all. Success audits generate an audit entry when the process being tracked succeeds. Failure audits generate an audit entry when the process being tracked fails.

Setting the value of **Audit process tracking** to **Success** or **Failure** will generate a large number of events, so typically it is set to **No auditing**. However, process tracking can be helpful in post-incident forensics because it provides a detailed log of which processes were started and the time they were started.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No auditing |
| Stand-Alone Server Default Settings | No auditing |
| DC Effective Default Settings | No auditing |
| Member Server Effective Default Settings | No auditing |

**Audit system events**
The **Audit system events** policy setting determines whether to audit when a user restarts or shuts down their computer, or when an event occurs that affects either system security or the security log.

The possible values for this Group Policy setting are:

- Success.
- Failure.
- No auditing.

**Discussion**
If you configure this policy setting, you can specify whether to audit successes, audit failures, or not audit the system events at all. Success audits generate an audit entry when a system event is executed successfully. Failure audits generate an audit entry when a system event is attempted unsuccessfully. Because only a few additional events will be recorded by setting **Audit system events** to both **Failure** and **Success**, and all of those events will be very significant, it is recommended that you set these values on all computers in your organization.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Success |
| Stand-Alone Server Default Settings | No auditing |
| DC Effective Default Settings | Success |
| Member Server Effective Default Settings | No auditing |

**User Rights Assignment**
User rights are tasks that a user is permitted to perform on a computer system or domain. There are two types of user rights: logon rights and privileges. Logon rights control who is authorized to log on to a computer and how they can log on. Privileges control access to system-wide resources on a computer and can override permissions set on specific objects. An example of a

logon right is the right to log on to a computer locally. An example of a privilege is the right to shut down the system. Both types of user rights are assigned by administrators to individual users or groups as part of the security policy settings for the computer.

The User Rights Assignment policy settings can be configured in the following location in Group Policy Object Editor:

Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Access this computer from the network**

The **Access this computer from the network** policy setting allows a user to connect to the computer from the network. This user right is required by a number of network protocols, including server message block (SMB)–based protocols, network BIOS (NetBIOS), Common Internet File System (CIFS), and Component Object Model Plus (COM+).

### Note

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

Users who can connect from their computer to the network can access resources on those computers for which they have permission. For example, this right is required for a user to connect to shared printers and folders. If this right is assigned to the Everyone group, and some shared folders have both share and NTFS file system permissions configured so that the Everyone group has read access, anyone will be able to view files in those shared folders. This is an unlikely situation for fresh installations of Windows Server 2003, because the default share and NTFS permissions in Windows Server 2003 do not include the Everyone group. For systems upgraded from Windows NT 4.0 or Windows 2000, this policy setting can have a higher level of risk because the default permissions for these operating systems are not as restrictive as the default permissions in Windows Server 2003.

It is advisable to assign the **Access this computer from the network** user right only to those users who require access to the server. For example, assigning this to the Administrators and Users groups will allow a user who logged on to the domain to access servers in the domain.

Removing this user right on domain controllers from all users will prevent anyone from logging on to the domain or using network resources. Removing this right on member servers will prevent users from connecting to those servers by way of the network. For these reasons, it is important to verify that authorized users have this right for the computers they need to access on the network.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Everyone, Administrators, Authenticated Users, ENTERPRISE DOMAIN CONTROLLERS, Pre-Windows 2000 Compatible Access |
| Stand-Alone Server Default Settings | Everyone, Administrators, Users, Power Users, Backup Operators |
| DC Effective Default Settings | Everyone, Administrators, Authenticated Users, ENTERPRISE DOMAIN CONTROLLERS, Pre-Windows 2000 Compatible Access |
| Member Server Effective Default Settings | Backup Operators, Power Users, Users, Administrators, Everyone |

**Act as part of the operating system**

The **Act as part of the operating system** user right allows a process to assume the identity of any user and thus gain access to the resources that the user is authorized to access. Typically, only low-level authentication services require this user right. Note that potential access is not limited to what is associated with the user by default; the calling process might request that arbitrary additional user rights be added to the access token. The calling process might also build an access token that does not provide a primary identity for events recorded in the security log.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
This user right is extremely powerful; anyone with this right can take complete control of the computer and erase virtually any evidence of their activities.

Limit the **Act as part of the operating system** user right to as few accounts as possible—it should not even be assigned to the Administrators group under normal circumstances. When a service requires this user right, configure the service to log on by using the local System account, which has this user right inherently. Do not create a separate account and assign this user right to it.

This user right is rarely needed by any accounts other than the local System account.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No one |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | No one |
| Member Server Effective Default Settings | Not defined |

**Add workstations to domain**
The **Add workstations to domain** user right allows the user to add a computer to a specific domain. For the user right to take effect, it must be assigned to the user as part of the Default Domain Controllers Policy for the domain. A user who has this user right can add up to 10 workstations to the domain. Users can also join a computer to a domain if they have been assigned the **Create Computer Objects** permission for an OU or for the Computers container in Active Directory. Users who have the **Create Computer Objects** permission can add an unlimited number of computers to the domain regardless of whether they have been assigned the **Add workstations to domain** user right.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
This user right has a moderate risk. Users with this right can add a computer to the domain that has been configured in a way that violates corporate security policies. For example, even if your organization does not want its users to have administrative user rights on their computer, a user could install Windows on their computer and then add the computer to the domain. They would know the password for the local Administrator account, and they could log on by using that account and then add their domain account to the local Administrators group.

Configure the **Add workstations to domain** user right so that only authorized members of the IT team are allowed to add computers to the domain. For organizations that have never allowed users to set up their own systems or add them to the

domain, this countermeasure will have no impact. For those that have allowed some or all users to configure their own computers, this countermeasure will force the organization to establish a formal process for these procedures.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Authenticated Users |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Authenticated Users |
| Member Server Effective Default Settings | Not defined |

**Adjust memory quotas for a process**
The **Adjust memory quotas for a process** user right allows a user to adjust the maximum memory available to a process. This user right is useful for system tuning, but it can be abused. In the wrong hands, it could be used to start a denial-of-service attack.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
A user with this right can reduce the amount of memory available to any process. This could cause business-critical network applications to slow down or even to fail.

Restrict the **Adjust memory quotas for a process** user right to users who require it to perform their job, such as application administrators who are responsible for maintaining database management systems or domain administrators responsible for managing the corporate directory and its supporting infrastructure.

Only organizations that have been lax with regard to restricting users to roles with limited user rights will find imposing this countermeasure difficult. For most organizations, implementing this restriction should have no impact.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | LOCAL SERVICE, NETWORK SERVICE, Administrators |
| Stand-Alone Server Default Settings | LOCAL SERVICE, NETWORK SERVICE, Administrators |
| DC Effective Default Settings | LOCAL SERVICE, NETWORK SERVICE, Administrators |
| Member Server Effective Default Settings | Administrators, NETWORK SERVICE, LOCAL SERVICE |

**Allow log on locally**
**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Allow log on locally** user right allows a user to start an interactive session on the computer. Users who do not have this

right can still start a remote interactive session on the computer if they have the **Allow log on through Terminal Services** user right.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Any account with the right to log on locally can be used to log on to the console of the computer. Not restricting this user right to legitimate users who need to be able to log on to the console of the system could result in unauthorized users downloading and executing malicious code to elevate their user rights.

For domain controllers, only assign the **Allow log on locally** user right to the Administrators group. For servers that fill other roles, add Backup Operators and Power Users. For end-user computers, assign this right to the Users group also.

Alternatively, you can add groups such as Account Operators, Server Operators, and Guests to the **Deny log on locally** user right. Denying access to these groups could limit the abilities of users assigned to specific administrative roles in your environment. Confirm that delegated activities will not be adversely affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators, Backup Operators, Account Operators, Server Operators, Print Operators |
| Stand-Alone Server Default Settings | Administrators, Users, Power Users, Backup Operators |
| DC Effective Default Settings | Administrators, Backup Operators, Account Operators, Server Operators, Print Operators |
| Member Server Effective Default Settings | Backup Operators, Power Users, Users, Administrators |

**Allow log on through Terminal Services**
The **Allow log on through Terminal Services** user right allows a user to log on to the computer by using a Remote Desktop connection. You should not assign this right to individual users or groups. Instead, it is a best practice to control who can open a Remote Desktop connection to the computer by adding users to or removing them from the Remote Desktop Users group.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Any account with the right to log on via Terminal Services can be used to log on to the remote console of the computer. Not restricting this user right to legitimate users who need to log on to the console of the system might allow unauthorized users to download and execute malicious code to elevate their user rights.

For domain controllers, only assign the **Allow log on through Terminal Services** user right to the Administrators group. For servers that fill other roles and end-user computers, add the Remote Desktop Users group. For all server roles other than Terminal Servers, ensure that only authorized members of the IT team who need to be able to manage the systems remotely belong to either of these groups.

For Terminal Servers, ensure that only users who require access to the server have accounts that belong to the Remote Desktop Users group, because this built-in group by default has this logon right.

Alternatively, you can assign the **Deny log on through Terminal Services** user right to groups such as Account Operators, Server Operators, and Guests. However, be careful when implementing this method because you might block access to legitimate administrators who also happen to belong to a group that has the **Deny log on through Terminal Services** logon right.

Changing membership in these default groups, or removing this user right from other groups, can limit the abilities of users assigned to specific administrative roles in your environment. Confirm that delegated activities will not be adversely affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Administrators, Remote Desktop Users |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Remote Desktop Users, Administrators |

**Back up files and directories**
The **Back up files and directories** user right allows the user to circumvent file and directory permissions to back up the system. This user right is selected only when an application attempts access via the NTFS backup application programming interface (API) by using, for example, Ntbackup.exe. Otherwise, normal file and directory permissions apply.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Users who are able to back up data from a computer might take the backup media to a computer that does not belong to the domain where they have administrative user rights and restore the data. They could then take ownership of the files and view anything contained within the backup set.

Limit the **Back up files and directories** user right to members of the IT team who need to be able to back up corporate data as part of their day-to-day responsibilities.

Changing membership of the groups that have this user right might limit the abilities of users assigned to specific administrative roles in your environment. Confirm that authorized backup administrators are still able to perform backup operations.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators, Backup Operators, Server Operators |
| Stand-Alone Server Default Settings | Administrators, Backup Operators |
| DC Effective Default Settings | Administrators, Backup Operators, Server Operators |
| Member Server Effective Default Settings | Backup Operators, Administrators |

**Bypass traverse checking**

**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Bypass traverse checking** user right allows a user who is navigating an object path in NTFS or the registry to pass through folders without checking for the special access permission Traverse Folder. This user right does not allow the user to list the contents of a folder, it only allows the user to traverse the folder's directories.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.

- Not defined.

**Discussion**
The default setting for this user right is to allow anyone to bypass traverse checking. For experienced Windows system administrators, this is the expected behavior, and they configure file-system access control lists (SACLs) accordingly. The only scenario where the default configuration might lead to a mishap is if the administrator who is configuring permissions expects that users who are unable to access a folder will be unable to access the contents of any child folders. This is an unlikely situation, and therefore the risk is very low.

Organizations that are extremely concerned about security might want to remove the Everyone group, or perhaps even the Users group, from the list of groups that have the **Bypass traverse checking** user right.

Windows and many applications have been designed with the expectation that anyone who can legitimately access the computer will have this user right. Therefore, removing the Everyone group from the list of users who have this user right by default might lead to operating-system instability or application failure. It is recommended that you leave this policy setting at its default.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Everyone, Administrators, Authenticated Users, Pre-Windows 2000 Compatible Access |
| Stand-Alone Server Default Settings | Everyone, Administrators, Users, Power Users, Backup Operators |
| DC Effective Default Settings | Everyone, Administrators, Authenticated Users, Pre-Windows 2000 Compatible Access |
| Member Server Effective Default Settings | Backup Operators, Power Users, Users, Administrators, Everyone |

**Change the system time**
The **Change the system time** user right allows the user to adjust the time on the computer's internal clock. This user right is not required to change the time zone or other display characteristics of the system time.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.

- Not defined.

**Discussion**
Users who are able to set a computer to the wrong time can cause several problems: Time stamps on event log entries will no longer be accurate; time stamps that indicate when files and folders are created or modified will not be correct; and, if the computer belongs to a domain, it might be unable to authenticate itself or users who try to log on to the domain from it. The

risk of this happening is mitigated on most domain controllers, member servers, and end-user computers because the Windows Time service automatically synchronizes time with domain controllers in the following ways:

- All client desktop computers nominate the authenticating domain controller as their inbound time partner.
- All member servers follow the same process that client desktop computers follow.
- All domain controllers in a domain nominate the primary domain controller (PDC) operations master as their inbound time partner.
- All PDC operations masters follow the hierarchy of domains in the selection of their inbound time partner.
- The PDC operations master at the root of the domain is authoritative for the organization; therefore, it is recommended that you synchronize it with a reliable external time server.

This issue becomes much more serious if a malicious user is able to change the system time and then stop the Windows Time service, or reconfigure it to be synchronized with a time server that is not accurate.

Limit the **Change the system time** user right to users who have a legitimate need to change the system time, such as members of the IT team.

There should be no impact for most organizations because time synchronization will be fully automated for all computers that belong to the domain. Computers that do not belong to the domain should be synchronized with an external source.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators, Server Operators |
| Stand-Alone Server Default Settings | Administrators, Power Users |
| DC Effective Default Settings | Administrators, Server Operators |
| Member Server Effective Default Settings | Power Users, Administrators |

**Create a page file**
The **Create a page file** user right allows the user to create and change the size of a paging file. This is done by clicking **Performance** on the **Advanced** tab of the **System Properties** property sheet and specifying a paging file size for a particular drive in the **Performance Options** dialog box.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Users who can change the paging file size can make it extremely small or move the file to a highly fragmented storage volume, which might lead to reduced system performance.

You should only assign the **Create a page file** user right to members of the Administrators group.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Create a token object**

The **Create a token object** user right allows a process to create a token. If the process uses NtCreateToken() or another token-creation API, it can use the token to access any local resources. It is advisable not to assign this user right to any users.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

The operating system determines the level of a user's privileges by examining the user's access token. Access tokens are built when users log on to the local computer or connect to a remote computer over a network. When you revoke a user right, the change is immediately recorded in the registry, but the change is not reflected in the user's access token until the next time the user logs on or connects. A user with the ability to create or modify tokens can change the level of access for any currently logged-on account. Such a user can escalate their own user rights or create a denial-of-service condition.

Do not assign the **Create a token object** right to any users. Processes that require this user right should use the local System account, which already includes this user right.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No one |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | No one |
| Member Server Effective Default Settings | Not defined |

**Create global objects**

The **Create global objects** user right is required for a user account to create global objects that are available to all sessions. Users can still create objects specific to their own session without being assigned this user right.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

Users who can create global objects can affect processes that run under other users' sessions. This could lead to a variety of problems, such as application failure or data corruption.

Only assign the **Create global objects** user right to members of the local Administrators and Service groups.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Administrators, SERVICE |
| DC Effective Default Settings | Administrators, SERVICE |
| Member Server Effective Default Settings | Administrators, SERVICE |

**Create permanent shared objects**
The **Create permanent shared objects** user right allows a user to create a directory object in the object manager. This means that users with this user right can create shared folders, printers, and other objects. This user right is useful for kernel-mode components that extend the object namespace. Components that run in kernel mode have this user right inherently; therefore, it is normally not necessary to specifically assign this user right.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Users with this user right can expose sensitive data to the network by creating a new shared object.

Do not assign the **Create permanent shared objects** right to any users. Processes that require this user right should use the local System account, which already includes this user right. Users who belong to the local Administrators group will still be able to create, modify, and delete shared folders and printers.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No one |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | No one |
| Member Server Effective Default Settings | Not defined |

**Debug programs**
The **Debug programs** user right allows the user to attach a debugger to any process. This user right provides access to sensitive and critical operating system components.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

The **Debug programs** user right can be exploited to capture sensitive system information from system memory. Some attack tools exploit the debug program's user right to extract hashed passwords and other private security information. The risk of attackers' being able to exploit this user right is mitigated by the fact that the debug program's user right is by default assigned only to administrators.

Revoke the **Debug programs** user right from all users and groups. Revoking this user right will mean that no one except administrators will be able to debug programs. However, under normal circumstances, debugging is rarely necessary on production systems. If a problem arises that requires debugging an application on a production server temporarily, move the server to a different OU and assign the **Debug programs** user right to the appropriate account.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Deny access to this computer from the network**
The **Deny access to this computer from the network** user right prohibits a user from connecting to the computer from the network.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Users who can log onto the computer over the network can enumerate lists of account names, group names, and shared resources. Users with permission to access shared folders and files can connect over the network and possibly view or modify data. Explicitly denying this logon right to high-risk accounts, such as the local Guest account and other accounts that have no business reason for accessing the computer over the network, provides an additional layer of protection.

Assign the **Deny access to this computer from the network** user right to the following accounts:

- ANONYMOUS LOGON
- The built-in local Administrator account
- The local Guest account
- The built-in Support account (the Support_388945a0 account is the logon account for Remote Assistance)
- All service accounts

  There is an important exception to this list: do not assign the logon right to any service accounts that are used to start services that need to connect to the computer over the network. For example, if you have configured a shared folder for Web servers to access, and you present content within that folder through a Web site, you might need to allow the account under which IIS is running to log on to the server with the shared folder via the network.

Configuring this logon right for other groups might limit the abilities of users assigned to specific administrative roles in your environment. Verify that delegated tasks will not be negatively affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | SUPPORT_388945a0 |
| Stand-Alone Server Default Settings | SUPPORT_388945a0 |
| DC Effective Default Settings | SUPPORT_388945a0 |
| Member Server Effective Default Settings | SUPPORT_388945a0 |

**Deny log on as a batch job**
The **Deny log on as a batch job** user right prohibits a user from logging on by using a batch-queue facility. Batch-queue in Windows Server 2003 is used for scheduling jobs that will be automatically started one or more times in the future. This user right is needed for any accounts that are used for scheduling jobs via the Task Scheduler service.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Accounts with this logon right might be used to schedule jobs that consume excessive system resources, leading to a denial-of-service condition.

Assign the **Deny log on as a batch job** user right to the built-in Support account — the Support_388945a0 account is the logon account for Remote Assistance — and the local Guest account. Configuring this logon right for other accounts might prevent users who are assigned to specific administrative roles from performing their required job activities. Confirm that delegated tasks will not be affected adversely.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |

| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | No one |
| Member Server Effective Default Settings | Not defined |

**Deny log on as a service**
The **Deny log on as a service** logon right prohibits a user from logging on as a service.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

Accounts that can log on as a service might be used to configure and start new unauthorized services such as a Trojan horse or backdoor (a backdoor is a hidden entrance to an operating system that can be used to download system information). The benefit of configuring this countermeasure is somewhat mitigated by the fact that only users with administrative user rights can install and configure services, and a malicious user who has already attained that level of access can configure the service to run under the local System account.

It is advisable to keep this user right in its default state; that is, do not assign the **Deny log on as a service** logon right to any accounts. Organizations that are extremely concerned about security might want to assign this logon right to groups and accounts that they are certain will never need to log on as a service. Assigning this user right to specific accounts can prevent services from being started, which might lead to a denial-of-service condition.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |

| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | No one |
| Member Server Effective Default Settings | Not defined |

**Deny log on locally**
The **Deny log on locally** logon right prohibits a user from logging on directly at the computer's keyboard.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Any account with the right to log on locally can be used to log on at the console of the computer. If this user right is not restricted to legitimate users who need to log on to the console of the system, unauthorized users can download and execute malicious code that elevates their user rights.

Assign the **Deny log on locally** logon right to the built-in Support account. The Support_388945a0 account is the logon account for Remote Assistance.

The Support_388945a0 account enables Help and Support Center interoperability with signed scripts. This account is primarily used to control access to signed scripts that are accessible from within Help and Support Center. Administrators can use this account to delegate the ability for an ordinary user, who does not have administrative access to a computer, to run signed scripts from links embedded within Help and Support Center. These scripts can be programmed to use the Support_388945a0 account credentials instead of the user's credentials to perform specific administrative operations on the local computer, operations that otherwise would not be supported by the ordinary user's account. When the delegated user clicks a link in Help and Support Center, the script runs under the security context of the Support_388945a0 account. This account has limited access to the computer and is disabled by default.

Assigning this logon right to additional accounts might limit the abilities of users assigned to specific administrative roles in your environment. Confirm that delegated activities will not be adversely affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|

| | |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | SUPPORT_388945a0 |
| Stand-Alone Server Default Settings | SUPPORT_388945a0 |
| DC Effective Default Settings | SUPPORT_388945a0 |
| Member Server Effective Default Settings | SUPPORT_388945a0 |

**Deny log on through Terminal Services**

The **Deny log on through Terminal Services** logon right prohibits a user from logging on to the computer by using a Remote Desktop connection.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

Any account with the right to log on using Terminal Services can be used to log on to the remote console of the computer. If this user right is not restricted to legitimate users who need to log on to the console of the system, unauthorized users might download and execute malicious code that elevates their user rights.

Assign the **Deny log on through Terminal Services** logon right to the built-in local Administrator account and all service accounts. Assigning this logon right to other groups might limit the abilities of users assigned to specific administrative roles in your environment. Confirm that delegated tasks will not be negatively affected.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Enable computer and user accounts to be trusted for delegation**

The **Enable computer and user accounts to be trusted for delegation** user right allows the user to change the **Trusted for Delegation** policy setting on a user or computer object in Active Directory. The user or computer that is assigned this user right must also have write access to the account control flags on the object.

### Note

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

Delegation of authentication is used by multitier client/server applications. It allows a front-end service to use the credentials of

a client while authenticating to a back-end service. For this to be possible, both client and server must be running under accounts that are trusted for delegation.

Misuse of this user right can lead to unauthorized users' impersonating other users' on the network. A malicious user can exploit this user right to gain access to network resources while appearing to be a different user, which could make post–security incident forensics more difficult.

It is advisable to assign the **Enable computer and user accounts to be trusted for delegation** user right only to the Administrators group on domain controllers. There is no reason to assign it to anyone on member servers or workstations that belong to a domain, because it has no meaning in those contexts; this user right is only relevant to domain controllers and stand-alone systems.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Not defined |

**Force shutdown from a remote system**
The **Force shutdown from a remote system** user right allows a user to shut down a computer from a remote location on the network.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Any user who can shut down a computer can cause a denial-of-service condition; therefore, this user right should be tightly restricted.

Only assign the **Force shutdown from a remote system** user right to members of the Administrators group. Removing the Server Operators group might limit the abilities of users assigned to specific administrative roles in your environment. Confirm that delegated activities will not be adversely affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators, Server Operators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators, Server Operators |
| Member Server Effective Default Settings | Administrators |

**Generate security audits**
The **Generate security audits** user right allows a process to generate audit records in the security log. The security log can be

used to trace unauthorized system access.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Accounts that are able to write to the security log can be used by a malicious user to fill that log with meaningless events. If the computer is configured to overwrite event logs as they fill up, the attacker can use this method to remove evidence of their unauthorized activities. If the computer is configured to shut down when it is unable to write to the security log, this method can be used to create a denial-of-service condition.

Ensure that only the Local Service and Network Service groups have the **Generate security audits** user right assigned to them.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | LOCAL SERVICE, NETWORK SERVICE |
| Stand-Alone Server Default Settings | LOCAL SERVICE, NETWORK SERVICE |
| DC Effective Default Settings | LOCAL SERVICE, NETWORK SERVICE |
| Member Server Effective Default Settings | LOCAL SERVICE, NETWORK SERVICE |

**Impersonate a client after authentication**
The **Impersonate a client after authentication** user right allows programs running on behalf of a user to impersonate a client. Requiring this user right for this kind of impersonation prevents an unauthorized user from convincing a client to connect — for example, by remote procedure call (RPC) or named pipes — to a service that they have created and then impersonating that client, which can elevate the unauthorized user's credentials to administrative or system levels.

Services that are started by the Service Control Manager have the built-in Service group added by default to their access tokens. COM servers started by the COM infrastructure that are configured to run under a specific account also have the Service group added to their access tokens. As a result, these services get this user right when they are started.

In addition, a user can also impersonate an access token if any of the following conditions exist.

- The access token that is being impersonated is for this user.
- The user, in this logon session, created the access token by logging on to the network with explicit credentials.
- The requested level is less than Impersonate, such as Anonymous or Identify.

Because of these factors, users do not usually need this user right.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
A user with this user right can trick a client into connecting to a service that they have created and then impersonating that

client. The user can then elevate their level of access to that of the other client.

Ensure that only the Administrators and Service groups have the **Impersonate a client after authentication** user right assigned to them.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Administrators, SERVICE |
| DC Effective Default Settings | Administrators, SERVICE |
| Member Server Effective Default Settings | Administrators, SERVICE |

**Increase scheduling priority**
The **Increase scheduling priority** user right allows a user to increase the base priority class of a process. Increasing relative priority within a priority class is not a privileged operation. This user right is not required by administrative tools supplied with the operating system, but might be required by software development tools.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
A user with this user right can increase the scheduling priority of a process to Real-Time. This might leave little processing time for all other processes, which could lead to a denial-of-service condition.

Only Administrators should have the **Increase scheduling priority** user right assigned to them.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Load and unload device drivers**
The **Load and unload device drivers** user right determines which users can dynamically load and unload device drivers. This user right is not required if a signed driver for the new hardware already exists in the Driver.cab file on the computer.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Device drivers run as highly privileged code. A user who has the **Load and unload device drivers** user right might unintentionally install malicious code that masquerades as a device driver. It is assumed that administrators will exercise greater care and only install drivers with verified digital signatures.

You must have this user right, and also be a member of either Administrators or Power Users, to install a new driver for a local printer or manage a local printer by setting defaults for options such as duplex printing. This requirement — to have the user right and also be a member of the Administrators or Power Users group — is new in the Windows XP and Windows Server 2003 operating systems.

Do not assign the **Load and unload device drivers** user right to any user or group other than Administrators. Removing this user right from the Print Operators group or other accounts might limit the abilities of users assigned to specific administrative roles in your environment. Ensure that delegated tasks will not be negatively affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators, Print Operators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators, Print Operators |
| Member Server Effective Default Settings | Administrators |

**Lock pages in memory**
The **Lock pages in memory** user right allows a process to keep data in physical memory, which prevents the system from paging the data to virtual memory on disk. Assigning this user right can result in significant degradation of system performance.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Users with this user right can assign physical memory to several processes, leaving little or no RAM for other processes. This could lead to a denial-of-service condition.

Do not assign the **Lock pages in memory** user right to any accounts.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No one |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | No one |
| Member Server Effective Default Settings | Not defined |

**Log on as a batch job**

The **Log on as a batch job** user right allows a user to log on by using a batch-queue facility such as the Task Scheduler service. When an administrator uses the Add Scheduled Task wizard to schedule a task to run under a particular user name and password, that user automatically receives the **Log on as a batch job** user right. When the scheduled time arrives, the Task Scheduler service logs the user on as a batch job rather than as an interactive user, and the task runs in the user's security context.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

For most organizations, the default values are sufficient. Allow the system to manage this user right automatically if you want to allow tasks to be scheduled to run for specific user accounts. If you do not want to use the Task Scheduler in this manner, configure the **Log on as a batch job** user right for only the Local Service group and the local support account (Support_388945a0). For Internet Information Services (IIS) servers, configure this policy locally, rather than through domain-based Group Policy, so you can ensure that the local IUSR_computername and IWAM_computername accounts have this logon right.

If you specify this policy setting through domain-based Group Policy, the system will not be able to assign this user right to accounts used for scheduled jobs in the Task Scheduler, and the IUSR_computername and IWAM_computername accounts will not have this logon right. This will cause IIS to be unable to run some COM objects that are necessary for proper functioning.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | LOCAL SERVICE, SUPPORT_388945a0 |
| Stand-Alone Server Default Settings | LOCAL SERVICE, SUPPORT_388945a0 |
| DC Effective Default Settings | LOCAL SERVICE, SUPPORT_388945a0 |
| Member Server Effective Default Settings | LOCAL SERVICE, SUPPORT_388945a0 |

**Log on as a service**

The **Log on as a service** logon right allows a security principal to log on as a service. Services can be configured to run under the Local System, Local Service, or Network Service accounts, which have a built-in right to log on as a service. Any service that runs under a separate user account must be assigned this right.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

This is a powerful logon right that allows accounts to start network services. The risk is mitigated by the fact that only users with administrative user rights can install and configure services. A malicious user who has already attained that level of access can configure the service to run under the local System account.

The default security principal with the **Log on as a service** logon right is Network Service, a built-in local group. Service accounts should be added to this local group, and you should monitor membership for this group and this user right to ensure that unexpected changes are not being made.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | NETWORK SERVICE |
| Stand-Alone Server Default Settings | NETWORK SERVICE |
| DC Effective Default Settings | NETWORK SERVICE |
| Member Server Effective Default Settings | NETWORK SERVICE |

**Manage auditing and security log**

The **Manage auditing and security log** user right allows a user to specify object access auditing options for individual resources such as files, Active Directory objects, and registry entries. Object access auditing is not performed unless you enable it by using Group Policy Object Editor and configuring Audit Policy in the following location:

Computer Configuration\Windows Settings\Security Settings\Local Policies\Audit Policy

A user who has this user right can also view and clear the security log from Event Viewer.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

The right to manage the security event log is a powerful user right, and it should be closely guarded. Anyone with this user right can clear the security log, possibly erasing important evidence of unauthorized activity.

Ensure that only the local Administrators group has the **Manage auditing and security log** user right.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Modify firmware environment values**

The **Modify firmware environment values** user right allows system environment variables to be modified, either by a process through an application programming interface (API) or by a user through **System Properties**.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

Anyone with this user right can configure the settings of a hardware component in such a way that it fails. This can lead to data

corruption or a denial-of-service condition.

Ensure that only the local Administratorsgroup has the **Modify firmware environment values** user right.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Perform volume maintenance tasks**
The **Perform volume maintenance tasks** user right allows a non- administrative or remote user to manage volumes or disks. Windows Server 2003 checks for the user right in a user's access token when a process running in the user's security context calls **SetFileValidData()**.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
A user with this user right can delete a volume, leading to the loss of data or a denial-of-service condition.

Ensure that only the local Administrators group has the **Perform volume maintenance tasks** user right.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Profile single process**
The **Profile single process** user right allows a user to sample the performance of an application process. Ordinarily, you do not need this user right to use the Performance snap-in; however, you do need the user right if System Monitor is configured to collect data by using Windows Management Instrumentation (WMI).

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
A malicious user with this user right can monitor a computer's performance to help identify critical processes that they might want to attack directly. The attacker can also determine what processes are running on the system and identify countermeasures that they should avoid — such as antivirus software or an intrusion-detection system — or identify which other users are logged on to the system.

Ensure that only the local Administrators group has the **Profile single process** user right. Removing this user right from the Power Users group or other accounts might limit the abilities of users who are assigned to specific administrative roles in your environment. Ensure that delegated tasks will not be negatively affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators, Power Users |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators, Power Users |

**Profile system performance**
The **Profile system performance** user right allows a user to sample the performance of system processes. Ordinarily, you do not need this user right to use the Performance snap-in; however, you do need the user right if System Monitor is configured to collect data by using WMI.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
This is a moderate risk. A malicious user with this user right can monitor a computer's performance to help identify critical processes that they might want to attack directly. The attacker might also be able to determine what processes are running on the system so they can identify countermeasures that they might need to avoid, such as antivirus software or an intrusion-detection system.

Ensure that only the local Administrators group has the **Profile system performance** user right.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |

| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Remove computer from docking station**
The **Remove computer from docking station** user right allows the user of a portable computer to undock the computer by

clicking **Eject PC** on the **Start** menu.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Anyone who has this user right can remove a portable computer that has been started from its docking station. The value of employing this countermeasure is reduced by several factors: If a malicious user can restart the computer, they can remove it from the docking station after the BIOS has started but before the operating system has started; or a malicious user might steal the computer and the docking station together. This setting will not affect servers, because they are not typically installed in a docking station

Ensure that only the local Administrators and Power Users groups have the **Remove computer from docking station** user right.

This is the default configuration, so it should have little impact; however, if your organization's end users are not members of the Power Users or Administrators groups, they will be unable to remove their own portable computers from their docking stations without shutting down the system. Therefore, on portable computers, you might want to assign this user right to the local Users group.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators, Power Users |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators, Power Users |

**Replace a process level token**
The **Replace a process level token** user right allows a parent process to replace the access token that is associated with a child process.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
If a user has this right and the **Adjust memory quotas for a process** user right, they can start processes as other users. They could use this method to hide the fact that they are performing unauthorized actions on the computer.

Ensure that only the Local Service and Network Service groups have the **Replace a process level token** user right.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |

| | |
|---|---|
| Default Domain Controller Policy | LOCAL SERVICE, NETWORK SERVICE |
| Stand-Alone Server Default Settings | LOCAL SERVICE, NETWORK SERVICE |
| DC Effective Default Settings | LOCAL SERVICE, NETWORK SERVICE |
| Member Server Effective Default Settings | LOCAL SERVICE, NETWORK SERVICE |

**Restore files and directories**

The **Restore files and directories** user right allows a user to circumvent file and directory permissions when restoring backed-up files and directories, and to set any valid security principal as the owner of an object.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

A malicious user with this user right can restore sensitive corporate data to a system, overwriting data that is more recent. This could lead to loss of important data, data corruption, or a denial-of-service condition.

This countermeasure will not prevent a malicious user from restoring data to an unmanaged system, so it is critical that organizations carefully protect the media they use for backing up data.

Ensure that only the local Administrators group has the **Restore files and directories** user right. Removing this user right from the Backup Operators group and other accounts might limit the abilities of users assigned to specific administrative roles in your environment. Ensure that delegated tasks will not be negatively affected.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators, Backup Operators, Server Operators |
| Stand-Alone Server Default Settings | Administrators, Backup Operators |
| DC Effective Default Settings | Administrators, Backup Operators, Server Operators |
| Member Server Effective Default Settings | Administrators, Backup Operators |

**Shut down the system**

The **Shut down the system** user right allows a user to shut down the local computer.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**

The ability to shut down domain controllers should be limited to a very small number of trusted administrators. Even though a system shutdown requires the ability to log on to the server, you should be very careful about the accounts and groups that you allow to shut down a domain controller.

Shutting down domain controllers makes them unavailable to perform such functions as processing logons, serving Group Policy, and answering Lightweight Directory Access Protocol (LDAP) queries. Shutting down domain controllers that have been

assigned operations master roles (also known as flexible single master operations or FSMO) roles can disable key domain functionality, such as processing logons for new passwords, which is performed by the PDC emulator operations master.

Ensure that only Administrators and Backup Operators have the **Shut down the system** user right on member servers, and that only Administrators have the user right on domain controllers. Removing these default groups might limit the abilities of users assigned to specific administrative roles in your environment. Ensure that delegated tasks will not be negatively affected.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators, Backup Operators, Server Operators, Print Operators |
| Stand-Alone Server Default Settings | Administrators, Power Users, Backup Operators, Users |
| DC Effective Default Settings | Administrators, Backup Operators, Server Operators, Print Operators |
| Member Server Effective Default Settings | Administrators, Power Users, Backup Operators, Users |

**Synchronize directory service data**
The **Synchronize directory service data** user right allows a process to read all objects and properties in the directory, regardless of the protection on the objects and properties. This user right is required in order to use LDAP directory synchronization (Dirsync) services.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
This user right affects domain controllers; only domain controllers should be able to synchronize directory service data. They have this right inherently because the synchronization process runs in the context of the System account on domain controllers. A malicious user who has this user right can view all information stored within the directory. They can then use some of that information to facilitate additional attacks or expose sensitive corporate data, such as direct telephone numbers or physical addresses.

Ensure that no accounts have the **Synchronize directory service data** user right.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | No one |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | No one |
| Member Server Effective Default Settings | Not defined |

**Take ownership of files or other objects**
The **Take ownership of files or other objects** user right allows a user to take ownership of any securable object in the system, including Active Directory objects, NTFS files and folders, printers, registry keys, services, processes, and threads.

The possible values for this Group Policy setting are:

- A user-defined list of accounts.
- Not defined.

**Discussion**
Any user with this ability can take control of any object regardless of the permissions on that object and then make any changes they want to that object. This can result in exposure of data, corruption of data, or a denial-of-service condition.

Ensure that only the local Administrators group has the **Take ownership of files or other objects** user right.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Administrators |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Security Options**
The Security Options section of Group Policy enables or disables computer security policy settings, such as digital data signing, Administrator and Guest account names, access to floppy disk and CD drives, driver installation behavior, and logon prompts. The Security Options policy settings can be configured in the following location in Group Policy Object Editor:

Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Accounts: Administrator account status**
The **Accounts: Administrator account status** policy setting enables or disables the Administrator account under normal operation. When a computer is booted in Safe Mode, the Administrator account is always enabled, regardless of this policy setting.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
For some organizations, periodically changing the password for local accounts can be a daunting management challenge, therefore they might want to disable the built-in Administrator account. Another reason to consider disabling this built-in account is that by default it cannot be locked out, no matter how many failed logons it accrues. This makes it a prime target for brute-force password-guessing attacks. Additionally, this account has a well-known security identifier (SID); some non-Microsoft tools allow you to authenticate over the network by specifying the SID rather than the account name. This means that even if you have renamed the Administrator account, a malicious user could start a brute-force attack by using the SID.

Disabling the Administrator account can become a maintenance issue under certain circumstances. For example, in a domain environment, if the secure channel that constitutes your connection fails for any reason, and there is no other local Administrator account, you must restart the computer in Safe Mode to fix the problem that broke your connection status.

If the current Administrator password does not meet the password requirements, you will not be able to enable the Administrator account again after it has been disabled. In this case, another member of the Administrators group must set the password on the Administrator account by using the Local Users and Groups tool.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Enabled |
| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Enabled |

**Accounts: Guest account status**
The **Accounts: Guest account status** policy setting determines whether the Guest account is enabled or disabled.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
This account allows unauthenticated network users to gain access to the system by logging in as Guest with no password. Unauthorized users can access any resources that are accessible to the Guest account over the network. This means that any network shares with permissions allowing access to the Guest account, the Guests group, or the Everyone group will be accessible over the network. This can lead to the exposure or corruption of data.

Set **Accounts: Guest account status** to **Disabled** so that the built-in Guest account is no longer usable. All network users will have to authenticate before they can access shared resources on the system. If the Guest account is disabled and **Network access: Sharing and security model for local accounts** is set to **Guest only**, network logons—such as those performed by the SMB Service—will fail. This should have little impact on most organizations because it is the default value for this policy setting in Windows 2000, Windows XP, and Windows Server 2003.

**Location**

| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Accounts: Limit local account use of blank passwords to console logon only**
The **Accounts: Limit local account use of blank passwords to console logon only** policy setting determines whether remote interactive logons by network services such as Terminal Services, Telnet, and File Transfer Protocol (FTP) are allowed for local accounts that have blank passwords. If this policy setting is enabled, a local account must have a nonblank password to be used to perform an interactive or network logon from a remote client.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
This policy setting does not affect interactive logons that are performed physically at the console, or logons that use domain accounts. It is possible for non-Microsoft applications that use remote interactive logons to bypass this policy setting.

Blank passwords are a serious threat to computer security and they should be forbidden through both corporate policy and suitable technical measures. In fact, the default policy settings for Windows Server 2003 Active Directory domains require complex passwords of at least seven characters. Nevertheless, if a user with the ability to create new accounts creates one that has bypassed your domain-based password policy settings, that account might have a blank password. For example, a user could build a stand-alone system, create one or more accounts with blank passwords, and then join the computer to the domain. The local accounts with blank passwords would still function. Anyone who knows the account name can then use accounts with blank passwords to log on to systems.

It is advisable to set **Accounts: Limit local account use of blank passwords to console logon only** to **Enabled**.

**Location**

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Enabled |
| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Enabled |

**Accounts: Rename administrator account**
The **Accounts: Rename administrator account** policy setting determines whether a different account name is associated with the SID for the Administrator account.

The possible values for this Group Policy setting are:

- User-defined text.
- Not defined.

**Discussion**
Because the Administrator account exists on all Windows 2000, Windows Server 2003, and Windows XP Professional computers, renaming the account makes it slightly more difficult for attackers to guess this user name and password combination. By default, the built-in Administrator account cannot be locked out no matter how many times a malicious user might use a bad password. This makes the Administrator account a popular target for brute-force password-guessing attacks. The value of this countermeasure is lessened because this account has a well-known SID and there are non-Microsoft tools that allow you to initiate a brute-force attack over the network by specifying the SID rather than the account name. This means that even if you have renamed the Administrator account, a malicious user could start a brute-force attacking by using the SID.

Rename the Administrator account by specifying a value for the **Accounts: Rename administrator account** policy setting.

This policy setting is not configured in the security templates, nor is a new user name for the account suggested here. This is so that numerous organizations reading this guide will not implement the same new user name in their environments.

Be sure to inform users who are authorized to use this account of the new account name.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |

| DC Effective Default Settings | Administrator |
| Member Server Effective Default Settings | Administrator |

**Accounts: Rename guest account**

The **Accounts: Rename guest account** policy setting determines whether a different account name is associated with the SID for the Guest account.

The possible values for this Group Policy setting are:

- User-defined text.
- Not defined.

**Discussion**

Because the Guest account exists on all Windows 2000, Windows Server 2003, and Windows XP Professional computers, renaming the Guest account makes it slightly more difficult for unauthorized persons to guess this privileged user name and password combination.

Rename the Guest account by specifying a value for the **Accounts: Rename guest account** policy setting.

This policy setting is not configured in the security templates.

The Guest account is disabled by default in Windows 2000, Windows XP, and Windows Server 2003.

**Audit: Audit the access of global system objects**

Enabling the **Audit: Audit the access of global system objects** policy setting creates system objects—such as mutexes, events, semaphores, and MS-DOS devices—with a default SACL. If the **Audit object access** policy setting is also enabled, access to these system objects is audited.

Global system objects, also known as *base system objects* or *base named objects*, are ephemeral kernel objects that have had names assigned to them by the application or system component that created them. These objects are most commonly used to synchronize multiple applications or multiple parts of a complex application. By virtue of having a name, these objects are global in scope, and therefore visible to all processes on the system. These objects all have a security descriptor, but typically have a NULL SACL. Enabling this policy setting at boot time causes the kernel to assign an SACL to these objects when they are created.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
The threat is that a globally visible named object, if incorrectly secured, might be acted on by a malicious program that knows the name of the object. For instance, if a synchronization object such as a mutex has a poorly chosen discretionary access control list (DACL), a malicious program can access that mutex by name and cause the program that created it to malfunction; however, the risk of this occurring is very low.

Enabling this policy setting can generate a large number of security events, especially on busy domain controllers and application servers. This might cause servers to respond slowly and force the security log to record numerous events of little significance. Auditing for access to global system objects is an all-or-nothing affair; there is no way to filter which events get recorded and which do not. Even if an organization has the resources to analyze events generated when this policy setting is enabled, it is unlikely to have the source code or a description of what each named object is used for; therefore, it is unlikely that many organizations could benefit from enabling this policy setting.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Audit: Audit the use of Backup and Restore privilege**
The **Audit: Audit the use of Backup and Restore privilege** policy setting determines whether to audit the use of all user rights, including Backup and Restore, when the **Audit privilege use** policy setting is configured. Enabling both policy settings generates an audit event for every file that is backed up or restored.

Enabling this policy setting in conjunction with the **Audit privilege use** policy setting records any instance of user rights being exercised in the security log. If **Audit privilege use** is enabled but **Audit: Audit the use of Backup and Restore privilege** is disabled, when users use Backup or Restore user rights, those events will not be audited.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Enabling this policy setting when the **Audit privilege use** policy setting is also enabled generates an audit event for every file that is backed up or restored. This can help you to track down an administrator who is accidentally or maliciously restoring data in an unauthorized manner.

It is advisable to set **Audit use of Backup and Restore privilege** to **Disabled**. Enabling this policy setting can generate a large number of security events, which might cause servers to respond slowly and force the security log to record numerous events of little significance.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |

| Member Server Effective Default Settings | Disabled |

**Audit: Shut down system immediately if unable to log security audits**
**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Audit: Shut down system immediately if unable to log security audits** policy setting determines whether the system shuts down if it is unable to log security events. This policy setting is a requirement for Trusted Computer System Evaluation Criteria (TCSEC)-C2 and Common Criteria certification to prevent auditable events from occurring if the audit system is unable to log those events. Microsoft has chosen to meet this requirement by halting the system and displaying a Stop message in the case of a failure of the auditing system. Enabling this policy setting stops the system if a security audit cannot be logged for any reason. Typically, an event fails to be logged when the security audit log is full and the value of **Retention method for security log** is either **Do not overwrite events (clear log manually)** or **Overwrite events by days**.

With **Audit: Shut down system immediately if unable to log security audits** set to **Enabled**, if the security log is full and an existing entry cannot be overwritten, the following Stop message appears:

STOP: C0000244 {Audit Failed}

An attempt to generate a security audit failed.

To recover, an administrator must log on, archive the log (optional), clear the log, and reset this option as desired.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
If the computer is unable to record events to the security log, critical evidence or important troubleshooting information might not be available for review after a security incident.

The administrative burden of enabling this policy setting can be very high, especially if you also set the **Retention methodfor security log** to **Do not overwrite events (clear log manually)**. This setting turns a repudiation threat (a backup operator could deny that they backed up or restored data) into a denial-of-service threat, because a server can be forced to shut down if it is overwhelmed with logon events and other security events that are written to the security log. Additionally, because the shutdown is not graceful, it is possible that irreparable damage to the operating system, applications, or data could result. Although NTFS will guarantee that the file system's integrity will be maintained during a sudden system shutdown, it cannot guarantee that every data file for every application will still be in a usable form when the system is restarted.

| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Devices: Allow undock without having to log on**

The **Devices: Allow undock without having to log on** policy setting determines whether a user must log on to request permission to remove a portable computer from a docking station. Enabling this policy setting allows a user to undock a computer by pressing the portable computer's physical eject button. Disabling this policy setting requires that the user log on to get undocking permission. Only users who have the **Remove computer from docking station** user right can be assigned this permission.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

This policy setting should only be disabled for portable computers that cannot be mechanically undocked. Otherwise, enabling the policy setting allows a user to physically remove the computer when they cannot log in and the eject button does not work.

Enabling this policy setting means that anyone with physical access to a computer that has been placed in its docking station can remove the computer and possibly tamper with it. For computers that do not have docking stations, this policy setting has no impact. However, for users with a mobile computer that is normally docked while they are in the office, this policy setting will help lower the risk of equipment theft or a malicious user gaining physical access to these computers.

It is advisable to disable the **Devices: Allow undock without having to log on** policy setting. Users who have docked their computers will have to log on to the local console before they can undock their systems.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |

**Devices: Allowed to format and eject removable media**

The **Devices: Allowed to format and eject removable media** policy setting determines who is allowed to format and eject removable media.

The possible values for this Group Policy setting are:

- Administrators.

- Administrators and Power Users.
- Administrators and Interactive Users.
- Not defined.

**Discussion**
Users can move removable disks to a different computer where they have administrative user rights and then take ownership of any file, assign themselves full control, and view or modify any file. The advantage of configuring this policy setting is diminished by the fact that most removable storage devices will eject media with the press of a button.

It is advisable to set **Allowed to format and eject removable media** to **Administrators**. Only administrators will be able to eject NTFS-formatted removable media.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |

| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Administrators |
| DC Effective Default Settings | Administrators |
| Member Server Effective Default Settings | Administrators |

**Devices: Prevent users from installing printer drivers**
For a computer to print to a network printer, the driver for that network printer must be installed on the local computer. The **Devices: Prevent users from installing printer drivers** policy setting determines who can install a printer driver as part of adding a network printer. When you set the value to **Enabled**, only Administrators and Power Users can install a printer driver as part of adding a network printer. Setting the value to **Disabled** allows any user to install a printer driver as part of adding a network printer. This setting prevents unprivileged users from downloading and installing an untrusted printer driver.

This setting has no impact if an administrator has configured a trusted path for downloading drivers. When using trusted paths, the print subsystem attempts to use the trusted path to download the driver. If the trusted path download succeeds, the driver is installed on behalf of any user. If the trusted path download fails, the driver is not installed and the network printer is not added.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Although it might be appropriate in some organizations to allow users to install printer drivers on their own workstations, this is not suitable for servers. Installing a printer driver on a server can cause the system to become less stable. Only administrators should have this user right on servers. A malicious user might deliberately try to damage the system by installing inappropriate printer drivers.

It is advisable to set **Devices: Prevent users from installing printer drivers** to **Enabled**. Only users in the Administrative, Power User, or Server Operator groups will be able to install printers on servers. If this policy setting is enabled, but the driver for a network printer already exists on the local computer, users can still add the network printer. This policy setting does not affect a user's ability to add a local printer.

**Devices: Restrict CD-ROM access to locally logged-on user only**

The **Devices: Restrict CD-ROM access to locally logged-on user only** policy setting determines whether a CD-ROM will be accessible to both local and remote users simultaneously. Enabling this policy setting allows only the interactively logged-on user to access removable CD-ROM media. If this policy setting is enabled and no one is logged on interactively, the CD-ROM can be accessed over the network.

The possible values for these Group Policy settings are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

The security benefit of enabling this policy setting is small because it only prevents network users from accessing the drive when someone is logged on to the local console of the system at the same time. Additionally, CD drives are not automatically made available as network shares; administrators must deliberately choose to share the drive. This is important when administrators are installing software or copying data from a CD-ROM and they do not want network users to be able to execute the applications or view the data.

If this policy setting is enabled, users connecting to the server over the network will not be able to use any CD drives installed on the server whenever anyone is logged on to the local console of the server. Enabling this policy setting is not suitable for a system that serves as a CD jukebox for network users.

| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Devices: Unsigned driver installation behavior**
The **Devices: Unsigned driver installation behavior** policy setting determines what happens when a user attempts to install a device driver that has not been certified by the Windows Hardware Quality Lab (WHQL) by means of Setup API.

The possible values for this Group Policy setting are:

- Silently succeed.
- Warn but allow installation.
- Do not allow installation.
- Not defined.

**Discussion**
This policy setting can prevent the installation of unsigned drivers or warn the administrator that an unsigned driver software is about to be installed. It can prevent Setup API from installing drivers that have not been certified to run on Windows Server 2003. This policy setting will not prevent a method used by some attack tools in which malicious .sys files are copied and registered to start as system services.

It is advisable to set **Unsigned driver installation behavior** to **Warn but allow installation**. This differs from the default value for this policy setting in Windows Server 2003, which is **Not defined**. A potential problem with setting **Unsigned driver installation behavior** to **Warn but allow installation** is that users who have sufficient user rights to install device drivers will still be able to install unsigned device drivers, which can result in stability problems for system servers. Another potential problem with this setting is that unattended installation scripts will fail if they attempt to install unsigned drivers.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |

| Stand-Alone Server Default Settings | Warn but allow installation |
| DC Effective Default Settings | Warn but allow installation |
| Member Server Effective Default Settings | Warn but allow installation |

**Domain controller: Allow server operators to schedule tasks**

The **Domain controller: Allow server operators to schedule tasks** policy setting determines whether users in the Server Operators group are allowed to submit jobs by means of the AT schedule service. This security option only affects the AT schedule facility, it does not affect the Task Scheduler service.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

Enabling this policy setting means that jobs created by server operators via the AT service will be executed in the context of the account that is running that service—by default, that is the local System account. This means that server operators can perform tasks that the System account is able to do but server operators would normally not be able to do, such as add their account to the local Administrators group.

The impact of enabling this policy setting should be small for most organizations. Users, including those in the Server Operators group, will still be able to create jobs by using the Task Scheduler Wizard, but those jobs will run in the context of the account the user authenticated with when they set up the job.

**Domain controller: LDAP server signing requirements**

### Note

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Domain controller: LDAP server signing requirements** policy setting determines whether the LDAP server requires LDAP clients to negotiate data signing.

The possible values for this Group Policy setting are:

- None.

Data signing is not required in order to bind with the server. If the client requests data signing, the server supports it.

- Require signature.

  The LDAP data-signing option must be negotiated unless Transport Layer Security/Secure Sockets Layer (TLS/SSL) is being used.

- Not defined.

**Discussion**
Unsigned network traffic is susceptible to man-in-the-middle attacks, where an intruder captures packets between the server and the client and modifies them before forwarding them to the client. In the case of an LDAP server, this means that a malicious user can cause a client to make decisions based on false records from the LDAP directory. You can lower the risk of a malicious user accomplishing this in a corporate network by implementing strong physical security measures to protect the network infrastructure. Furthermore, implementing Internet Protocol security (IPsec) Authentication Header (AH) mode, which provides mutual authentication and packet integrity for IP traffic, can make all types of man-in-the-middle attacks extremely difficult.

It is advisable to set **Domain controller: LDAP server signing requirements** to **Require signature**. Clients that do not support LDAP signing will be unable to execute LDAP queries against the domain controllers. This means that all computers in your organization that are managed from Windows Server 2003 or Windows XP-based computers using NTLM authentication and the Windows Server 2003 Administration Tools Pack must either have Windows 2000 Service Pack 3 (SP3) or later installed.

| Member Server Effective Default Settings | Not defined |

**Domain member: Digitally encrypt or sign secure channel data (multiple related policy settings)**

**Note**

- Misuse of these policy settings is a common error that can cause data loss or problems with data access or security.

The following policy settings determine whether a secure channel can be established with a domain controller that is not capable of signing or encrypting secure channel traffic:

- Domain member: Digitally encrypt or sign secure channel data (always)
- Domain member: Digitally encrypt secure channel data (when possible)
- Domain member: Digitally sign secure channel data (when possible)

Setting **Domain member: Digitally encrypt or sign secure channel data (always)** to **Enabled** prevents establishing a secure channel with any domain controller that cannot sign or encrypt all secure channel data.

To protect authentication traffic from man-in-the-middle, replay, and other types of network attacks, Windows-based computers create a communication channel through NetLogon called secure channels. These channels authenticate computer accounts. They also authenticate user accounts when a remote user connects to a network resource and the user account exists in a trusted domain. This is called pass-through authentication, and it allows a computer running Windows that has joined a domain to have access to the user account database in its domain and in any trusted domains.

To enable the **Domain member: Digitally encrypt or sign secure channel data (always)** policy setting on a member workstation or server, all domain controllers in the domain that the member belongs to must be capable of signing or encrypting all secure-channel data. This means that all such domain controllers must be running Windows NT 4.0 Service Pack 6a (SP6a) or later.

Enabling the **Domain member: Digitally encrypt or sign secure channel data (always)** policy setting automatically enables the **Domain member: Digitally sign secure channel data (when possible)** policy setting.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

When a Windows Server 2003 system joins a domain, a computer account is created. After joining the domain, the computer uses the password for that account to create a secure channel with the domain controller for its domain every time that it restarts. Requests sent on the secure channel are authenticated—and sensitive information such as passwords are encrypted—but the integrity of the channel is not checked, and not all information is encrypted. If a system is set to always encrypt or sign secure channel data, a secure channel cannot be established with a domain controller that is not capable of signing or encrypting all secure channel traffic. If the computer is configured to encrypt or sign secure channel data when possible, a secure channel can be established, but the level of encryption and signing is negotiated.

The following values are advised:

- Set **Domain member: Digitally encrypt or sign secure channel data (always)** to **Enabled**.

- Set **Domain member: Digitally encrypt secure channel data (when possible)** to **Enabled**.
- Set **Domain member: Digitally sign secure channel data (when possible)** to **Enabled**.

Digital encryption and signing of the secure channel is a good idea where it is supported. The secure channel protects domain credentials as they are sent to the domain controller. However, only Windows NT 4.0 SP6a or later supports digital encryption and signing of the secure channel. Windows 98 Second Edition clients do not support it (unless they have the dsclient installed). Thus, you cannot enable the **Domain member: Digitally encrypt or sign secure channel data (always)** policy setting on domain controllers that support Windows 98 clients as members of the domain. The potential impact of such a setting can include making it impossible to create or delete trust relationships with earlier versions, disabling logons from earlier-version clients, and not being able to authenticate other domains' users from a trusted domain that is running an earlier version of Windows.

You can enable this policy setting after you eliminate all Windows 95, Windows 98, and Windows Millennium Edition clients from the domain and upgrade all Windows NT 4.0 servers and domain controllers from trusted or trusting domains to Windows NT 4.0 SP6a. You can enable the other two policy settings, **Domain member: Digitally encrypt secure channel data (when possible)** and **Domain member: Digitally sign secure channel data (when possible)**, on all computers in the domain that support these policy settings without affecting earlier-version clients and applications.

**Domain member: Digitally encrypt or sign secure channel data (always)**

**Note**

**Domain member: Disable machine account password changes**

The **Domain member: Disable machine account password changes** policy setting determines whether a domain member periodically changes its computer account password. Setting its value to **Enabled** prevents the domain member from changing its computer account password. Setting it to **Disabled** allows the domain member to change its computer account password as specified by the value of the **Domain member: Maximum machine account password age** policy setting, which is every 30 days by default.

Do not enable this policy setting. Computer account passwords are used to establish secure channel communications between members and domain controllers and—within the domain—between the domain controllers themselves. After it is established, the secure channel transmits sensitive information that is necessary for making authentication and authorization decisions.

Do not use this policy setting in an attempt to support dual-boot scenarios that use the same computer account. If you want to dual-boot two installations that are joined to the same domain, give the two installations different computer names. This policy setting was added to Windows to make it easier for organizations that stockpile prebuilt computers that are put into production months later; those computers do not have to be rejoined to the domain.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

The default configuration for computers running Windows Server 2003 that belong to a domain is that they are automatically required to change the passwords for their accounts every 30 days. Disabling this feature causes computers running Windows Server 2003 to retain the same passwords as their computer accounts. Computers that are no longer able to automatically change their account password are at risk of a malicious user determining the password for the system's domain account.

Verify that the **Domain member: Disable machine account password changes** option is set to **Disabled**.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Domain member: Maximum machine account password age**

The **Domain member: Maximum machine account password age** policy setting determines the maximum allowable age for a computer account password. This policy setting also applies to computers running Windows 2000, but it is not available through the Security Configuration Manager tools on those computers.

The possible values for this Group Policy setting are:

- A user-defined number of days from 0 through 999.
- Not defined.

**Discussion**

In Active Directory–based domains, each computer has an account and password just like every user. By default, the domain members automatically change their domain password every 30 days. Increasing this interval significantly, or setting it to **0** so that the computers no longer change their passwords, gives a malicious user more time to undertake a brute-force password-guessing attack against one of the computer accounts.

It is often advisable to set **Domain member: Maximum machine account password age** to about **30** days.

Some organizations prebuild computers and then store them for later use or ship them to remote locations. If the computer's account has expired, it will no longer be able to authenticate with the domain. Computers that cannot authenticate with the domain must be removed from the domain and rejoined to it. For this reason, some organizations might want to create a special OU for computers that are prebuilt and configure the value for this policy setting to a larger number of days.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 30 days |
| DC Effective Default Settings | 30 days |
| Member Server Effective Default Settings | 30 days |

**Domain member: Require strong (Windows 2000 or later) session key**

**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Domain member: Require strong (Windows 2000 or later) session key** policy setting determines whether a secure channel can be established with a domain controller that is not capable of encrypting secure channel traffic with a strong, 128-bit session key. Enabling this policy setting prevents establishing a secure channel with any domain controller that cannot encrypt secure channel data with a strong key. Disabling this policy setting allows 64-bit session keys.

**Note**

- To enable this policy setting on a member workstation or server, all domain controllers in the domain that the member belongs to must be capable of encrypting secure channel data with a strong, 128-bit key. This means that all such domain controllers must be running Windows 2000 or Windows Server 2003.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Session keys used to establish secure channel communications between domain controllers and member computers are much stronger in Windows 2000 and Windows Server 2003 than they were in previous Microsoft operating systems.

Whenever possible, you should take advantage of these stronger session keys to help protect secure channel communications from eavesdropping and session-hijacking network attacks. Eavesdropping is a form of hacking in which network data is read or altered in transit. The data can be modified to hide or change the name of the sender, or it can be redirected.

It is advisable to set **Domain member: Require strong (Windows 2000 or later) session key** to **Enabled**. Enabling this policy setting ensures that all outgoing secure channel traffic will require a strong, Windows 2000 or Windows Server 2003 encryption key. Disabling this policy setting requires that key strength be negotiated. Only enable this option if the domain controllers in all trusted domains support strong keys. By default, this value is disabled.

You will not be able to join computers with this policy setting enabled to Windows NT 4.0 domains, nor will you be able to join computers that do not support this policy setting to domains where the domain controllers have this policy setting enabled.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Interactive logon: Do not display last user name**
The **Interactive logon: Do not display last user name** policy setting determines whether the **Log on to Windows** dialog box displays the name of the last user who logged on to the computer. If the value is **Enabled**, the **Log on to Windows** dialog box does not display the name of the last user who logged on. If it is **Disabled**, the dialog box does display the name of the last user to log on.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
A malicious user with access to the console—for example, someone with physical access or someone who is able to connect to the server via Terminal Services—can view the name of the last user who logged on to the server. The attacker might then

attempt to log on to the server by guessing the password, using a dictionary, or by brute-force attack.

It is advisable to set **Do not display last user name in logon screen** to **Enabled**. Users will always have to type their user names when they log on to the servers.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Interactive logon: Do not require CTRL+ALT+DEL**
The **Interactive logon: Do not require CTRL+ALT+DEL** policy setting determines whether pressing CTRL+ALT+DELETE is required before a user can log on. Enabling this policy setting on a computer allows a user to log on without pressing CTRL+ALT+DELETE. Disabling this policy setting requires users to press CTRL+ALT+DELETE before logging on, unless they are using a smart card for Windows logon. A smart card is a tamper-proof device that stores security information.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Microsoft developed this feature to make it easier for users with certain types of physical impairments to log on to computers running Windows; however, not having to press the CTRL+ALT+DELETE key combination leaves users susceptible to attacks that attempt to intercept their passwords. Requiring CTRL+ALT+DELETE before users log on ensures that users are communicating by means of a trusted path when entering their passwords.

A malicious user might install a Trojan horse program that looks like the standard Windows logon dialog box and capture a user's password. The attacker can then log on to the compromised account with whatever level of user rights that user has.

It is advisable to set **Disable CTRL+ALT+DEL requirement for logon** to **Disabled**. Unless they are using a smart card to log on, users will have to simultaneously press three keys before the logon dialog box appears.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Interactive logon: Message text for users attempting to log on**

The **Interactive logon: Message text for users attempting to log on** and **Interactive logon: Message title for users attempting to log on** policy settings are closely related. **Interactive logon: Message text for users attempting to log on** specifies a text message to be displayed to users when they log on. **Interactive logon: Message title for users attempting to log on** specifies a title to appear in the title bar of the window that contains the text message. This text is often used for legal reasons — for example, to warn users about the ramifications of misusing company information, or to warn them that their actions might be audited.

Windows XP Professional adds support for configuring logon banners that can exceed 512 characters in length and can also contain carriage return/line feed sequences. However, Windows 2000 clients cannot interpret and display message text that is created by Windows XP Professional computers. You must use a Windows 2000 computer to create a logon message that applies to Windows 2000 computers. If you inadvertently create a logon message by using a Windows XP Professional computer, and you discover that it is not displayed properly on Windows 2000 computers, do the following:

- Undefine the setting.
- Redefine the setting by using a Windows 2000 computer.

Simply changing a Windows XP Professional–defined logon message setting by using a Windows 2000 computer does not work. The setting must be undefined first.

The possible values for these Group Policy settings are:

- User-defined text.
- Not defined.

**Discussion**

Not using this warning-message policy setting leaves your organization legally vulnerable to trespassers who unlawfully penetrate your network. Legal precedents have established that organizations that display warnings to users who connect to their servers over a network have a higher rate of successfully prosecuting trespassers.

It is advisable to set **Message text for users attempting to log on** to the following value:

This system is restricted to authorized users. Individuals attempting unauthorized access will be prosecuted. If unauthorized, terminate access now! Clicking OK indicates your acceptance of the information in the background.

It is advisable to set **Message title for users attempting to log on** to a value similar to the following:

IT IS AN OFFENSE TO CONTINUE WITHOUT PROPER AUTHORIZATION.

Any warning that you display should first be approved by representatives from your organization's legal and human resources departments.

When these policy settings are configured, users will see a dialog box before they can log on to the server console.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Interactive logon: Number of previous logons to cache (in case domain controller is not available)**

The **Interactive logon: Number of previous logons to cache (in case domain controller is not available)** policy setting determines whether a user can log on to a Windows domain by using cached account information. Logon information for domain accounts can be cached locally so that, if a domain controller cannot be contacted on subsequent logons, a user can still log on. This policy setting determines the number of unique users whose logon information is cached locally.

If a domain controller is unavailable and a user's logon information is cached, the user is prompted with the following message:

A domain controller for your domain could not be contacted. You have been logged on using cached account information. Changes to your profile since you last logged on might not be available.

If a domain controller is unavailable and a user's logon information is not cached, the user is prompted with this message:

The system cannot log you on now because the domain <DOMAIN_NAME> is not available.

The possible values for this Group Policy setting are:

- A user-defined number from 0 through 50.
- Not defined.

**Discussion**

The value of this policy setting indicates the number of users whose logon information the server caches locally. If the value is **10**, the server caches logon information for 10 users. When an eleventh user logs on to the computer, the server overwrites the oldest cached logon session.

Users who access the server console will have their logon credentials cached on that server. A malicious user who is able to access the file system of the server can locate this cached information and use a brute-force attack to determine user passwords. Windows mitigates this type of attack by encrypting the information and keeping the cached credentials in the system's registries, which are spread across numerous physical locations.

It is advisable to set **Interactive logon: Number of previous logons to cache (in case domain controller is not available)** to **0**. Setting this value to 0 disables the local caching of logon information. Additional countermeasures include enforcing strong password policies and physically securing the computers. If the value is set to **0**, users will be unable to log on to any computers if there is no domain controller available to authenticate them. Organizations might want to set **Interactive logon: Number of previous logons to cache (in case domain controller is not available)** to **2** for end-user systems, especially for mobile users. Setting this value to 2 means that the user's logon information will still be in the cache even if a member of the IT department has recently logged on to their computer to perform system maintenance. This way, those users will be able to log on to their computers when they are not connected to the corporate network.

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 10 logons |
| DC Effective Default Settings | 10 logons |
| Member Server Effective Default Settings | 10 logons |

**Interactive logon: Prompt user to change password before expiration**

The **Interactive logon: Prompt user to change password before expiration** policy setting determines how many days in advance users are warned that their passwords are about to expire. With this advance warning, the user has time to construct a password that is sufficiently strong.

The possible values for this Group Policy setting are:

- A user-defined number of days from 1 through 999.

- Not defined.

**Discussion**
It is recommended that user passwords be configured to expire periodically. Users will need warning their passwords are going to expire, or they might inadvertently get locked out of the system. This could lead to confusion for users who access the network locally, or make it impossible for users who access the network via dial-up or virtual private network (VPN) connections to log on.

It is advisable to set **Prompt user to change password before expiration** to **14** days. When their password expiration date is 14 or fewer days away, users will see a dialog box each time they log on to the domain.

**Location**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 14 days |
| DC Effective Default Settings | 14 days |
| Member Server Effective Default Settings | 14 days |

**Interactive logon: Require Domain Controller authentication to unlock workstation**
Unlocking a locked computer requires logon information. For domain accounts, the **Interactive logon: Require Domain Controller authentication to unlock workstation** policy setting determines whether it is necessary to contact a domain controller to unlock a computer. Enabling this policy setting requires a domain controller to authenticate the domain account that is being used to unlock the computer. Disabling this policy setting allows a user to unlock the computer without the computer verifying the logon information with a domain controller. However, if **Interactive logon: Number of previous logons to cache (in case domain controller is not available)** is set to a value greater than zero, the user's cached credentials will be used to unlock the system.

This policy setting also applies to computers running Windows 2000, but it is not available through the Security Configuration Manager on those computers.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
The computer caches the credentials of any users that have been authenticated locally in memory. The computer uses these cached credentials to authenticate anyone who attempts to unlock the console.

When cached credentials are used, any changes that have recently been made to the account — such as user rights assignments, account lockout, or the account being disabled — are not considered or applied after this authentication process. This means not only that user rights are not updated, but more importantly that disabled accounts are still able to unlock the console of the system.

It is advisable to set **Interactive logon: Require Domain Controller authentication to unlock workstation** to **Enabled** and set **Interactive logon: Number of previous logons to cache (in case domain controller is not available)** to **0**. When the console of a computer is locked, either by a user or automatically by a screen saver time-out, the console can only be unlocked if the user is able to reauthenticate to the domain controller. If no domain controller is available, users cannot unlock their workstations.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Interactive logon: Require smart card**
The **Interactive logon: Require smart card** policy setting requires users to log on to a computer by using a smart card.

This policy setting also applies to Windows 2000 computers, but it is not available through the Security Configuration Manager on those computers.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Requiring users to use long, complex passwords for authentication enhances network security, especially if the users must change their passwords regularly. This reduces the chance that a malicious user will be able to guess a user's password via a brute-force attack. Using smart cards rather than passwords for authentication dramatically increases security because, with today's technology, it is nearly impossible for a malicious user to impersonate another user. Smart cards that require personal identification numbers (PINs) provide two-factor authentication: the user who attempts to log on must possess the smart card and know its PIN. A malicious user who captures the authentication traffic between the user's computer and the domain controller will find it extremely difficult to decrypt the traffic: even if they do, the next time the user logs on to the network, a new session key will be generated for encrypting traffic between the user and the domain controller.

It is advisable to set **Interactive logon: Require smart card** to **Enabled**. All users will have to use smart cards to log on to the network. This means that the organization must have a reliable public key infrastructure (PKI) in place, and provide smart cards and smart card readers for all users. These are significant challenges, because planning for and deploying these technologies requires expertise and resources; however, Windows Server 2003 includes Certificate Services, a highly advanced server for implementing and managing certificates that—when combined with Windows XP—includes features such as automatic user and computer enrollment and renewal.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |

| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Interactive logon: Smart card removal behavior**

The **Interactive logon: Smart card removal behavior** policy setting determines what happens when the smart card for a logged-on user is removed from the smart card reader.

The possible values for this Group Policy setting are:

- No Action.
- Lock Workstation.
- Force Logoff.
- Not defined.

**Discussion**

If smart cards are used for authentication, the computer should automatically lock itself when the card is removed—that way, if users forget to manually lock their workstations when they are away from them, malicious users cannot gain access.

It is advisable to set **Interactive logon: Smart card removal behavior** to **Lock Workstation**. If you select **Lock Workstation** in the property sheet for this policy setting, the workstation is locked when the smart card is removed. This allows users to leave the area, take their smart card with them, and still maintain a protected session.

If you select **Force Logoff** in the property sheet for this policy setting, the user is automatically logged off when the smart card is removed. Users will have to reinsert their smart cards and reenter their PINs when they return to their workstations.

| Member Server Effective Default Settings | No Action |

**Microsoft network client and server: Digitally sign communications (four related policy settings)**

**Note**

- Misuse of these policy settings is a common error that can cause data loss or problems with data access or security.

There are four separate policy settings relating to digitally signing SMB communications: **Microsoft network client: Digitally sign communications (always)**, **Microsoft network server: Digitally sign communications (always)**, **Microsoft network client: Digitally sign communications (if server agrees)**, and **Microsoft network server: Digitally sign communications (if client agrees**).

The possible values for these Group Policy settings are:

- Enabled.
- Disabled.
- Not defined.

Implementing digital signing in high-security networks helps to prevent the impersonation of clients and servers. This type of impersonation is known as "session hijacking," in which a malicious user who has access to the same network as the client or

server interrupts, ends, or steals a session in progress. Attackers can potentially intercept and modify unsigned SMB packets, then modify the traffic and forward it so the server performs undesirable actions. Alternatively, the attacker can pose as the server or client after a legitimate authentication and gain unauthorized access to data.

SMB is the resource-sharing protocol supported by many Microsoft operating systems. It is the basis of NetBIOS and many other protocols. SMB signing authenticates both the user and the server hosting the data. If either side fails the authentication process, data transmission will not take place.

An alternative countermeasure that can protect all network traffic is to implement digital signatures by using IPsec. There are hardware-based accelerators for IPsec encryption and signing that can be used to minimize the performance impact on the servers' CPUs. There are no such accelerators available for SMB signing.

The following values are advisable

- Set **Microsoft network client: Digitally sign communications (always)** to **Disabled**.
- Set **Microsoft network server: Digitally sign communications (always)** to **Disabled**.
- Set **Microsoft network client: Digitally sign communications (if server agrees)** to **Enabled**.
- Set **Microsoft network server: Digitally sign communications (if client agrees)** to **Enabled**.

Some sources recommend setting all of these policy settings to **Enabled**, but enabling them can cause slower performance on client computers and prevent them from communicating with legacy SMB applications and operating systems.

The Windows 2000, Windows Server 2003, and Windows XP Professional file and print sharing protocol SMB supports mutual authentication, which closes session-hijacking attacks and supports message authentication, thus preventing man-in-the-middle attacks. SMB signing provides this authentication by placing a digital signature into each SMB, which is then verified by both the client and the server. Implementing SMB signing can cause a noticeable performance impact as a result of having to sign and verify each packet between the servers. Configuring computers to ignore all unsigned SMB communications prevents legacy applications and operating systems from connecting. Completely disabling all SMB signing leaves the computers vulnerable to session-hijacking attacks.

**Microsoft network client: Send unencrypted password to third-party SMB servers**

Enabling the **Microsoft network client: Send unencrypted password to third-party SMB servers** policy setting allows the

SMB redirector to send plaintext passwords to non-Microsoft SMB servers that do not support password encryption during authentication.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Enabling this policy setting allows the server to transmit passwords in plaintext across the network to other systems that offer SMB services. These others systems might not use any of the SMB security mechanisms included with Windows Server 2003.

It is advisable to set **Microsoft network client: Send unencrypted password to connect to third - party SMB servers** to **Disabled**. Some very old applications and operating systems such as MS-DOS, Windows for Workgroups 3.11, and Windows 95 might not be able to communicate with the servers in your organization via the SMB protocol.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Microsoft network server: Amount of idle time required before suspending session**
The **Microsoft network server: Amount of idle time required before suspending session** policy setting determines the amount of continuous idle time that must pass in an SMB session before the session is suspended due to inactivity. Administrators can use this policy setting to control when a computer suspends an inactive SMB session. The session is automatically reestablished when client activity resumes.

For this policy setting, a value of **0** means to disconnect an idle session as quickly as is reasonably possible. The maximum value is 99,999, which is 208 days—in effect, this disables the policy setting.

The possible values for this Group Policy setting are:

- A user-defined number of minutes from 0 through 99,999.
- Not defined.

**Discussion**
Each SMB session consumes server resources. Establishing numerous null sessions will slow or possibly crash the server. A malicious user might repeatedly establish SMB sessions until the server stops responding; at this point, SMB services will become slow or unresponsive.

It is advisable to set **Microsoft network server: Amount of idle time required before disconnecting session** to **15** minutes. There will be little impact because SMB sessions will be reestablished automatically if the client resumes activity.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | 15 minutes |
| DC Effective Default Settings | 15 minutes |
| Member Server Effective Default Settings | 15 minutes |

**Microsoft network server: Disconnect clients when logon hours expire**

The **Microsoft network server: Disconnect clients when logon hours expire** policy setting determines whether to disconnect users who are connected to the local computer outside their user account's valid logon hours. This policy setting affects the SMB component. Enabling this policy setting causes client sessions with the SMB service to be forcibly disconnected when the client's logon hours expire. Disabling this policy setting maintains an established client session after the client's logon hours have expired. When you enable this policy setting, you should also enable **Network security: Force logoff when logon hours expire**.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

If your organization has configured logon hours for users, it makes sense to enable this policy setting; if it is disabled, users who are assumed to be unable to access network resources outside their logon hours might actually be able to continue to use those resources with sessions that were established during allowed hours.

Enable the **Microsoft network server: Disconnect clients when logon hours expire** policy setting. If logon hours are not used in your organization, enabling this policy setting will have no impact. If logon hours are used, existing user sessions will be forcibly terminated when their logon hours expire.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Enabled |
| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Enabled |

**Network access: Allow anonymous SID/Name translation**

**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Network access: Allow anonymous SID/Name translation** policy setting determines whether an anonymous user can request SID attributes for another user.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
If this policy setting is enabled, a user might use the well-known Administrators SID to get the real name of the built-in Administrator account, even if the account has been renamed. That person might then use the account name to initiate a brute-force password-guessing attack.

It is advisable to set **Network access: Allow anonymous SID/Name translation** to **Disabled**. This is the default value on member computers; therefore, it will have no impact on them. The default value for domain controllers is **Enabled**. Disabling this policy setting on domain controllers means that legacy systems might be unable to communicate with Windows Server 2003-based domains. For example, the following systems might not work:

- Windows NT 4.0–based Remote Access Service servers.
- Microsoft SQL Server running on Windows NT 3.51–based or Windows NT 4.0–based computers.
- Remote Access Service or Microsoft SQL Server running on Windows 2000–based computers that are located in Windows NT 3.51 domains or Windows NT 4.0 domains.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |

| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Disabled |

**Network access: Do not allow anonymous enumeration of SAM accounts**
### Note

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Network access: Do not allow anonymous enumeration of SAM accounts** policy setting determines which additional permissions will be assigned for anonymous connections to the computer. Windows allows anonymous users to perform certain activities, such as enumerating the names of domain accounts and network shares. This is convenient, for example, when an administrator wants to give access to users in a trusted domain that does not maintain a reciprocal trust. However, even with this policy setting enabled, anonymous users will still have access to any resources that have permissions that explicitly include the special built-in group ANONYMOUS LOGON.

This policy setting has no impact on domain controllers.

In Windows 2000, a similar policy setting named **Additional Restrictions for Anonymous Connections** managed a registry entry **RestrictAnonymous**, located in the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\LSA key. In Windows Server 2003, the policy settings **Network access: Do not allow anonymous enumeration of SAM accounts** and **Network access: Do not allow anonymous enumeration of SAM accounts and shares** replace the Windows 2000 policy setting. They manage the registry entries **RestrictAnonymousSAM** and **RestrictAnonymous**, respectively, both located in the HKLM\System\CurrentControlSet\Control\Lsa\ key.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

A malicious user can anonymously list account names and use the information to attempt to guess passwords or perform social-engineering attacks. "Social engineering" is a term for tricking people into revealing their password or some other form of security information.

If you set **Network access: Do not allow anonymous enumeration of SAM accounts** to **Enabled**, it will be impossible to establish trusts with Windows NT 4.0–based domains. This value will also cause problems with earlier-version clients such as Windows NT 3.51 and Windows 95 that are trying to use resources on the server.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |

| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Enabled |
| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Enabled |

**Network access: Do not allow anonymous enumeration of SAM accounts and shares**

### Note

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Network access: Do not allow anonymous enumeration of SAM accounts and shares** policy setting determines which additional permissions will be assigned for anonymous connections to the computer. Windows allows anonymous users to perform certain activities, such as enumerating the names of domain accounts and network shares. This is convenient, for example, when an administrator wants to give access to users in a trusted domain that does not maintain a reciprocal trust. However, even with this policy setting enabled, anonymous users will still have access to any resources that have permissions that explicitly include the special built-in group ANONYMOUS LOGON.

This policy setting has no impact on domain controllers.

In Windows 2000, a similar policy setting named **Additional Restrictions for Anonymous Connections** managed a registry value **RestrictAnonymous**, located in the HKLM\SYSTEM\CurrentControlSet\Control\LSA key. In Windows Server 2003, the policy settings **Network access: Do not allow anonymous enumeration of SAM accounts** and **Network access: Do not allow anonymous enumeration of SAM accounts and shares** replace the Windows 2000 policy setting. They manage the registry entries **RestrictAnonymousSAM** and **RestrictAnonymous**, respectively, both located in the HKLM\System\CurrentControlSet\Control\Lsa\ key.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
If this policy setting is disabled, an unauthorized user could anonymously list account names and use the information to attempt to guess passwords or perform social-engineering attacks.

It is advisable to set **Network access: Do not allow anonymous enumeration of SAM accounts and shares** to **Enabled**. Note that when this is enabled, it will be impossible to establish trusts with Windows NT 4.0–based domains. This policy setting will also cause problems with earlier-version clients such as Windows NT 3.51 and Windows 95 that are trying to use resources on the server.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Network access: Do not allow storage of credentials or .NET Passports for network authentication**
The **Network access: Do not allow storage of credentials or .NET Passports for network authentication** policy setting determines whether Stored User Names and Passwords saves passwords or credentials for later use when it gains domain authentication. Enabling this policy setting prevents Stored User Names and Passwords from storing passwords and credentials.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Passwords cached by Stored User Names and Passwords can be accessed by a user when logged on to the computer. A problem can arise if the user unknowingly executes hostile code that reads the passwords and forwards them to another, malicious user.

It is advisable to set **Network access: Do not allow storage of credentials or .NET Passports for network authentication** to **Enabled**. Users will be forced to enter passwords whenever they log on to their Passport account or other network resources that are not accessible to their domain account. This will not have an impact when the user visits Web sites that require him to log on, because enabling this policy setting does not prevent passwords from being saved when the user requests that they be. Enabling this policy setting should have no impact on users when they access network resources that have been configured to allow access with their Active Directory–based domain account.

**Location**

| Stand-Alone Server Default Settings | Disabled |

| | |
|---|---|
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Network access: Let Everyone permissions apply to anonymous users**

The **Network access: Let Everyone permissions apply to anonymous users** policy setting determines which additional permissions are assigned for anonymous connections to the computer. Enabling this policy setting allows anonymous users to perform certain activities, such as enumerating the names of domain accounts and network shares. This is convenient, for example, when an administrator wants to give access to users in a trusted domain that does not maintain a reciprocal trust. By default, the token created for anonymous connections does not include the Everyone SID; therefore, permissions assigned to the Everyone group do not apply to anonymous users. Enabling this policy setting adds the Everyone SID to the token created for anonymous connections, which allows anonymous users to access any resource for which the Everyone group has been given permissions.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

A malicious user might anonymously list account names and shared resources and use the information to attempt to guess passwords or perform social-engineering attacks. It is advisable to set **Network access: Let Everyone permissions apply to anonymous users** to **Disabled**.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Network access: Named Pipes that can be accessed anonymously**

The **Network access: Named Pipes that can be accessed anonymously** policy setting determines which communication sessions, or pipes, will have attributes and permissions that allow anonymous access.

The possible values for this Group Policy setting are:

- A user-defined list of shares.
- Not defined.

**Discussion**

Restricting access over named pipes such as COMNAP and LOCATOR helps prevent unauthorized access to the network. The following table lists default named pipes and their purpose.

### Default Named Pipes That Are Accessible Anonymously

| Named Pipe | Purpose |
|---|---|

| | |
|---|---|
| COMNAP | SnaBase named pipe. Systems Network Architecture (SNA) is a collection of networking protocols originally developed for IBM mainframe computers. |
| COMNODE | SNA Server named pipe. |
| SQL\QUERY | Default named pipe for SQL Server. |
| SPOOLSS | Named pipe for the Print Spooler service. |
| EPMAPPER | End Point Mapper named pipe. |
| LOCATOR | RPC Locator service named pipe. |
| TrkWks | Distributed Link Tracking Client named pipe. |
| TrkSvr | Distributed Link Tracking Server named pipe. |

It is advisable to set **Network access: Named Pipes that can be accessed anonymously** to a null value; that is, enable the policy setting, but do not enter named pipes in the text box. This will disable null session access over named pipes, and applications that rely on this feature or on unauthenticated access to named pipes will no longer function. For example, with Microsoft Commercial Internet System 1.0, the Internet Mail Service runs under Inetinfo.exe. Inetinfo.exe starts in the context of the System account. When Internet Mail Service needs to query the Microsoft SQL Server database, it uses the System account, which uses null credentials to access a SQL pipe on the computer running SQL Server.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | COMNAP,COMNODE, SQL\QUERY, SPOOLSS, EPMAPPER, LOCATOR,TrkWks,TrkSvr |
| DC Effective Default Settings | COMNAP,COMNODE, SQL\QUERY, SPOOLSS, EPMAPPER, LOCATOR,TrkWks,TrkSvr |
| Member Server Effective Default Settings | COMNAP,COMNODE, SQL\QUERY, SPOOLSS, EPMAPPER, LOCATOR,TrkWks,TrkSvr |

**Network access: Remotely accessible registry paths**
The **Network access: Remotely accessible registry paths** policy setting determines which registry paths will be accessible after referencing the WinReg key to determine access permissions to those paths.

The possible values for this Group Policy setting are:

- A user-defined list of paths.
- Not defined.

**Discussion**
The registry is a database for computer configuration information, much of which is sensitive. A malicious user can use the registry to facilitate unauthorized activities. To reduce the risk of this happening, suitable access control lists (ACLs) are assigned throughout the registry to help protect it from access by unauthorized users.

It is advisable to set **Network access: Remotely accessible registry paths** to a null value; that is, enable the policy setting but do not enter any paths in the text box. Remote management tools, such as the Microsoft Baseline Security Analyzer and Microsoft Systems Management Server (SMS), require remote access to the registry. Removing the default registry paths from the list of accessible paths might cause these and other management tools to fail.

If you do want to allow remote access, you must also enable the Remote Registry service.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | A (see below) |
| DC Effective Default Settings | A (see below) |
| Member Server Effective Default Settings | A (see below) |

A = System\CurrentControlSet\Control\ProductOptions, System\CurrentControlSet\Control\Server Applications, Software\Microsoft\Windows NT\CurrentVersion

**Network access: Remotely accessible registry paths and sub-paths**

The **Network access: Remotely accessible registry paths and sub-paths** policy setting determines which registry paths and subpaths will be accessible after referencing the WinReg key to determine access permissions to those paths.

The possible values for this Group Policy setting are:

- A user-defined list of paths.
- Not defined.

**Discussion**

The registry is a database for computer configuration information, much of which is sensitive. A malicious user can use it to facilitate unauthorized activities. The chance of this happening is reduced by the fact that the default ACLs assigned throughout the registry are fairly restrictive, and they help protect it from access by unauthorized users.

It is advisable to set **Networkaccess: Remotely accessible registry paths and sub-paths** to a null value; that is, enable the policy setting but do not enter any paths in the text box. Remote management tools such as the Microsoft Baseline Security Analyzer and SMS require remote access to the registry. Removing the default registry paths from the list of accessible paths might cause these and other management tools to fail.

If you do want to allow remote access, you must also enable the Remote Registry service.

| Member Server Effective Default Settings | A (see below) |

A = System\CurrentControlSet\Control\Print\Printers, System\CurrentControlSet\Services\Eventlog, Software\Microsoft\OLAP Server, Software\Microsoft\Windows NT\CurrentVersion\Print, Software\Microsoft\Windows NT\CurrentVersion\Windows, System\CurrentControlSet\Control\ContentIndex, System\CurrentControlSet\Control\Terminal Server, System\CurrentControlSet\Control\Terminal Server\UserConfig, System\CurrentControlSet\Control\Terminal Server\DefaultUserConfiguration, Software\Microsoft\Windows NT\CurrentVersion\Perflib, System\CurrentControlSet\Services\SysmonLog

**Network access: Restrict anonymous access to Named Pipes and Shares**

When enabled, the **Network access: Restrict anonymous access to Named Pipes and Shares** policy setting restricts

anonymous access to shares and pipes to the settings for **Network access: Named pipes that can be accessed anonymously** and **Network access: Shares that can be accessed anonymously**. This setting controls null session access to shares on your computers by adding the registry entry **RestrictNullSessAccess** with the value **1** to the registry key HKLM\System\CurrentControlSet\Services\LanManServer\Parameters. This registry entry toggles null session shares on or off to determine whether the Server service restricts access to clients that have logged on to the System account without user name and password authentication.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Null sessions are a weakness that can be exploited through the various shares on the computers in your environment.

It is advisable to set **Network access: Restrict anonymous access to Named Pipes and Shares** to **Enabled**. Enabling this policy setting restricts null session access to unauthenticated users to all server pipes and shares except those listed in the **NullSessionPipes** and **NullSessionShares** registry entries.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |

| Member Server Effective Default Settings | Enabled |

**Network access: Shares that can be accessed anonymously**
The **Network access: Shares that can be accessed anonymously** policy setting determines which network shares anonymous users can access.

The possible values for this Group Policy setting are:

- A user-defined list of shares.
- Not defined.

**Discussion**
Enabling this policy setting is very dangerous. Any shares listed can be accessed by any network user. This might lead to the exposure or corruption of sensitive corporate data.

It is advisable to set **Network access: Shares that can be accessed anonymously** to a null value. There should be little impact because this is the default value. All users will have to be authenticated before they can access shared resources on the server.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|

| | |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | COMCFG,DFS$ |
| DC Effective Default Settings | COMCFG,DFS$ |
| Member Server Effective Default Settings | COMCFG,DFS$ |

**Network access: Sharing and security model for local accounts**

The **Network access: Sharing and security model for local accounts** policy setting determines how network logons that use local accounts are authenticated. If it is set to **Classic - local users authenticate as themselves**, network logons that use local account credentials authenticate by using those credentials. If it is set to **Guest only - local users authenticate as Guest**, network logons that use local accounts are automatically mapped to the Guest account. The Classic model allows fine control over access to resources. By using the Classic model, you can assign different types of access to different users for the same resource. Using the Guest-only model treats all users equally. All users authenticate as Guest, and they all receive the same level of access to a given resource, which can be either Read Only or Modify.

The default value for this policy setting on stand-alone Windows XP Professional is **Guest only**. The default for Windows XP systems joined to a domain and Windows Server 2003 systems is **Classic**. This policy setting does not affect network logons that use domain accounts, nor does it affect interactive logons that are performed remotely by using services such as Telnet or Terminal Services.

When the computer is not joined to a domain, this policy setting also tailors the **Sharing** and **Security** tabs in Windows Explorer to correspond to the sharing and security model that is being used. This policy setting has no effect on Windows 2000 computers.

The possible values for this Group Policy setting are:

- Classic - local users authenticate as themselves.
- Guest only - local users authenticate as Guest.
- Not defined.

**Discussion**

When the value of this policy setting is **Guest only - local users authenticate as Guest**, any user who can access your computer over the network does so with Guest user rights. This means that they will probably be unable to write to those shares. Although this does increase security, it makes it impossible for authorized users to access shared resources on those systems. When the value is **Classic - local users authenticate as themselves**, local accounts must be password-protected; otherwise, anyone can use those user accounts to access shared system resources.

For network servers, set **Network access: Sharing and security model for local accounts** to **Classic - local users authenticate as themselves**. On end-user systems, set it to **Guest only - local users authenticate as Guest**.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Classic (local users authenticate as themselves) |
| DC Effective Default Settings | Classic (local users authenticate as themselves) |
| Member Server Effective Default Settings | Classic (local users authenticate as themselves) |

**Network security: Do not store LAN Manager hash value on next password change**

The **Network security: Do not store LAN Manager hash value on next password change** policy setting determines whether, at the next password change, LAN Manager will be prevented from storing hash values for the new password.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
By attacking the Security Accounts Manager file, attackers can potentially gain access to user names and password hashes. Attackers can use a password-cracking tool to determine what the password is. After they have access to this information, they can use it to gain access to resources on your network by impersonating users. Enabling this policy setting will not prevent these types of attacks, but it will make them much more difficult.

It is advisable to set **Network security: Do not store LAN Manager hash value on next password change** to **Enabled**. Require all users to set new passwords the next time they log on to the domain so that LAN Manager hashes are removed. Legacy operating systems—such as Windows 95, Windows 98, and Windows Millennium Edition—will fail, as will some non-Microsoft applications.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |

| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Network security: Force logoff when logon hours expire**
The **Force logoff when logon hours expire** policy setting determines whether to disconnect users who are connected to the local computer outside their user account's valid logon hours. This policy setting affects the SMB component. Enabling this policy setting forcibly disconnects client sessions with the SMB Service when the client's logon hours expire. Disabling this policy setting maintains an established client session after the client's logon hours have expired.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
If this policy setting is disabled, a user can remain connected to the system outside of their allotted logon hours. It is advisable to set **Network security: Force logoff when logon hours expire** to **Enabled**. SMB sessions will be terminated on member servers when a user's logon time expires, and the user will be unable to log on to the system until their next scheduled access time begins.

This policy setting does not apply to Administrator accounts.

**Location**

**Network security: LAN Manager authentication level**

**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

LAN Manager (LM) is a family of early Microsoft client/server software that allows users to link personal computer systems together on a single network. Networking capabilities include transparent file and print sharing, user security features, and network administration tools. In Active Directory domains, Kerberos is the default for authentication, but if Kerberos is not negotiated for some reason, Active Directory will use LM, NTLM, or NTLM version 2 (NTLMv2).

LM authentication—including the LM, NTLM, and NTLMv2 variants—is the protocol used to authenticate all Windows clients for such operations as:

- Joining a domain.
- Authenticating between Active Directory forests.
- Authenticating to earlier-version domains.
- Authenticating to systems that are not based on Windows 2000, Windows Server 2003, or Windows XP.
- Authenticating to systems that are not in the domain.

The **Network security: LAN Manager authentication level** policy setting determines which challenge/response authentication protocol is used for network logons. This choice affects the authentication protocol level clients use, the session security level the systems negotiate, and the authentication level servers accept, as follows:

- **Send LM & NTLM responses.** Clients use LM and NTLM authentication and never use NTLMv2 session security; domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Send LM & NTLM - use NTLMv2 session security if negotiated.** Clients use LM and NTLM authentication and use NTLMv2 session security if the server supports it. Domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Send NTLM response only.** Clients use NTLM authentication only and use NTLMv2 session security if the server supports it. Domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Send NTLMv2 response only.** Clients use NTLMv2 authentication only and use NTLMv2 session security if the server supports it. Domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Send NTLMv2 response only\refuse LM.** Clients use NTLMv2 authentication only and use NTLMv2 session security if the server supports it. Domain controllers refuse LM (accept only NTLM and NTLMv2 authentication).
- **Send NTLMv2 response only\refuse LM & NTLM.** Clients use NTLMv2 authentication only and use NTLMv2 session security if the server supports it. Domain controllers refuse LM and NTLM (accept only NTLMv2 authentication).

The possible values for this Group Policy setting are:

- Send LM & NTLM responses.
- Send LM & NTLM - use NTLMv2 session security if negotiated.
- Send NTLM responses only.
- Send NTLMv2 responses only.
- Send NTLMv2 responses only\refuse LM.
- Send NTLMv2 responses only\refuse LM & NTLM.
- Not defined.

These settings correspond to the levels discussed in other Microsoft documents, as follows:

- **Level 0–Send LM and NTLM response; never use NTLMv2 session security.** Clients use LM and NTLM authentication, and never use NTLMv2 session security. Domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Level 1–Use NTLMv2 session security if negotiated.** Clients use LM and NTLM authentication, and use NTLMv2 session security if the server supports it. Domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Level 2–Send NTLM response only.** Clients use only NTLM authentication, and use NTLMv2 session security if the server supports it. Domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Level 3–Send NTLMv2 response only.** Clients use NTLMv2 authentication, and use NTLMv2 session security if the server supports it. Domain controllers accept LM, NTLM, and NTLMv2 authentication.
- **Level 4–Domain controllers refuse LM responses**. Clients use NTLM authentication, and use NTLMv2 session security if the server supports it. Domain controllers refuse LM authentication, that is, they accept NTLM and NTLMv2.
- **Level 5–Domain controllers refuse LM and NTLM responses (accept only NTLMv2).** Clients use NTLMv2 authentication, use and NTLMv2 session security if the server supports it. Domain controllers refuse NTLM and LM authentication (they accept only NTLMv2).

**Discussion**

Windows 2000, Windows Server 2003, and Windows XP are configured by default to send LM and NTLM authentication responses. Windows 95, Windows 98, and Windows Millennium Edition clients only send LM. The default server setting allows all clients to authenticate with servers and use their resources; however, this means that LM responses—the weakest form of authentication response—are sent over the network, and it is potentially possible for attackers to sniff that traffic to more easily reproduce a user's password.

The Windows 95, Windows 98, Windows Me, and Windows NT operating systems cannot use the Kerberos version 5 protocol for authentication. For this reason, in a Windows Server 2003 domain, these systems authenticate by default with both the LM and NTLM protocols for network authentication. You can enforce a more secure authentication protocol for Windows 95, Windows 98, Windows Me, and Windows NT by using NTLMv2. For the logon process, NTLMv2 uses a secure channel to protect the authentication process. Even if you do use NTLMv2 for legacy clients and servers, Windows-based clients and servers that are members of the domain will authenticate with Windows Server 2003 domain controllers by using the Kerberos protocol.

Windows NT 4.0 requires Service Pack 4 (SP4) to support NTLMv2, and Windows 95, Windows 98, and Windows Me need the directory service client installed in order to support NTLMv2.

It is advisable to set **LAN Manager Authentication Level** to **Send NTLMv2 responsesonly**. When all clients support NTLMv2, this level of authentication is strongly recommended by Microsoft and a number of independent organizations. Clients that do not support NTLMv2 authentication will not be able to authenticate in the domain or access domain resources

by using LM and NTLM.

| Stand-Alone Server Default Settings | Send NTLM response only |
| DC Effective Default Settings | Send NTLM response only |
| Member Server Effective Default Settings | Send NTLM response only |

**Network security: LDAP client signing requirements**

**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

The **Network security: LDAP client signing requirements** policy setting determines the level of data signing that is requested on behalf of clients that issue LDAP BIND requests, as follows:

- **None.** The LDAP BIND request is issued with the caller-specified options.
- **Negotiate signing.** If TLS/SSL has not been started, the LDAP BIND request is initiated with the LDAP data signing option set in addition to the caller-specified options. If TLS/SSL has been started, the LDAP BIND request is initiated with the caller-specified options.
- **Require signature.** This is the same as **Negotiate signing**. However, if the LDAP server's intermediate saslBindInProgress response does not indicate that LDAP traffic signing is required, the caller is told that the LDAP BIND command request failed.

This policy setting does not have any impact on ldap_simple_bind or ldap_simple_bind_s. No Microsoft LDAP clients that are included with Windows XP Professional use ldap_simple_bind or ldap_simple_bind_s to communicate with a domain controller.

The possible values for this Group Policy setting are:

- None.
- Negotiate signing.
- Require signature.
- Not defined.

**Discussion**
Unsigned network traffic is susceptible to man-in-the-middle attacks, where an intruder captures the packets between the client and server and modifies them before forwarding them to the server. In the case of an LDAP server, this means that a malicious user might cause a server to make decisions based on false queries from the LDAP client. You can lower this risk in a corporate network by implementing strong physical security measures to protect the network infrastructure. Furthermore, all types of man-in-the-middle attacks can be made extremely difficult by requiring digital signatures on all network packets via IPsec Authentication Headers.

It is advisable to set **Domain controller: LDAP server signing requirements** to **Require signature**. If you set the server to require LDAP signatures, you must also set the client to do so. Not setting the client will prevent the client from communicating

with the server—this can cause many features to fail, including user authentication, Group Policy, and logon scripts.

**Network security: Minimum session security for NTLM SSP based (including secure RPC) clients**
The **Network security: LDAP client signing requirements** security policy setting determines the level of data signing that is requested on behalf of clients issuing LDAP BIND requests, as follows:

- **None:** The LDAP BIND request is issued with the caller-specified options.
- **Negotiate signing:** If TLS/SSL has not been started, the LDAP BIND request is initiated with the LDAP data-signing option set in addition to the caller-specified options. If TLS/SSL has been started, the LDAP BIND request is initiated with the caller-specified options.
- **Require signature:** This is the same as **Negotiate signing**. However, if the LDAP server's intermediate saslBindInProgress response does not indicate that LDAP traffic signing is required, the caller is told that the LDAP BIND command request failed.

This policy setting does not have any impact on ldap_simple_bind or ldap_simple_bind_s. No Microsoft LDAP clients that are included with Windows XP Professional use ldap_simple_bind or ldap_simple_bind_s to communicate with a domain controller.

The possible values for this Group Policy setting are:

- None.
- Negotiate signing.
- Require signature.
- Not defined.

**Discussion**
Unsigned network traffic is susceptible to man-in-the-middle attacks, where an intruder captures the packets between the client and server and modifies them before forwarding them to the server. In the case of an LDAP server, this means that a malicious user could cause a server to make decisions based on false queries from the LDAP client. You can lower this risk in a corporate network by implementing strong physical security measures to protect the network infrastructure. Furthermore, all types of man-in-the-middle attacks can be made extremely difficult by requiring digital signatures on all network packets by way of IPsec Authentication Headers.

It is advisable to set **Domain controller: LDAP server signing requirements** to **Require signature**. If you set the server to require LDAP signatures, you must also set the client. Not setting the client will prevent the client from communicating with the server — this can cause many features to fail, including user authentication, Group Policy, and logon scripts.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | No minimum |
| DC Effective Default Settings | No minimum |
| Member Server Effective Default Settings | No minimum |

**Network security: Minimum session security for NTLM SSP based (including secure RPC) servers**

The **Network security: Minimum session security for NTLM SSP based (including secure RPC) servers** policy setting allows a server to require the negotiation of message confidentiality (encryption), message integrity, 128-bit encryption, or NTLMv2 session security. These values are dependent on the value of the **Network security: LAN Manager authentication level** policy setting.

The possible values for this Group Policy setting are:

- Require message confidentiality.

  The connection will fail if encryption is not negotiated. Encryption converts data into a form that is not readable by anyone until it is decrypted.

- Require message integrity.

  The connection will fail if message integrity is not negotiated. The integrity of a message can be assessed through message signing. Message signing proves that the message has not been tampered with by attaching a cryptographic signature, which identifies the sender and contains a numeric representation of the contents of the message.

- Require 128-bit encryption.

  The connection will fail if strong encryption (128-bit) is not negotiated.

- Require NTLMv2 session security.

  The connection will fail if the NTLMv2 protocol is not negotiated.

- Not defined.

**Discussion**

Setting all of these values for this policy setting will help protect network traffic that uses the NTLM Security Support Provider (NTLM SSP) from being exposed or tampered with by a malicious user who has gained access to the same network. That is, these settings help protect against man-in-the-middle attacks.

Enable all four values that are available for the **Network security: Minimum session security for NTLM SSP based (including secure RPC) servers** object. Legacy clients that do not support these policy settings will be unable to communicate with the computer.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |

| | |
|---|---|
| Stand-Alone Server Default Settings | No minimum |
| DC Effective Default Settings | No minimum |
| Member Server Effective Default Settings | No minimum |

**Recovery console: Allow automatic administrative logon**

The **Recovery console: Allow automatic administrative logon** policy setting determines whether a user must give the Administrator account password before getting access to the system. Enabling this policy setting allows any user to automatically log on to the system without giving a password at the Recovery Console.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

The Recovery Console can be very useful when troubleshooting and repairing systems that cannot be restarted; however, enabling this policy setting so a user can automatically log on to the console is dangerous. Anyone can walk up to the server, shut it down by disconnecting the power, reboot it, select **Recovery Console** from the **Restart** menu, and then assume full control of the server.

It is advisable to set **Recovery Console: Allow automatic administrative logon** to **Disabled**. This requires a user to enter a user name and password to access the Recovery Console account.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Recovery console: Allow floppy copy and access to all drives and all folders**

Enabling the **Recovery console: Allow floppy copy and access to all drives and all folders** policy setting makes the Recovery Console SET command available, which allows you to set the following Recovery Console environment variables.

- **AllowWildCards.** Enables wildcard support for some commands (such as the DEL command).
- **AllowAllPaths.** Allows access to all files and folders on the computer.
- **AllowRemovableMedia.** Allows files to be copied to removable media, such as a floppy disk.
- **NoCopyPrompt.** Do not prompt when overwriting an existing file.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.

- Not defined.

**Discussion**
An authorized administrator might forget to remove a CD or floppy disk with sensitive data or applications that a malicious user could then steal. An authorized administrator could accidentally leave a startup disk in the computer after using the Recovery Console. If the computer is restarted for any reason and the BIOS has been configured to boot from the CD-ROM or floppy disk drive before the hard disk, the server will start from the removable disk. This causes the server's network services to be unavailable.

It is advisable to set **Recovery Console: Allow floppy copy and access to drives and folders** to **Disabled**. Users who have started a server by using the Recovery Console and logged in with the built-in Administrator account will not be able to copy files and folders to a floppy disk.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Shutdown: Allow system to be shut down without having to log on**
The **Shutdown: Allow system to be shut down without having to log on** policy setting determines whether a computer can be shut down by a user who has not logged on to Windows. Enabling this policy setting makes the **Shut Down** command available on the Windows logon screen. Disabling this policy setting removes the **Shut Down** command from the Windows logon screen. When the setting is disabled, users must be able to log on to the computer successfully and have the **Shut down the system** user right before they can perform a system shutdown.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
Users who can access the console locally can shut the system down. Attackers or misguided users can connect to the server using Terminal Services and shut it down or restart it without having to identify themselves. A malicious user might also cause a temporary denial-of-service condition by walking up to the local console and restarting the server, or shutting down the server and thus rendering unavailable all its applications and services.

It is advisable to set the **Allow system to be shut down without having to log on** user right to **Disabled**. Administrators must log on to servers to shut them down or restart them.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |

| | |
|---|---|
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**Shutdown: Clear virtual memory page file**

The **Shutdown: Clear virtual memory page file** policy setting determines whether the virtual memory paging file is cleared when the system is shut down. Virtual memory support uses a system paging file to swap pages of memory to disk when they are not used. On a running system, this paging file is opened exclusively by the operating system, and it is well-protected. However, systems that have been configured to allow starting other operating systems might have to make sure that the system paging file is wiped clean when the running system shuts down. This will ensure that sensitive information from process memory that might have been written to the paging file is not available to an unauthorized user who might manage to access the paging file directly.

When this policy setting is enabled, it clears the system paging file when the system shuts down properly. On a portable computer system on which hibernation has been disabled, the system will also clear the hibernation file, Hiberfil.sys.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

Important information kept in real memory might be written periodically to the paging file. This helps Windows Server 2003 handle multitasking functions. A malicious user who has physical access to a server that has been shut down can view the contents of the paging file. The attacker can move the system volume into a different computer and then analyze the contents of the paging file. This is a time-consuming process, but it can expose data cached from RAM to the paging file. A malicious user who has physical access to the server can bypass this countermeasure by simply unplugging the server from its power source.

It is advisable to set **Shutdown: Clear virtual memory page file** to **Enabled**. This causes Windows Server 2003 to clear the paging file when the system is shut down. Depending on the size of the paging file, this process might take several minutes before the system completely shuts down. This delay in shutting down the server is especially noticeable on servers with large paging files. For a server with 2 gigabytes (GB) of RAM and a 2-GB paging file, this setting can add 20 to 30 minutes, or more, to the shutdown process. For some organizations, this downtime violates their internal service level agreements. Use caution when implementing this countermeasure in your environment.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**System cryptography: Force strong key protection for user keys stored on the computer**

The **System cryptography: Force strong key protection for user keys stored on the computer** policy setting determines

whether users can use private keys, such as their Secure/Multipurpose Internet Mail Extensions (S/MIME) key, without a password.

The possible values for this Group Policy setting are:

- User input is not required when new keys are stored and used.
- User is prompted when the key is first used.
- User must enter a password each time they use a key.
- Not defined.

**Discussion**
Configuring this policy setting so that users must provide a password every time they use a key — in addition to their domain password — makes it more difficult for a malicious user to access locally-stored user keys, even if the attacker takes control of the user's computer and determines their logon password.

It is advisable to set **System cryptography: Force strong key protection for user keys stored on the computer** to **User must enter a password each time they use a key**. Users must enter their password every time they access a key that is stored on their computer. For example, if users use an S/MIME certificate to digitally sign their e-mail, they will be forced to enter the password for that certificate every time they send a signed e-mail message. For some organizations, the overhead caused by using this value might be too high, but even they should set the value at a minimum to **User is prompted when the key is first used**.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**System cryptography: Use FIPS compliant algorithms for encryption, hashing, and signing**
The **System cryptography: Use FIPS compliant algorithms for encryption, hashing, and signing** policy setting determines whether the TLS/SSL security provider will only support the strong cipher suite known as TLS_RSA_WITH_3DES_EDE_CBC_SHA. In effect, this means that the provider only supports the TLS protocol as a client and as a server, if applicable. It uses only the Triple Data Encryption Standard (3DES) encryption algorithm for the TLS traffic encryption, only the Rivest - Shamir-Adleman (RSA) public key algorithm for the TLS key exchange and authentication, and only the Secure Hash Algorithm version 1 (SHA-1) hashing algorithm for the TLS hashing requirements.

For Encrypting File System (EFS), it supports only the 3DES encryption algorithm for encrypting file data supported by NTFS. By default, EFS uses the DESX algorithm (a variation of the DES algorithm) for encrypting file data.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

Enabling this policy setting ensures that the computer will use the most powerful algorithms available for digital encryption, hashing, and signing. This minimizes the risk of a malicious user compromising digitally encrypted or signed data.

It is advisable to set **System cryptography: Use FIPS compliant algorithms for encryption, hashing, and signing** to **Enabled**. Clients with this policy setting enabled will be unable to communicate via digitally encrypted or signed protocols with servers that do not support these algorithms. Network clients that do not support these algorithms will not be able to use servers that require them for network communications. If you enable this policy setting, you must also configure Internet Explorer to use TLS.

**To enable Internet Explorer to use TLS**

1. In Internet Explorer, on the **Tools** menu, click **Internet Options**.
2. Click the **Advanced** tab.
3. Select the **Use TLS 1.0** check box.

It is also possible to configure this setting by using Group Policy or the Internet Explorer Administrators Kit.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Disabled |
| DC Effective Default Settings | Disabled |
| Member Server Effective Default Settings | Disabled |

**System objects: Default owner for objects created by members of the Administrators group**
The **System objects: Default owner for objects created by members of the Administrators group** policy setting determines whether the Administrators group or the object creator is the default owner of any system objects that are created.

The possible values for this Group Policy setting are:

- Administrators group.
- Object creator.
- Not defined.

**Discussion**
Setting the value to **Administrators group** makes it impossible to hold individuals accountable for creating new system objects.

It is advisable to set **System objects: Default owner for objects created by members of the Administrators group** to **Object creator**. When a system object is created, its ownership reflects which specific account created the object, rather than the more generic Administrators group.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|

| | |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |

| DC Effective Default Settings | Administrators group |
| Member Server Effective Default Settings | Administrators group |

**System objects: Require case insensitivity for non-Windows subsystems**

The **System objects: Require case insensitivity for non-Windows subsystems** policy setting determines whether case-insensitivity is enforced for all subsystems. The Microsoft Win32 subsystem is not case-sensitive; however, the kernel supports case-sensitivity for other subsystems, such as Portable Operating System Interface for UNIX (POSIX). Enabling this policy setting enforces case-insensitivity for all directory objects, symbolic links, and input/output (I/O) objects, including file objects. Disabling this policy setting does not allow the Win32 subsystem to become case-sensitive.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

Because Windows is case-insensitive but the POSIX subsystem will support case-sensitivity, if this policy setting is not enforced it will be possible for a user of that subsystem to create a file with the same name as another file but with a different mix of capital letters. That might confuse users when they try to access these files by using normal Win32 tools, because only one of the files will be available.

It is advisable to set **System objects: Require case insensitivity for non-Windows subsystems** to **Enabled**. All subsystems will be forced to observe case-insensitivity. This might confuse users who are familiar with one of the UNIX-based operating systems and are used to a case-sensitive operating system.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Enabled |
| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Enabled |

**System objects: Strengthen default permissions of internal system objects (e.g. Symbolic Links)**

The **System objects: Strengthen default permissions of internal system objects (e.g. Symbolic Links)** policy setting determines the strength of the default discretionary access control list (DACL) for objects. Windows maintains a global list of shared system resources, such as MS-DOS device names, mutexes, and semaphores. By using this list, processes can locate and share objects.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.

- Not defined.

**Discussion**
This policy setting determines the strength of the default DACL for objects. Windows Server 2003 maintains a global list of shared system resources such as MS-DOS device names, mutexes, and semaphores. By using this list, processes can locate and share objects. Each type of object is created with a default DACL that specifies who can access the objects with what permissions. Enabling this policy setting strengthens the default DACL and allows users who are not administrators to read, but not to modify, shared objects that they did not create.

It is advisable to set **Strengthen default permissions of global system objects (for example, Symbolic Links)** to **Enabled**.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Enabled |
| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Enabled |

**System settings: Optional subsystems**
The **System settings: Optional subsystems** policy setting determines which subsystems support your applications. With this policy setting, you can specify as many support subsystems as your environment demands.

The possible values for this Group Policy setting are:

- A user-defined list of subsystems.

- Not defined.

**Discussion**
The POSIX subsystem is an Institute of Electrical and Electronic Engineers (IEEE) standard that defines a set of operating system services. The POSIX subsystem is required if the server supports applications that use that subsystem.

The subsystem introduces a security risk relating to processes that can potentially persist across logons. If a user starts a process and then logs out, the next user who logs on to the system might access the process the previous user started. This is dangerous, because the process started by the first user can retain that user's system user rights; therefore, anything the second user does using that process is performed with the user rights of the first user. This makes it difficult to trace who creates processes and objects, which is essential for post-security incident forensics.

It is advisable to set the **System settings: Optional subsystems** policy setting to a null value. The default value is **POSIX**, so applications that rely on the POSIX subsystem will no longer run. For example, Microsoft Services for UNIX 3.0 installs an updated version of the POSIX subsystem. Reset this policy setting in Group Policy for any servers that use Services for UNIX 3.0.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |

| | |

| Stand-Alone Server Default Settings | Posix |
| DC Effective Default Settings | Posix |
| Member Server Effective Default Settings | Posix |

**System settings: Use Certificate Rules on Windows Executables for Software Restriction Policies**

The **System settings: Use Certificate Rules on Windows Executables for Software Restriction Policies** policy setting determines whether digital certificates are processed when a user or process attempts to run software with an .exe file name extension. This policy setting enables or disables certificate rules (a type of Software Restriction Policies rule). By using policy settings under Software Restriction Policies, you can create a certificate rule that allows or disallows the running of Authenticode-signed software, based on the digital certificate that is associated with the software. In order for certificate rules to take effect, you must enable this policy setting.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**

Software restriction policies help to prevent users and computers from executing unauthorized code, such as viruses or Trojan horses.

It is advisable to set **System settings: Use Certificate Rules on Windows Executables for Software Restriction Policies** to **Enabled**. Enabling certificate rules results in software restriction policies checking a certificate revocation list (CRL) to make sure the software's certificate and signature are valid. When you start signed programs, this setting can decrease system performance. You can disable CRLs by editing Software Restriction Policies in the desired GPO. In the **Trusted Publishers Properties** dialog box, clear the **Publisher** and **Timestamp** check boxes.

# Event Log Policy Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Event Log**

The Event Log service records events on the system by writing to one of three default logs that you can read in Event Viewer: the security, application, and system logs. The security log records audit events. You use the settings under Event Log to specify attributes of the security, application, and system logs, such as maximum log size, access rights for each log, and retention settings and methods.

Event Log policy settings can be configured in the following location in Group Policy Object Editor:

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Event Log\

**Maximum event log size (settings for application, security and system logs)**

**Note**

- Misuse of these policy settings is a common error that can cause data loss or problems with data access or security.

These policy settings specify the maximum size of the application, security, and system logs. Although you can specify values as large as 4 GB in Group Policy Object Editor and Event Viewer, there are factors that make the effective maximum size for these logs much smaller.

The Event Log service uses memory-mapped files, and it runs as Eventlog.dll, one of the services under the Services.exe process. When files are loaded in this way, the entire file is loaded into system memory. All of the current versions of Windows have an architectural limitation regarding memory-mapped files: no process can have more than 1 GB of memory-mapped files in total. This means that all of the services running under the Services.exe process must share the 1-GB pool. The memory is assigned as contiguous 64-KB chunks of memory. If the system is unable to assign additional memory needed to expand memory-mapped files, problems will arise.

For the Event Log service, this means that regardless of how large the log has been configured to be, events might no longer be written to the log. Error messages will not be displayed. The events will simply not appear in the event log, or they might overwrite other events that have been recorded previously. Fragmentation of the log files in memory has also been shown to lead to significant performance problems on busy systems.

Due to these limitations — even though the theoretical limit for memory-mapped files suggests that you should be able to configure up to 1 GB for all the event logs, and you can actually specify as much as 4 GB per log — Microsoft has verified that the practical size limit for all event logs combined is around 300 megabytes (MB) on most servers. On Windows XP, member servers, and stand-alone servers, the combined size of the application, security, and system event logs should not exceed 300 MB. On domain controllers, the combined size of these three logs — plus the Directory Service, File Replication Service, and DNS Server logs — should not exceed 300 MB.

These limitations have caused problems for some Microsoft customers, but addressing them will require fundamental changes to the architecture for recording system events. Microsoft plans to resolve these problems in the next version of Windows by rewriting the event logging system from the ground up.

Although you will need to use trial and error to determine the best log size for a particular server, you can use the fact that the average event writes about 500 bytes to each log. Estimate the average number of events generated each day for each type of log in your enterprise. Remember that log file sizes must be a multiple of 64 KB.

For example, if your file server generates 5,000 events per day in its security log and you want to ensure that you have at least four weeks of data available at all times, you want to set the size of that log to about 70 MB (500 bytes 5,000 events/day 28 days = 70,000,000 bytes.) Then, check the servers occasionally over the following four weeks to verify that the logs are retaining enough events. Event log size and log wrapping should be configured to match the business and security requirements you determined when you designed your enterprise security plan.

The possible values for this Group Policy setting are:

- A user-defined number of kilobytes from 64 through 4,194,240; however, it must be a multiple of 64.

If you significantly increase the number of objects to audit in your organization, you run the risk of filling the security log to

capacity and thus forcing the system to shut down. If this occurs, the system will be unusable until an administrator clears the security log. To prevent this, disable the **Audit: Shut down system immediately if unable to log security audits** policy setting and increase the security log size.

All computers in your organization should have sensible log size policy settings enabled so that legitimate users can be held accountable for their actions, unauthorized activity can be detected and tracked, and system problems can be detected and diagnosed.

When event logs fill to capacity, entries can no longer be written to them unless the retention method for each is set so that the system will overwrite the oldest entries with the most recent ones. The risk of the event logs' not containing recent entries can be mitigated by setting the retention method so that older events are overwritten as needed. The consequence of this action is that older events will be removed from the logs. Attackers can use this to their advantage by generating a large number of extraneous events to overwrite any evidence of their attack.

Ideally, all specifically monitored events will be sent to a server by using Microsoft Operations Manager (MOM) or some other automated monitoring tool. This is particularly important because an attacker who successfully compromises a server could clear the security log. If all events are sent to a monitoring server, you will be able to gather post-incident forensic information about the attacker's activities.

**Maximum application log size**

**Note**

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

**Prevent local guests group from accessing application log**
The **Prevent local guests group from accessing application log** policy setting determines whether guests are prevented from accessing the application log.

The possible values for this Group Policy setting are:

- Enabled.
- Disabled.
- Not defined.

**Discussion**
An attacker who has successfully logged on to a computer with guest user rights can learn important information about the system by viewing the application log. The attacker might then use this information to launch additional attacks.

It is advisable to enable this policy setting.

This policy setting does not appear in the Local Computer Policy object. It only affects computers running Windows 2000, Windows XP, and Windows Server 2003.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Event Log\

| DC Effective Default Settings | Enabled |
| Member Server Effective Default Settings | Enabled |

**Retain application log**

The **Retain application log** policy setting determines how many days' worth of events to retain, if the retention method specified for the log is **By Days**.

The possible values for this Group Policy setting are:

- A user-defined number of days from 1 through 365.
- Not defined.

**Discussion**

If you archive the log at scheduled intervals, in the property sheet for this policy setting, specify the appropriate number of days and select **Overwrite events by days** for the event log retention method. Also, ensure that the maximum log size is large enough to accommodate the amount of information you want to gather during the archive interval.

It is advisable to set the value of the **Retain event logs** policy setting for all three event logs to **Not defined**.

This policy setting does not appear in the Local Computer Policy object. A user must have been assigned the **Manage auditing and security log** user right to access the security log.

**Location**

*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Event Log\

### Default Values

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Retention method for event log (separate policy settings for application, security and system logs)**

**Note**

- Misuse of these policy settings is a common error that can cause data loss or problems with data access or security.

The **Retention method for event log** policy settings determine the wrapping method for the application, security, and system logs.

If you do not want to archive the logs, in the property sheet for this policy setting, select the **Define this policy setting** check box, and then click **Overwrite events as needed**.

If you want to archive the log at scheduled intervals, in the property sheet for this policy setting, select the **Define this policy setting** check box, click **Overwrite events by days**, and then specify the appropriate number of days in the **Retain**

**application log** policy setting. Ensure that the maximum log size is large enough to accommodate the amount of information you expect to gather during the archive interval.

If you must retain all the events in the log, in the property sheet for this policy setting, select the **Define this policy setting** check box, and then click **Do not overwrite events (clear log manually)**. This value requires that the log be cleared manually. When the maximum log size is reached, new events are not written to the log, they are discarded.

The possible values for these Group Policy settings are:

- Overwrite events by days.
- Overwrite events as needed.
- Do not overwrite events (clear log manually).
- Not defined.

These policy settings do not appear in the Local Computer Policy object.

If you significantly increase the number of objects you audit in your organization, you run the risk of filling the security log to capacity and thus forcing the system to shut down. If this occurs, the system will be unusable until an administrator clears the security log. To prevent this, disable the **Audit: Shut down system immediately if unable to log security audits** policy setting and then increase the security log size.

If you set the value of **Event log retention method** to **Do not overwrite events (clear log manually)** or **Overwrite events by days**, important recent events might not be recorded, or you might suffer a denial-of-service attack.

It is advisable to set **Event log retention method** for all three event logs to the value **Overwrite events as needed**. Some resources recommend configuring this policy setting to **Do not overwrite events (clear log manually)**; however, the administrative burden that this setting imposes is too high for most organizations. Ideally, all significant events will be sent to a monitoring server by using MOM or some other automated monitoring tool.

# Restricted Groups Policy Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Restricted Groups**
This security setting allows an administrator to define two properties for security-sensitive groups (or *restricted* groups). The two properties are **Members** and **Member Of**.

The **Members** list defines exactly who belongs and who does not belong to the restricted group. Both inclusion on the list and exclusion from the list, are enforced.

The **Member Of** list specifies groups in which the restricted group is included. Only inclusion in the **Member Of** list is enforced, not exclusion: If you remove a group from the **Member Of** list, the restricted group is allowed to remain a member of the removed group.

### Note

- Misuse of this policy setting is a common error that can cause data loss or problems with data access or security.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Restricted Groups\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Discussion**
The Restricted Groups folder is available only in Group Policy objects associated with domains, organizational units, and sites. The Restricted Groups folder does not appear in the local Group Policy object.

If a restricted group is defined so that it has no members (that is, the **Members** list is empty), all members of the group are removed when the policy is enforced on the computer. If the **Member Of** list is empty, no changes are made to any groups to which the restricted group belongs.

# System Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**System Services**
This security setting allows you to define the startup mode (manual, automatic, or disabled) and access permissions for all services (**Start**, **Stop**, or **Pause**). You can also edit other security properties of the service, such as which user or group accounts have permission to read, write, delete, or execute inheritance settings or auditing and ownership permission by clicking **Edit Security**.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\System Services\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined for any service |
| Default Domain Controller Policy | Not defined for any service |
| Stand-Alone Server Default Settings | Not defined for any service |
| DC Effective Default Settings | Not defined for any service |
| Member Server Effective Default Settings | Not defined for any service |

**Discussion**
System services are processes that normally run in the background. An administrator uses the Services snap-in to manage system services directly. To manage system services through security policy, administrators can use the System Services security setting.

This security setting does not appear in the local Group Policy object.

If you choose to set system service startup to **Automatic**, perform adequate testing to verify that the services can start without user intervention.

For performance optimization, set unnecessary or unused services to **Manual**.

To find descriptions of each individual service (including what happens when you stop it from running), see the “System Services chapter of Threats and Countermeasures: Security Settings” in Windows Server 2003 and Windows XP, which can be downloaded from the Microsoft Web site.

# Registry

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Registry**
This security setting allows you to define access permissions and audit settings, and to take or assign ownership of individual registry keys.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Registry\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined for any key |
| Default Domain Controller Policy | Not defined for any key |
| Stand-Alone Server Default Settings | Not defined for any key |
| DC Effective Default Settings | Not defined for any key |
| Member Server Effective Default Settings | Not defined for any key |

**Discussion**
The default permissions on registry keys allow full control by administrators and the system. Users have read-only permission, and the creator/owner can take or assign ownership of the key. This security setting can be used to change these default permissions, or to set specific permissions for other users and groups.

This security setting does not appear in the local Group Policy object.

# File System

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**File System**
This security setting allows you to define access permissions and audit settings, and to take or assign ownership of files and folders.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\File System\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Discussion**
The default permissions on files and folders allow full control by administrators and the system. Users have read-only permission, and the creator/owner can take or assign ownership of them. This security setting can be used to change these default permissions, or to set specific permissions for other users and groups.

This security setting does not appear in the local Group Policy object.

# Wireless Network (IEEE 802.11) Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Wireless Network (IEEE 802.11) Policies**
This security setting allows you to create or change a wireless network policy.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Wireless Network (IEEE 802.11) Policies\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Discussion**
When you create a wireless network policy, you can restrict computers from accessing some kinds of wireless networks.

You can choose to permit:

1. **Wireless access to any available network.** With this choice, the policy client computer will preferentially connect to infrastructure in the form of fixed Institute of Electrical and Electronic Engineers (IEEE) 802.11 transmitter/receivers. The policy client will make ad-hoc connections to wireless-enabled computers if there is no access point available.

2. **Access point (infrastructure) networks only.**

3. **Computer-to-computer (ad hoc) networks only.**

A wireless network policy can also designate preferred networks, and key types for encryption and authentication. You can employ Smart Cards or certificates, if you enable access control through IEEE 802.1x.

You can create at most one wireless network policy per Group Policy object (GPO). It is recommended that you use a domain-linked GPO.

This security setting does not appear in the local GPO.

# Public Key Policy Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Public Key Policies**
Use this security setting to specify how to manage certificates and certificate life cycles.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Public Key Policies\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Discussion**
This security setting specifies whether certificates are automatically enrolled, renewed when they are expired, and removed when they are revoked.

You can specify certificates for data recovery, and you can specify Trusted Root Certification Authorities, and Enterprise Trust lists.

This security setting does not appear in the local Group Policy object.

# Software Restriction Policy Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Software Restriction Policies**
This security setting allows you create or change a software restriction policy.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\Software Restriction Policies\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Discussion**
When you create a software restriction policy, you can prohibit users from running administratively specified software on their computers. More restrictively, you can prevent the use of all except administratively specified software on their computers. Optionally, local administrators can be exempted from software restriction policy.

You can exempt software from restriction if the software publisher is trusted by the group that you specify: End users, local computer administrators, or Enterprise administrators.

You can create rules to override the default security level. These rules can be based on certificates, hashes, Internet zones, and paths.

You can create at most one wireless network policy per Group Policy object (GPO).

The wireless network policies security setting does not appear in the local GPO.

# IP Security Policies on Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP Security Policies on Active Directory**
This security setting allows you to permit, block, or negotiate security for TCP/IP traffic.

**Location**
*GPO_name*\Computer Configuration\Windows Settings\Security Settings\IP Security Policies on Active Directory\

**Default Values**

| Server Type or GPO | Default Value |
|---|---|
| Default Domain Policy | Not defined |
| Default Domain Controller Policy | Not defined |
| Stand-Alone Server Default Settings | Not defined |
| DC Effective Default Settings | Not defined |
| Member Server Effective Default Settings | Not defined |

**Discussion**
Use this setting to create filter lists and corresponding actions. Filter lists are based on ports, protocols, and whether the traffic is incoming or outgoing. Actions you specify are carried out when traffic matches a filter in the list. Actions include blocking, permitting, and requiring or requesting that traffic be secured through encryption.

Specify authentication methods. Choices include Kerberos V5, certificates, and (for testing only) preshared keys.

IP Security Policy can also be set in the local Group Policy object. IP Security Policy that is set in Active Directory takes precedence.

# Windows Firewall Settings

Updated: July 10, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Firewall Settings**

**In this topic:**

- Windows Firewall Settings: Optional Components
- Windows Firewall Settings: Remote Administration Tools
- Windows Firewall Settings: Server Roles
- Windows Firewall Settings: Services

This technical reference provides a summary of the Windows Firewall settings you need to configure for each Microsoft® Windows Server™ 2003 optional component, remote administration tool, server role, and service.

Windows Firewall supports configuring its settings in two profiles: domain and standard. Only one profile is active at a time. If all of the network connections on a computer allow the computer to reach a domain controller for the domain to which it is joined, then the domain profile is used. If ANY network connection is to a network through which a domain controller cannot be reached, then the standard profile is used. For more information about profiles, see Help: Understanding Windows Firewall Profiles (http://go.microsoft.com/fwlink/?linkid=157699).

For more information about Windows Firewall, see Windows Firewall Operations Guide (http://go.microsoft.com/fwlink/?LinkId=43262) and Help: Windows Firewall (http://go.microsoft.com/fwlink/?LinkId=43263).

# Windows Firewall Settings: Optional Components

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Firewall is a stateful host firewall that blocks all unsolicited incoming TCP/IP traffic, including Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) traffic. If you enable Windows Firewall on a server and you install and use an optional component that listens for unsolicited incoming traffic, you must usually configure Windows Firewall settings so that the optional component can receive unsolicited traffic. Although you can configure Windows Firewall settings manually, the recommended method is to use the Security Configuration Wizard (SCW).

To use an optional component with Windows Firewall, you usually need to add a program or port to the Windows Firewall exceptions list. When you add a program or port to the exceptions list, you instruct Windows Firewall to allow unsolicited incoming traffic to reach the specified program or pass through the specified port. In some cases, you might need to change a registry setting or enable one of the preconfigured Windows Firewall exceptions, such as the File and Printer Sharing exception or the Remote Administration exception.

| **Caution** |
| --- |
| The Remote Administration exception allows traffic through numerous ports, which can make your computer more accessible to attack. Be sure to read the Windows Firewall documentation so that you understand the risks of using the Remote Administration exception. Incorrectly editing the registry can severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. |

For more information about configuring Windows Firewall exceptions, see Managing Program, Port, and Service Exceptions (http://go.microsoft.com/fwlink/?LinkId=43261) and Help: Understanding Windows Firewall Exceptions (http://go.microsoft.com/fwlink/?LinkId=43260). For more information about SCW, see Security Configuration Wizard Overview on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=43259).

Use the A-Z list to find out how to configure Windows Firewall for use with the following optional components.

A | B | C | D | E | F | G | H | I | J | K | L | M | N | O | P | Q | R | S | T | U | V | W | X | Y | Z

# Windows Firewall Settings: Remote Administration Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Firewall is a stateful host firewall that blocks all unsolicited incoming TCP/IP traffic, including Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) traffic. If you enable Windows Firewall on a server and you want to manage the server with a remote administration tool, usually you must configure Windows Firewall settings on the server so that the server can receive unsolicited traffic from the remote administration tool. You might also have to configure Windows Firewall settings on the computer that is running the remote administration tool if Windows Firewall is enabled on that computer. Although you can configure Windows Firewall settings manually, the recommended method is to use the Security Configuration Wizard (SCW).

To use a remote administration tool with Windows Firewall, you usually need to add a program or port to the Windows Firewall exceptions list. When you add a program or port to the exceptions list, you instruct Windows Firewall to allow unsolicited incoming traffic to reach the specified program or pass through the specified port. In some cases, you might need to configure a registry setting or enable one of the preconfigured Windows Firewall exceptions, such as the File and Printer Sharing exception or the Remote Administration exception.

| **Caution** |
| --- |
| The Remote Administration exception allows traffic through numerous ports, which can make your computer more accessible to attack. Be sure to read the Windows Firewall documentation so that you understand the risks of using the Remote Administration exception. Incorrectly editing the registry can severely damage your system. Before you make changes to the registry, you should back up any valued data on the computer. |

For more information about configuring Windows Firewall exceptions, see Managing Program, Port, and Service Exceptions (http://go.microsoft.com/fwlink/?LinkId=43261) and Help: Understanding Windows Firewall Exceptions (http://go.microsoft.com/fwlink/?LinkId=43260). For more information about SCW, see Security Configuration Wizard Overview on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=43259).

Use the A-Z list to find out how to configure Windows Firewall for use with the following remote administration tools.

A | B | C | D | E | F | G | H | I | J | K | L | M | N | O | P | Q | R | S | T | U | V | W | X | Y | Z

# Windows Firewall Settings: Server Roles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Firewall is a stateful host firewall that blocks all unsolicited incoming TCP/IP traffic, including Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) traffic. If you enable Windows Firewall on a server and you install or configure a server role that listens for unsolicited incoming traffic, you must usually configure Windows Firewall settings so that the server role can receive unsolicited traffic. Although you can configure Windows Firewall settings manually, the recommended method is to use the Security Configuration Wizard (SCW).

To use a server role work with Windows Firewall, you usually need to add one or more programs or ports to the Windows Firewall exceptions list. When you add a program or port to the exceptions list, you instruct Windows Firewall to allow unsolicited incoming traffic to reach the specified program or pass through the specified port. In some cases, you might need to configure a registry setting or enable one of the preconfigured Windows Firewall exceptions, such as the File and Printer Sharing exception or the Remote Administration exception.

| **Caution** |
| --- |
| The Remote Administration exception allows traffic through numerous ports, which can make your computer more accessible to attack. Be sure to read the Windows Firewall documentation so that you understand the risks of using the Remote Administration exception. Incorrectly editing the registry can severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. |

For more information about configuring Windows Firewall exceptions, see Managing Program, Port, and Service Exceptions (http://go.microsoft.com/fwlink/?LinkId=43261) and Help: Understanding Windows Firewall Exceptions (http://go.microsoft.com/fwlink/?LinkId=43260). For more information about SCW, see Security Configuration Wizard Overview on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=43259).

Use the A-Z list to find out how to configure Windows Firewall for use with the following server roles.

# Windows Firewall Settings: Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Firewall is a stateful host firewall that blocks all unsolicited incoming TCP/IP traffic, including Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) traffic. If you enable Windows Firewall on a server and the server uses a service that listens for unsolicited incoming traffic, you must usually configure Windows Firewall settings so that the service can receive unsolicited traffic. Although you can configure Windows Firewall settings manually, the recommended method is to use the Security Configuration Wizard (SCW).

To use a service with Windows Firewall, you usually need to add a program or port to the Windows Firewall exceptions list. When you add a program or port to the exceptions list, you instruct Windows Firewall to allow unsolicited incoming traffic to reach the specified program or pass through the specified port. In some cases, you might need to change a registry setting or enable one of the preconfigured Windows Firewall exceptions, such as the File and Printer Sharing exception or the Remote Administration exception.

| **Caution** |
| --- |
| The Remote Administration exception allows traffic through numerous ports, which can make your computer more accessible to attack. Be sure to read the Windows Firewall documentation so that you understand the risks of using the Remote Administration exception. Incorrectly editing the registry can severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. |

For more information about configuring Windows Firewall exceptions, see Managing Program, Port, and Service Exceptions (http://go.microsoft.com/fwlink/?LinkId=43261) and Help: Understanding Windows Firewall Exceptions (http://go.microsoft.com/fwlink/?LinkId=43260). For more information about SCW, see Security Configuration Wizard Overview on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=43259).

Use the A-Z list to find out how to configure Windows Firewall for use with the following services.

A | B | C | D | E | F | G | H | I | J | K | L | M | N | O | P | Q | R | S | T | U | V | W | X | Y | Z

# IIS 6.0 Technical Reference

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Welcome to Internet Information Services (IIS) 6.0 Technical Reference from Microsoft.

Microsoft® Windows® Server™ 2003 and Internet Information Services (IIS) 6.0 provide the services to support a secure, available, and scalable Web server on which to run your Web sites and applications. Whether you manage a single Web server or many, Internet Information Services (IIS) 6.0 Technical Reference will help you effectively plan, deploy, operate, and troubleshoot your IIS 6.0 solution. This comprehensive technical resource delivers an in-depth description of the new IIS 6.0 architecture, as well as reference information about IIS 6.0 features and services. It also includes practical information and tools to help you accomplish everyday administrative tasks.

This guide contains the following sections:

Introducing IIS 6.0

IIS 6.0 Architecture

Running IIS 6.0 as an Application Server

Working with the Metabase

Managing a Secure IIS 6.0 Solution

Optimizing IIS 6.0 Performance

Web Server Scalability

Configuring Internet Sites and Services

IIS 6.0 Administration Scripts, Tips, and Tricks

Analyzing Log Files

Troubleshooting IIS 6.0

Common IIS 6.0 Administrative Tasks

Using FrontPage 2002 Server Extensions with IIS 6.0

IPv6 and IIS 6.0

Running 32-bit Applications on 64-bit Windows

IIS 6.0 Administration Reference

# Introducing IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Internet Information Services (IIS) 6.0 is a significant new release. Completely redesigned — from its core components and architecture to its default locked-down installation — IIS 6.0 offers organizations significant advantages over previous versions for reliability, manageability, security, scalability, and performance. Whether you manage a single Web server or are a system administrator at a large Internet service provider, *Internet Information Services (IIS) 6.0 Technical Reference* provides the conceptual and practical information you need to work with IIS 6.0. You will find information about how IIS 6.0 is different from previous versions; how IIS 6.0 works and integrates with the Microsoft® Windows® Server 2003 operating system; and how to manage, maintain, and troubleshoot IIS.

In This Section

Internet Information Services 6.0

What's Changed in IIS 6.0

IIS 6.0 Resource Kit Tools

Additional Resources for IIS 6.0

# Internet Information Services 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 is tightly integrated with the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; Windows® Server 2003, Web Edition; and Windows® Server 2003, Datacenter Edition operating systems. Along with Windows Server 2003, IIS 6.0 provides Web server capabilities over an intranet, the Internet, or an extranet. A versatile tool for creating a reliable communications platform of dynamic network applications, IIS 6.0 can be deployed in many different environments. Small businesses and organizations might use one server running IIS 6.0 to host a single Web site and a small intranet. Large organizations, including Internet service providers (ISPs), corporations, and educational institutions, can manage many application servers, each hosting thousands of Web sites and applications.

Organizations also use IIS 6.0 to host File Transfer Protocol (FTP) sites and route news or e-mail by using the Network News Transfer Protocol (NNTP) and the Simple Mail Transfer Protocol (SMTP). Because IIS 6.0 supports the latest Web standards, such as ASP.NET, XML, and Simple Object Access Protocol (SOAP), it is a robust platform for the development, implementation, and management of new Web sites and applications.

Installing IIS as an Application Server

To help protect your systems from attackers who target unused or unmonitored services, IIS 6.0 is not installed on Windows Server 2003 by default. You must install IIS 6.0 manually when you are ready to deploy your Web solutions.

To install IIS 6.0, you can use the Configure Your Server wizard, which is included in Windows Server 2003. The wizard allows you to install or remove Windows Server 2003 services that are grouped into different *server roles*. These server roles include file server, print server, terminal server, DNS server, DHCP server, and application server. The application server role can include the following services:

- Internet Information Services (IIS) 6.0
- COM+ for remote transactions
- Distributed Transaction Coordinator (DTC) for remote access
- ASP.NET
- FrontPage Server Extensions

For more information about the application server role, see Running IIS 6.0 as an Application Server. For information about installing IIS, see Internet Information Services (IIS) 6.0 overview in Help and Support Center for Windows Server 2003.

Enabling Web Service Extensions to Serve Dynamic Content

When you initially install IIS, Web service extensions are locked down, which means that IIS 6.0 only serves static content until you enable specific extensions. To protect your server, select and enable features like ASP, ASP.NET, Server-Side Includes, WebDAV publishing, and FrontPage® 2002 Server Extensions from Microsoft *only if you need them*. If you do not enable these features before you try to serve dynamic content, IIS returns an HTTP 404 level error message (File or directory not found).

For information about enabling Web service extensions, see Enabling Dynamic Content in IIS 6.0 Operations Guide, which is accessible from IIS Manager.

# What's Changed in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 core components and architecture are redesigned, which makes this version of IIS significantly different from previous versions. IIS 6.0 meets organizations demands for the following improvements:

- **Reliability.** Greater reliability by providing a way to isolate one application from another.
- **Manageability.** Better manageability by providing a configurable XML-based metabase.
- **Security.** Tighter security by providing a locked-down security strategy.
- **Performance and scalability.** Improved performance by providing isolation in-process. Built-in scalability by offering an architecture that allows you to consolidate sites and applications on fewer servers.

# Reliability Improvements

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 promotes greater reliability and reduces the chance of defective applications compromising overall server performance and application reliability. Applications that do not function properly can adversely affect any Web server, regardless of the reason for the applications faulty functionality. For example, one application can consume CPU resources, causing other applications to perform slowly. In addition, a Web application that fails can potentially bring down a Web server, including all its sites and applications. Web server administrators must sometimes restart the entire Web server, bringing down all its applications and sites, in an attempt to update or fix one faulty application. IIS 6.0 offers solutions for all these scenarios.

The IIS 6.0 redesigned architecture, which includes two new request processing models, worker process isolation mode and IIS 5.0 isolation mode, helps you avoid the problems caused by faulty applications. Worker process isolation mode, which is the default application isolation mode for IIS 6.0, separates key components of the World Wide Web Publishing Service (WWW service) from the effects of malfunctioning applications by using isolated worker processes. In IIS 5.0 isolation mode, requests are processed similarly to how they were processed in IIS 5.0. This process model is intended for existing applications that do not initially work when you test them during deployment testing in worker process isolation mode. For more information about IIS architecture changes, see IIS 6.0 Architecture.

Worker process isolation mode is the default process model in IIS 6.0 because it enables the greatest number of benefits, many of which are achieved by using application pools. An *application pool* is a grouping of one or more URLs that are served by a worker process or set of worker processes. You can configure specific settings for each application pool and the worker processes that serve it.

If your server is running applications that contain imperfect code, using worker process isolation mode allows you to isolate a defective application in an application pool. You can then use health monitoring (a feature that makes an application pool self-healing), worker process recycling (periodic restarts of unstable applications or ones that leak memory), and rapid-fail protection (auto-restart of failed applications) to specifically address the applications faulty functionality, which results in fewer or no system restarts. For more information about how IIS improves reliability of applications, see Running IIS 6.0 as an Application Server.

# Manageability Improvements

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Whether you are responsible for one Web server or for many clusters of Web servers, you can find new features and improvements in IIS 6.0 that will make your Web server easier to manage than with previous versions of IIS. For example, changes in the IIS metabase, additions to programmatic administration, logging enhancements, and debugging improvements can help you manage your Web servers more efficiently. From propagating configuration changes across multiple servers to pinpointing the problem in a slow-to-respond Web site, you can administer your Web servers more quickly and easily with IIS 6.0.

Metabase Improvements

The metabase configuration and schema for IIS 4.0 and IIS 5.0 were stored in a binary file, which was difficult to read or edit. IIS 6.0 replaces the single binary file (MetaBase.bin), with two XML files, which are named MetaBase.xml and MBSchema.xml. In IIS 6.0, administrators who want to manage IIS by editing the metabase directly can use a simple text editor, such as Microsoft Notepad, to edit MetaBase.xml (the metabase configuration file). Editing the metabase configuration file directly is a good solution for administrators who do not want to use scripts or code to administer IIS, and it is a faster administration solution than using IIS Manager when you are working remotely over a slow network connection. For more information about the IIS metabase, see Working with the Metabase.

Programmatic Administration Additions

Many administrators prefer to manage IIS programmatically by using scripts and batch files, rather than by using IIS Manager, which provides a graphical user interface. Administrators working in an ISP environment with many servers — both local and remote — and thousands of Web sites, can save time by managing IIS programmatically.

IIS 6.0 includes a Windows Management Instrumentation (WMI) provider that allows administrators to control services and applications programmatically. In addition, you can still administer IIS programmatically by using Active Directory Services Interfaces (ADSI) and other custom scripts and batch files. For more information about ADSI and WMI, see IIS 6.0 Administration Scripts, Tips, and Tricks.

| **Note** |
| --- |
| In previous releases of IIS, IIS Manager was called the Internet Service Manager. For information about using IISManager to administer IIS, see Common Administrative Tasks. |

Logging Enhancements

You can manage and troubleshoot your Web server more effectively if you understand how to read and analyze log files. In IIS 6.0, logging differs from previous versions in several ways, so be sure to familiarize yourself with the changes before you configure logging on your server.

In IIS 5.0, Inetinfo.exe (a user-mode process) performed all logging. In the redesigned architecture of IIS 6.0, if a request is cached, the response is served from the HTTP.sys kernel-mode cache without passing through Inetinfo.exe or another user-mode component; therefore, HTTP.sys handles most logging in IIS 6.0 (Open Database Connectivity [ODBC] and custom logging are the exceptions) to ensure that responses are recorded.

IIS 6.0 provides the following additional enhancements to logging:

- Substatus error code logging allows you to record substatus error codes for requests that fail (substatus error codes are not returned to the client).
- Centralized binary logging provides a way to record detailed information about all your Web sites but to use a minimum of system resources. For example, you can use a single log file to record data for all your sites.
- HTTP.sys error logging ensures that all errors generated by HTTP.sys can be recorded, including error reasons.
- Remote logging allows you to write log data to a remote share over a network by using a Universal Naming Convention (UNC) path.

For more information about IIS logging, see Analyzing Log Files.

Troubleshooting

Troubleshooting and debugging can be time-consuming tasks for an administrator. To help you troubleshoot effectively, be sure you are aware of the changes and new features in IIS 6.0 and Windows Server 2003 that can make troubleshooting easier. For example, Windows Server 2003 provides a new framework, Enterprise Tracing for Windows (ETW), which you can use for debugging and capacity planning. IIS 6.0 (through ETW) implements several different tracing providers to trace key transitions for an HTTP request, following its progress through the IIS service framework. These tracing providers include HTTP.sys, IIS Web Server, IIS ISAPI Filter, IIS ISAPI Extension, and IIS ASP traces. The information generated by these providers can help you determine where, in the lifetime of a request, a problem is occurring. For more information about troubleshooting, including how to use new and existing features, tools, and techniques with IIS 6.0, see Troubleshooting IIS 6.0.

# Security Improvements

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Attackers and malicious users can take advantage of a system with services that are running but not being used. Such an attack is possible because if administrators do not use a service, they might forget to maintain it with current hotfixes, service packs, and patches. To reduce this security risk, IIS 6.0 is locked down by default — only request handling for static Web pages is enabled, and only the WWW service is installed. None of the applications that run on IIS — including ASP, ASP.NET, Common Gateway Interface (CGI) scripting, FrontPage 2002 Server Extensions, and WebDAV — are turned on by default.

IIS 6.0 improves security in other ways as well. Many aspects of IIS 6.0, including default functionality and settings, perform different than they did in previous versions. These changes can result in existing applications or sites performing in unexpected ways. To save troubleshooting time, familiarize yourself with the security features in IIS 6.0. For more information about IIS 6.0 security, see Managing a Secure IIS 6.0 Solution.

# Performance and Scalability Improvements

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

If you want to host many applications or Web sites on the same server or if you have applications that consume large amounts of system resources, such as bandwidth or CPU processing, you can host those applications on IIS 6.0 and still obtain good performance. IIS 6.0 architecture provides the foundation for a number of performance enhancements in the Web server. For example, Web gardens, processor affinity, idle timeout, bandwidth throttling, HTTP compression, and CPU monitoring are a few of the features that help you conserve system resources while optimizing performance.

When your Web server is running in worker process isolation mode, you can create *Web gardens*, which enable multiple worker processes to serve one application pool. Web gardens can improve performance because if one worker process in an application pool is busy processing a request, other worker processes can also accept and process requests for that application pool.

IIS 6.0 enables you to configure application pools to establish affinity between worker processes and specific processors in a multiprocessor computer. Processor affinity, when set, enables IIS to efficiently use the caches on multiprocessor servers. Also, you can configure an application pool to have its worker processes request a shutdown if the worker processes are idle for a configurable amount of time. Shutting down idle worker processes frees up unused resources, allowing CPU resources to be used where needed. For more information about idle timeout, see Running IIS 6.0 as an Application Server.

If the network or Internet connection that your Web server uses is also used by other services, such as e-mail or news, you can monitor (and limit) the CPU usage of individual worker processes so that a portion of CPU resources are available for those other services. If your Web server hosts more than one Web site, you can individually throttle the bandwidth used by each site. In turn, you can make best use of available bandwidth by enabling HTTP compression, which allows faster transmission of pages between the Web server and compression-enabled clients. Also, IIS 6.0 supports HTTP Keep-Alives, an HTTP specification that increases server efficiency by reducing server activity and resource consumption.

If your server hosts applications that have workloads requiring large amounts of cached data, you can configure IIS 6.0 to cache up to 64 gigabytes (GB) on an x86-based (or compatible processor) system. For more information about these features and how to improve Web server performance, see Optimizing IIS 6.0 Performance.

IIS supports Windows scalability solutions, such as clustering and network load balancing; however, IIS 6.0 also provides a number of specific changes that can improve Web server scalability. Scalability is particularly important for organizations that want to reduce overhead and maintenance costs by consolidating sites and applications on fewer servers.

Another way to extend a system is to store content in a remote location, such as on a UNC–based drive. IIS 6.0 provides caching, authentication, and administration changes that make it easier for you to create, secure, and manage centralized content storage.

For more information about these and other scalability features in IIS 6.0, see Web Server Scalability.

# IIS 6.0 Resource Kit Tools

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The IIS 6.0 Resource Kit Tools includes 14 tools to help you implement and administer IIS 6.0 more effectively. You can install the IIS 6.0 Resource Kit Tools, which includes Help documentation, by running IIS60rkt.exe from the Microsoft Download Center. When you perform a default installation of the Resource Kit Tools, most of the files are installed in the *LocalDrive*:\Program Files\IIS Resources folder. A few tools are installed in other directories. Read the Help documentation that is included with the tools if you want to know the installation directory for a specific tool.

After installing the tools, you can access the tools and their documentation from the **Start** menu (point to **All Programs** and then **IIS Resources**).

The IIS 6.0 Resource Kit Tools provides the following tools for migrating to IIS 6.0, troubleshooting IIS, testing and improving IIS performance, applying IIS security settings, and administering IIS.

| **Important** |
| --- |
| These tools are provided as-is without a warranty of any kind. Use these tools at your own risk. Microsoft disclaims any implied warranty of merchantability and fitness for a particular purpose. |

Migration Tools

The IIS 6.0 Resource Kit Tools includes two migration tools, the IIS 6.0 Migration Tool and the Apache to IIS 6.0 Migration Tool.

**IIS 6.0 Migration Tool (IISmt.exe)**

Use the IIS 6.0 Migration Tool to migrate Web site content and configuration settings from a server running IIS 4.0, IIS 5.0, or IIS 6.0 to a server running IIS 6.0. The IIS 6.0 Migration tool saves time and reduces the chance of errors by automating many of the repetitive processes involved with moving sites manually. This command-line tool is not documented in Resource Kit Tools Help, but a separate user guide is included in the IIS 6.0 Migration Tool folder and is also available from the Start menu.

**Apache to IIS 6.0 Migration Tool (Wsmk_targ_virdir.exe and Wsmk_windows.exe)**

Use this tool to migrate Web sites — for example, FrontPage Server Extensions, .htaccess files, and home directories — from Linux-based servers that run Apache Web applications to servers running IIS 6.0 on Windows Server 2003. Use this Perl-based command-line tool to migrate both Web content and configuration settings. This migration tool supports a variety of both Linux and Apache versions. The tool is not documented in Resource Kit Tools Help, but a separate user guide is included in the Apache to IIS 6.0 Migration Tool folder and is also available from the Start menu.

Performance and Troubleshooting Tools

The IIS 6.0 Resource Kit Tools provides several tools to help you improve performance and to troubleshoot an application server that is running IIS 6.0. These tools include the Web Capacity Analysis Tool (WCAT), Log Parser, IISState, Wfetch, and TinyGet.

**WCAT (Wcclient.exe and Wcctl.exe)**

Use the two WCAT tools, Wcclient.exe and Wcctl.exe, as a stress client to simulate clients and as a controller to initiate and monitor the testing. WCAT can test how your IIS 6.0-based server and your network configuration respond to a variety of client requests for content, data, or Web pages. Then use the test results to determine the optimal server and network configuration for your environment.

**Log Parser (LogParser.exe or LogParser.dll)**

Use Log Parser to perform many tasks related to log files, such as filtering entries, converting log files to other formats, and performing data mining. Log Parser supports many different input formats, including all the IIS log file formats and multiple output formats, such as text files and database tables. You can use Log Parser to obtain logging information for WCAT and TinyGet. Log Parser is available as a command-line tool (LogParser.exe) and as a set of COM objects that support scripting (LogParser.dll).

**IISState (IISState.exe and IISState.log)**

Use IISState to troubleshoot slow performance and application failures for applications running on IIS 6.0. IISState can also help you identify the causes of ASP0115 error messages and the causes of errors detected by Dr. Watson. For example, IISState can analyze an application like Inetinfo.exe as it executes, record all running threads, and display and log the analysis. IISState

also identifies each thread, and displays the raw thread stack and the time that each thread spent executing in kernel and user modes. IISState is a command-line tool.

**WFetch**

Use WFetch to troubleshoot, test, and log HTTP connections between a server and client. For example, you can use Wfetch to test the performance of new Web sites or Web sites that contain new elements, such as ASP or wireless protocols. Because Wfetch provides only HTTP connection information, it provides a faster way to analyze and troubleshoot HTTP performance than by running a Network Monitor trace. Wfetch provides a graphical user interface (GUI).

**TinyGet (TinyGet.exe)**

Use TinyGet to troubleshoot, test, and log HTTP connections between a server and client. With TinyGet.exe, you can customize each test request by configuring many different factors, including the authentication method, HTTP version, and output format. You can also use scripts that specify looping and multithreading. TinyGet.exe is a command-line tool.

Security Tools

The IIS 6.0 Resource Kit Tools provides several tools to help secure your Web server and troubleshoot security issues, including CustomAuth, Permissions Verifier, SelfSSL, and IISCertDeploy.vbs.

**CustomAuth (CustomAuth.dll and CustomAuth.ini)**

Use CustomAuth as a Web client authentication alternative to Basic, NTLM, and other IIS authentication methods. With CustomAuth, you can create a custom logon form for collecting user credentials, or you can use or modify the logon form that is included with the tool. As an ISAPI filter that must also be installed as a wildcard application map, CustomAuth runs at the beginning of every request, regardless of the extension of the requested file. Because CustomAuth allows users to log off after they complete a session, it is a good solution for a public kiosk.

**Permissions Verifier (Permissions Verifier.js)**

Use Permissions Verifier and its accompanying XML sample to verify that IIS is configured with the minimum permissions required to run. The tool checks the access control lists (ACLs) set for users and groups to help you determine whether permissions issues are causing any Web server problems.

**SelfSSL (SelfSSL.exe)**

Use SelfSSL to generate and install a self-signed Secure Sockets Layer (SSL) certificate. Because SelfSSL.exe generates a self-signed certificate that does not originate from a commonly trusted source, use this tool only when you need to troubleshoot third-party certificate problems or when you need to create a secure private channel between your server and a limited, known group of users, such as exists in a software test environment. SelfSSL.exe is a command-line tool.

**IISCertDeploy.vbs**

Use IISCertDeploy.vbs to deploy and back up SSL certificates on servers running IIS 6.0.

Administration Tools

The IIS 6.0 Resource Kit Tools provides several tools to help you administer your Web server and manage your sites, including IIS Host Helper Service, RemapURL, and Metabase Explorer.

**IIS Host Helper Service (IISHostsvc.exe)**

Use IIS Host Helper Service to register IIS host header strings with name resolution services. You can use IIS Host Helper Service in corporate intranet settings when you want to allow users to access Web sites by using host header names, but you do not want to register each sites name statically with Windows Internet Name Service (WINS) or a DNS server. When you install the IIS 6.0 Resource Kit Tools, IISHostsvc.exe is placed in the *systemroot*\System32\Inetsrv directory, and an IIS Host Helper Service log file directory is created at *systemroot*\System32\LogFiles\Iishostsvc.

**RemapURL (RemapUrl.ini and RemapUrl.dll)**

Use RemapURL to redirect client HTTP requests for URLs. RemapURL is a sample ISAPI filter that redirects HTTP requests by using an ISAPI PREPROC_HEADERS notification. This method enables you to redirect client GET or POST requests in a way that is completely transparent to the user. You can also use RemapURL if you want to display custom error messages.

**Metabase Explorer**

Use Metabase Explorer for viewing and editing the IIS 6.0 metabase. You can also use this tool to edit security settings for keys, export and import keys and subkeys, copy and paste keys and subkeys, and compare records. Metabase Explorer provides a GUI.

# Additional Resources for IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

These resources contain additional information and tools related to this section.

# IIS 6.0 Architecture

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Internet Information Services (IIS) version 6.0, which runs on all editions of the Microsoft® Windows® Server 2003 operating system, provides a new architecture that offers flexibility in the choice of two application isolation modes. The new architecture helps you run a faster Web service that is more reliable and secure. Read this chapter to obtain a detailed review of the new architecture so that you can understand how IIS works and can effectively deploy, manage, and troubleshoot IIS 6.0.

# Overview of IIS 6.0 Architecture

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 provides a redesigned World Wide Web Publishing Service (WWW service) architecture that can help you achieve better performance, reliability, scalability, and security for your Web sites, whether they run on a single server running IIS or on multiple servers.

IIS 6.0 runs a server in one of two distinct request processing models, called application isolation modes. *Application isolation* is the separation of applications by process boundaries that prevents one application or Web site from affecting another and reduces the time that you spend restarting services to correct problems related to applications.

In IIS 6.0, application isolation is configured differently for each of the two IIS application isolation modes. Both modes rely on the *HTTP protocol stack* (also referred to as *HTTP.sys*) to receive Hypertext Transfer Protocol (HTTP) requests from the Internet and return responses. HTTP.sys resides in *kernel mode*, where operating system code, such as device drivers, runs. HTTP.sys listens for, and queues, HTTP requests. For more information about HTTP.sys, see HTTP Protocol Stack.

The new request-processing architecture and application isolation environment enables individual Web applications, which always run in *user mode*, to function within a self-contained worker process. A *worker process* is user-mode code whose role is to process requests, such as returning a static page or invoking an Internet Server API (ISAPI) extension or filter. Worker processes use HTTP.sys to receive requests and send responses over HTTP. For more information about worker processes, see Worker Processes.

**IIS 6.0 Request Processing Models**

*Worker process isolation mode* is the new IIS request processing model. In this application isolation mode, you can group Web applications into *application pools*, through which you can apply configuration settings to the worker processes that service those applications. An application pool corresponds to one request routing queue within HTTP.sys and one or more worker processes.

Worker process isolation mode enables you to completely separate an application in its own process, with no dependence on a central process such as Inetinfo.exe to load and execute the application. All requests are handled by worker processes that are isolated from the Web server itself. Process boundaries separate each application pool so that when an application is routed to one application pool, applications in other application pools do not affect that application. By using application pools, you can run all application code in an isolated environment without incurring a performance penalty. For more information about application pools, see How Application Pools Work.

For a visual representation of worker process isolation mode architecture, see Figure 2.1.

Worker process isolation mode delivers all the benefits of the new IIS 6.0 architecture, including multiple application pools, health monitoring and recycling, increased security and performance, improved scalability, and processor affinity. For example, the new health monitoring features can help you discover and prevent application failures, and can also help protect your Web server from imperfect applications.

*IIS 5.0 isolation mode* provides compatibility for applications that were designed to run in earlier versions of IIS. When IIS 6.0 is running in IIS 5.0 isolation mode, request processing is almost identical to the request processing in IIS 5.0. When a server is working in IIS 5.0 isolation mode, application pools, recycling, and health monitoring features are unavailable.

For a visual representation of IIS 5.0 isolation mode architecture, see Figure 2.2. The dashed line in Figure 2.2 indicates the dependency of the worker process on the WWW service, which manages the worker process. For more information about the role of the WWW service, see WWW Service Administration and Monitoring.

Use IIS 5.0 isolation mode only if components or applications do not function in worker process isolation mode. The latter mode is designed to provide an environment in which most existing applications or sites function correctly.

For more information about IIS 6.0 isolation modes, see Application Isolation Modes.

**IIS 6.0 Services**

IIS 6.0 provides four Internet services: the World Wide Web Publishing Service (WWW service) for hosting Internet and intranet content; the File Transfer Protocol (FTP) service for hosting sites where users can upload and download files; the Network News Transfer Protocol (NNTP) service for hosting discussion groups; and the Simple Mail Transfer Protocol (SMTP) service for sending and receiving e-mail messages.

After installing these services, you can create sites or virtual servers, configure properties and security settings, and set up components to further customize your system. For more information about IIS services, see IIS 6.0 Services later in this section and Configuring Internet Sites and Services.

WWW Service Administration and Monitoring, which is a new set of features that were added to the WWW service in IIS 6.0, manages worker processes, supports the new request processing model, and is responsible for health management and maintenance, including application pool health monitoring, recycling worker processes, and rapid-fail protection.

IIS Admin service is a service of the Microsoft® Windows® Server 2003, Standard Edition; Microsoft® Windows® Server 2003, Enterprise Edition; Microsoft® Windows® Server 2003, Web Edition; and Microsoft® Windows® Server 2003, Datacenter Edition operating systems. The IIS Admin service manages the IIS metabase, which stores IIS configuration data. The IIS Admin service makes metabase data available to applications and the core components of IIS. For more information about the IIS metabase, see The IIS Metabase.

**Comparing Basic Functionality Between IIS 6.0 and Earlier IIS Versions**

For a quick preview of IIS architecture, comparing IIS 6.0 architecture with the architecture for earlier versions of IIS, see Table 2.1, which summarizes the basic functionality for different versions of IIS.

**Table 2.1 Basic Functionality in Different Versions of IIS**

| Functionality | IIS 4.0 | IIS 5.0 | IIS 5.1 | IIS 6.0 |
|---|---|---|---|---|
| Platform | Microsoft® Windows NT® 4.0 operating system | Microsoft® Windows® 2000 Server operating system | Microsoft® Windows® XP Professional operating system | Windows Server 2003 |
| Architecture | 32-bit | 32-bit | 32-bit and 64-bit | 32-bit and 64-bit |
| Network subsystem | TCP/IP kernel | TCP/IP kernel | TCP/IP kernel | HTTP.sys kernel |
| Application request processing model | **MTX.exe:** Multiple DLL hosts in High application isolation.<br>**Inetinfo.exe**: In-process as DLLs with Low isolation. | **DLLHost.exe:** Multiple DLL hosts in Medium or High application isolation.<br>**Inetinfo.exe:** In-process as DLLs with Low isolation. | **DLLHost.exe:** Multiple DLL hosts in Medium or High application isolation.<br>**Inetinfo.exe:** In-process as DLLs with Low isolation. | **W3wp.exe:** In worker process isolation mode (multiple worker processes).<br>**Inetinfo.exe:** Only in IIS 5.0 isolation mode with *in-process* applications.<br>**DLLHost.exe**: Only in IIS 5.0 isolation mode with *out-of-process* applications. |

administrators to manage IIS Web servers by using a standard Web browser, such as Microsoft® Internet Explorer, as the client-side interface.

# IIS 6.0 Services

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 offers four Internet services that you can use to create sites or virtual servers, configure properties and security settings, and set up components to customize your system.

When you install IIS 6.0 on a computer that does not contain an earlier version of IIS, IIS 6.0 automatically installs the following two services:

- The WWW service, which hosts Internet and intranet content.
- The IIS Admin service, which manages the IIS metabase.

You can also choose to install one or more of the following services:

- The FTP service for hosting sites from which users can upload and download files.
- The NNTP service for hosting discussion groups.
- The SMTP service for sending and receiving e-mail messages.

Table 2.2 lists the IIS services, their core components, and their service hosts.

**Table 2.2 Basic Services Provided by IIS 6.0**

| Service Name | Description | Service Short Name | Core Component | Host |
|---|---|---|---|---|
| World Wide Web Publishing Service (WWW service) | Delivers Web publishing services. | W3SVC | Iisw3adm.dll | Svchost.exe |
| File Transfer Protocol (FTP) | Allows file uploads and downloads from remote systems. | MSFTPSVC | Ftpsvc2.dll | Inetinfo.exe |
| Simple Mail Transfer Protocol (SMTP) | Sends and receives electronic messages (e-mail). | SMTPSVC | Smtpsvc.dll | Inetinfo.exe |
| Network News Transfer Protocol (NNTP) | Distributes network news messages. | NNTPSVC | Nntpsvc.dll | Inetinfo.exe |
| IIS Admin Service | Manages the metabase. | IISADMIN | Iisadmin.dll | Inetinfo.exe |

**World Wide Web Publishing Service**

The World Wide Web Publishing Service (WWW service) provides Web publishing for IIS, connecting client HTTP requests to Web sites running on an IIS-based Web server.

The WWW service manages and configures the IIS core components that process HTTP requests. These core components include the HTTP protocol stack (HTTP.sys) and the worker processes.

The WWW service includes these subcomponents: Active Server Pages (ASP), Internet Data Connector, Remote Administration (HTML), Remote Desktop Web Connection, server-side includes (SSI), Web Distributed Authoring and Versioning (WebDAV) publishing, and ASP.NET.

**FTP Service**

IIS provides an FTP service, which you can use to allow users on remote computer systems to copy files to and from your server on a network that uses TCP/IP. The IIS FTP service is an implementation of the File Transfer Protocol, RFC 959, File Transfer Protocol (FTP), and several extensions. The FTP protocol is implemented on top of TCP, which ensures that file transfers are complete and that data transfer is accurate.

You can deploy the FTP service across an arbitrary number of front-end and back-end servers, which increases reliability and availability. By adding virtual directories and servers, you can easily scale FTP without affecting end users.

In IIS 6.0, the FTP service allows you to isolate users at the site level, a feature known as *FTP user isolation*, to help administrators secure and commercialize their Internet sites. Because of the easy availability and wide adoption of FTP, Internet service providers (ISPs) and application service providers (ASPs) traditionally have used FTP to upload their Web content. IIS 6.0 allows the isolation of users into their own directory, thus preventing users from viewing or overwriting other users Web content. The user's top-level directory appears as the root of the FTP site, thus restricting access by not allowing users to navigate farther up the directory tree or across to other users home directories. Within the users own site, the user can create, modify, or delete files and folders.

**SMTP Service**

The SMTP service in IIS processes messages by using the Simple Mail Transfer Protocol (SMTP), which is a TCP/IP protocol that is used to send and receive messages from one computer to another on a network. This protocol is used in intranets and on the Internet to route e-mail.

SMTP is the Internet standard for transporting and delivering electronic messages. Based on specifications in RFCs 2821 and 2822, Microsoft SMTP service is included in the Windows Server 2003 operating system. In Windows Server 2003, the SMTP service is actually a component of IIS and runs as part of Inetinfo.exe. Windows Server 2003 uses SMTP as its native transport protocol to route all messages internally and externally. SMTP is also the default transport for Microsoft® Exchange 2000 Server.

The SMTP component of IIS can send or receive SMTP e-mail messages. You can program the server to automatically send messages in response to events — for example, to confirm a successful form submission by a user. You can also use SMTP to receive messages — for example, to collect feedback from Web site customers.

SMTP does not provide a complete e-mail service. To obtain complete e-mail services for your users, use Microsoft® Exchange Server. For more information about Exchange Server, see the Microsoft Exchange Server TechCenter.

**NNTP Service**

IIS provides a Network News Transfer Protocol (NNTP) service, which you can use to distribute network news messages to NNTP servers and to NNTP clients (news readers) on the Internet. NNTP provides for the distribution, inquiry, retrieval, and posting of news articles by using a reliable stream-based transmission of news on the Internet. With NNTP, news articles are stored on a server in a central database from which users select specific items to read. Indexing, cross-referencing, and expiration of aged messages also are provided.

You can host NNTP local discussion groups on a single computer. Because this feature complies fully with the NNTP protocol, users can use any NNTP client to participate in the newsgroup discussions. The IIS NNTP service does not support news feeds or replication. To use news feeds or to replicate a newsgroup across multiple computers, use Microsoft Exchange Server.

| **Note** |
| --- |
| For more information about these four IIS Internet services, see Configuring Internet Sites and Services. |

**IIS Admin Service**

IIS Admin service is a Windows Server 2003 service that manages the IIS metabase. The metabase stores IIS configuration data in a plaintext XML file that you can read and edit by using common text editors. IIS Admin service makes metabase data available to other applications, including the core components of IIS, applications built on IIS, and applications that are independent of IIS, such as management or monitoring tools. For more information about the IIS metabase, see The IIS Metabase and Working with the Metabase.

# IIS 6.0 Core Components

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 contains several core components that perform important functions in the new IIS architecture. The more that you know about these components, the better you can use IIS 6.0 to your advantage and effectively troubleshoot any issues that might arise.

Most of these core components were briefly described in Overview of IIS 6.0 Architecture. This section provides additional details, including how these core components interact with each other or how they function in each of the two application isolation modes. For example, you can read about the following topics in this section:

- **HTTP Protocol Stack (HTTP.sys).** How the HTTP protocol stack protects the operating system kernel from the effects of imperfect application code, and how it handles kernel-mode queuing.
- **Worker processes.** How the worker process is controlled by the WWW service in both application isolation modes, but in different ways.
- **WWW Service Administration and Monitoring.** How the WWW Service Administration and Monitoring component manages the lifetime of the worker process.
- **Inetinfo.exe.** How the role of Inetinfo.exe has changed since IIS 5.0.
- **IIS Metabase.** Benefits of the new XML metabase, especially in diagnosing possible metabase corruption or in reading and editing the metabase configuration.

# HTTP Protocol Stack

Updated: August 22, 2005

Applies To: Windows Server 2003 with SP1

The HTTP listener is implemented as a kernel-mode device driver called the HTTP protocol stack (HTTP.sys). IIS 6.0 uses HTTP.sys, which is part of the networking subsystem of the Windows operating system, as a core component.

Earlier versions of IIS use Windows Sockets API (Winsock), which is a user-mode component, to receive HTTP requests. By using HTTP.sys to process requests, IIS 6.0 delivers the following performance enhancements:

- Kernel-mode caching. Requests for cached responses are served without switching to user mode.
- Kernel-mode request queuing. Requests cause less overhead in context switching, because the kernel forwards requests directly to the correct worker process. If no worker process is available to accept a request, the kernel-mode request queue holds the request until a worker process picks it up.

Using HTTP.sys and the new WWW service architecture provides the following benefits:

- When a worker process fails, service is not interrupted; the failure is undetectable by the user because the kernel queues the requests while the WWW service starts a new worker process for that application pool.
- Requests are processed faster because they are routed directly from the kernel to the appropriate user-mode worker process instead of being routed between two user-mode processes.

For information about improvements made to HTTP.sys for Windows Server 2003 SP1, see the HTTP API in Windows Server 2003 SP1 white paper.

**How HTTP.sys Works**

When you create a Web site, IIS registers the site with HTTP.sys, which then receives any HTTP requests for the site. HTTP.sys functions like a forwarder, sending the Web requests it receives to the request queue for the user-mode process that runs the Web site or Web application. HTTP.sys also sends responses back to the client.

Other than retrieving a stored response from its internal cache, HTTP.sys does not process the requests that it receives. Therefore, no application-specific code is ever loaded into kernel mode. As a result, bugs in application-specific code cannot affect the kernel or lead to system failures.

HTTP.sys provides the following services in IIS 6.0:

- Routing HTTP requests to the correct request queue.
- Caching of responses in kernel mode.
- Performing all text-based logging for the WWW service.
- Implementing Quality of Service (QoS) functionality, which includes connection limits, connection timeouts, queue-length limits, and bandwidth throttling.

**How HTTP.sys Handles Kernel-Mode Queuing**

When IIS 6.0 runs in worker process isolation mode, HTTP.sys listens for requests and queues those requests in the appropriate queue. Each request queue corresponds to one application pool. An *application pool* corresponds to one request queue within HTTP.sys and one or more worker processes.

When IIS 6.0 runs in IIS 5.0 isolation mode, HTTP.sys runs like it runs in worker process isolation mode, except that it routes requests to a single request queue.

If a defective application causes the user-mode worker process to terminate unexpectedly, HTTP.sys continues to accept and queue requests, provided that the WWW service is still running, queues are still available, and space remains in the queues.

When the WWW service identifies an unhealthy worker process, it starts a new worker process if outstanding requests are waiting to be serviced. Thus, although a temporary disruption occurs in user-mode request processing, an end user does not experience the failure because TCP/IP connections are maintained, and requests continue to be queued and processed.

# Worker Processes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

A *worker process* is user-mode code whose role is to process requests, such as processing requests to return a static page, invoking an ISAPI extension or filter, or running a Common Gateway Interface (CGI) handler.

In both application isolation modes, the worker process is controlled by the WWW service. However, in worker process isolation mode, a worker process runs as an executable file named W3wp.exe, and in IIS 5.0 isolation mode, a worker process is hosted by Inetinfo.exe. Figure 2.2, which depicts the architecture for IIS 5.0 isolation mode, uses a dashed line to suggest the relationship between the worker process and the WWW service.

Worker processes use HTTP.sys to receive requests and to send responses by using HTTP. Worker processes also run application code, such as ASP.NET applications and XML Web services. You can configure IIS to run multiple worker processes that serve different application pools concurrently. This design separates applications by process boundaries and helps achieve maximum Web server reliability.

By default, worker processes in worker process isolation mode run under the Network Service account, which has the strongest security (least access) compatible with the functionality that is required. For more information about Network Service accounts, including Windows Server 2003 built-in security accounts, see Running IIS 6.0 as an Application Server, and IIS and Built-in Accounts.

# WWW Service Administration and Monitoring

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The WWW Service Administration and Monitoring component, which is hosted in Svchost.exe, is a set of new features contained in the WWW service. Like the worker process, this new component runs in user mode, and like HTTP.sys, this component contains critical IIS 6.0 functionality that never loads external code. IIS 6.0 completely isolates external application code from this component by running only the external code in worker processes.

| **Note** |
| --- |
| Because the WWW Service Administration and Monitoring component implements and controls a set of new features contained in the WWW service, to simplify the text, the term *WWW service* is used when discussing these new features instead of the term *WWW Service Administration and Monitoring component*. |

The WWW service is responsible for two roles in IIS: HTTP administration and worker process management.

**HTTP administration**
The WWW service interacts with the metabase to obtain the configuration data that is needed to set up HTTP.sys and that is used to manage the worker process.

When you start a server that is running IIS, and the WWW service is started, this service reads metabase information and initializes the HTTP.sys namespace routing table with one entry for each application. HTTP.sys then uses the routing table data to determine which application pool responds to requests from what parts of the namespace. When HTTP.sys receives a request, it signals the WWW service to start a worker process for the application pool.

When you add or delete an application pool, the WWW service processes the configuration changes, which includes adding or deleting the application pool queue from HTTP.sys. The WWW service also listens for and processes configuration changes that occur as a result of application pool recycling.

**Managing the lifetime of the worker process**
The WWW service is responsible for managing the worker processes, which includes starting the worker processes and maintaining information about the running worker processes. This service also determines when to start a worker process, when to recycle a worker process, and when to restart a worker process if it becomes blocked and is unable to process any more requests.

In worker process isolation mode, the WWW service is responsible for health management and maintenance, including application pool health monitoring, recycling worker processes, and rapid-fail protection. For more information about these new features, see Features of Worker Process Isolation Mode, and Running IIS 6.0 as an Application Server.

The WWW service runs under the Local System account. For more information about Local System accounts, including Windows Server 2003 built-in security accounts, see Running IIS 6.0 as an Application Server and Managing a Secure IIS 6.0 Solution.

# Inetinfo.exe

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When IIS 6.0 runs in worker process isolation mode, Inetinfo.exe is a user-mode component that hosts the IIS metabase and that also hosts the non-Web services of IIS 6.0, including the FTP service, the SMTP service, and the NNTP service. Inetinfo.exe depends on IIS Admin service to host the metabase.

When IIS 6.0 runs in IIS 5.0 isolation mode, Inetinfo.exe functions much as it did in IIS 5.0. In IIS 5.0 isolation mode, however, Inetinfo.exe hosts the worker process, which runs ISAPI filters, Low-isolation ISAPI extensions, and other Web applications.

**Important**

In IIS6.0, regardless of the application isolation mode used, the services that run in Inetinfo.exe run as dynamic-link libraries (DLLs) under the Local System account. Because a Local System account allows users access to every resource on the local computer, use caution when you run services in Inetinfo.exe, especially on computers that provide services on the Internet.

**Note**

When you run services in Inetinfo.exe that can be accessed from the Internet, be sure to protect your system by using a firewall, such as Microsoft® Internet Security and Acceleration (ISA) Server, or by disabling services that you do not use.

# The IIS Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The IIS *metabase* is a plaintext, XML data store that contains most IIS configuration information. Although most of the IIS configuration settings are stored in the IIS metabase, a few settings are maintained in the Windows registry. If a configuration setting is one that you might need to configure or change, or if you can access the setting in the IIS 6.0 user interface, then the setting is typically stored in the IIS metabase.

The new XML metabase allows administrators to directly read and edit the configuration file without using scripts or code, by using a common text editor such as Notepad. The XML metabase makes it easier to diagnose potential metabase corruption, and to back up and restore your metabase files.

If you upgrade to IIS 6.0, the existing binary metabase is automatically converted to the new XML metabase. The metabase is 100 percent compatible with IIS 5.*x* metabase application programming interfaces (APIs) and Active Directory® directory service Service Interfaces (ADSI), ensuring that existing scripts and code continue to work.

For more information about the metabase, see Working with the Metabase.

**Metabase Elements**

IIS 6.0 replaces the single binary file (MetaBase.bin) of earlier IIS versions with two XML files: MetaBase.xml and MBSchema.xml. IIS stores these files in the *systemroot*\System32\Inetsrv folder of your computer. To view and modify these files, you must be a member of the Administrators group.

The metabase consists of the following elements:

- **MetaBase.xml file.** This file stores IIS configuration information that is specific to an installation of IIS.
- **MBSchema.xml file.** This file contains the metabase schema. The MBSchema.xmlfileis a master configuration file that defines default attributes for all metabase properties and enforces rules for constructing and placing metabase entries within the metabase.
- **In-memory metabase.** The in-memory metabase contains the most current metabase and metabase schema configuration. The in-memory metabase accepts changes to the metabase configuration and schema, storing them in RAM, and periodically writing changes to the on-disk metabase and metabase schema files.

When IIS starts, the MetaBase.xml and MBSchema.xml files are read by the IIS storage layer and copied to the in-memory metabase. While IIS is running, any changes that you make to the in-memory metabase are periodically written to disk. IIS also saves the in-memory metabase to disk when you stop IIS.

The IIS Admin service makes the metabase available (by means of the Admin Base Object) to other applications, including the core components of IIS, applications built on IIS, and applications that are independent of IIS, such as management or monitoring tools.

**Automatic Versioning and History**

IIS 6.0 also provides automatic versioning and history. This metabase history feature automatically tracks any changes to the metabase that are written to disk. When the metabase is written to disk, IIS marks the new MetaBase.xml file with a version number and saves a copy of the file in the history folder. Each history file is marked with a unique version number, which is then available, if needed, for metabase rollback or restore. The metabase history feature is enabled by default.

For more information about the metabase, see Working with the Metabase.

# Application Isolation Modes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 runs a server in one of two distinct request processing models, called *application isolation modes*. In each isolation mode, IIS functions differently, although both application isolation modes rely on HTTP.sys as the HTTP listener.

**Worker process isolation mode**
Worker process isolation mode takes advantage of the redesigned architecture for IIS 6.0. In this application isolation mode, you can group Web applications into application pools, through which you can apply specific configuration settings to groups of applications and to the worker processes servicing those applications. By using application pools, you can run all application code in an isolated environment; however, unlike earlier versions of IIS, IIS 6.0 provides isolation without a performance penalty, because there are no added process hops.

Worker process isolation mode provides application (or site) compatibility for most existing applications. This application isolation mode is specified by a **false** value for the metabase property **IIs5IsolationModeEnabled**.

**IIS 5.0 isolation mode**
IIS 5.0 isolation mode is provided for applications that depend upon specific features and behaviors of IIS 5.0. Use this mode only if an application has a compatibility issue when it runs in worker process isolation mode and you cannot resolve the problem.

In this application isolation mode, you can isolate applications as you did in IIS 5.0: in Low isolation (in-process), Medium isolation (pooled out-of-process), or High isolation (out-of-process). This application isolation mode is specified by a **true** value for the **IIs5IsolationModeEnabled** metabase property.

Whenever possible, run your server in worker process isolation mode, which is more secure and reliable than IIS 5.0 isolation mode and is also the default application isolation mode for a clean installation of IIS 6.0. For more information about IIS 6.0 application isolation mode defaults, see Application Isolation Mode Defaults.

# Evaluating Application Isolation Modes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The IIS application isolation mode that you choose affects performance, reliability, security, and feature availability. Worker process isolation mode is the recommended mode of operation for IIS 6.0 because it provides a more robust platform for applications and the ability to isolate applications in separate application pools without incurring a performance penalty. Also, in the default configuration, worker process isolation mode provides a higher level of security than does IIS 5.0 isolation mode because its default host process identity is Network Service.

Some applications might have compatibility problems when they run in worker process isolation mode. If compatibility problems occur, you might need to use IIS 5.0 isolation mode. For applications that run in IIS 5.0 isolation mode, Local System is the only available process identity when you run an application in-process in Inetinfo.exe. For more information about IIS security, see Managing a Secure IIS 6.0 Solution. Also see Configuring Worker Process Identities and IIS and Built-in Accounts.

**Important**

IIS6.0 cannot run both application isolation modes simultaneously on the same computer. Therefore, on a single computer running IIS6.0, you cannot run some Web applications in worker process isolation mode and others in IIS5.0 isolation mode. If your applications require different modes, you must run them on separate computers.

When you are deciding which application isolation mode to use, follow these guidelines:

- Use worker process isolation mode unless you need to use IIS 5.0 isolation mode because of a specific compatibility problem. For example, an application that checks to see if an application is running in a process named Inetinfo.exe is incompatible with worker process isolation mode.
- For Web sites that contain static content and simple ASP applications, run the applications in worker process isolation mode because these Web sites usually require little or no modification.
- For applications that run correctly on IIS 5.0, try running them first in worker process isolation mode. If they do not work correctly, change them back to IIS 5.0 isolation mode until you can diagnose and fix the incompatibility.

**Applications that cannot run in worker process isolation mode**

Applications that run in worker process isolation mode can take advantage of all the worker process behaviors, which include multi-instancing, recycling, and configurable process identity. Certain application characteristics conflict with the architecture of worker process isolation mode and must be run in IIS 5.0 isolation mode until you can modify them.

The following applications or application characteristics conflict with worker process isolation mode:

- **Read raw data filters.** This type of filter can be loaded only in IIS 5.0 isolation mode.
- **Dependency on Inetinfo.exe.** Applications that must run in an Inetinfo.exe worker process can run only in IIS 5.0 isolation mode because applications cannot run in Inetinfo.exe in worker process isolation mode.
- **Requires Dllhost.exe.** Web applications that must run in a Dllhost.exe environment can run only in IIS 5.0 isolation mode because running Web applications in Dllhost.exe is not an option in worker process isolation mode.

**Applications that use SF_NOTIFY_READ_RAW_DATA filters**

ISAPI filters that use SF_NOTIFY_READ_RAW_DATA notifications work differently depending on the isolation mode in which IIS 6.0 is running. To understand the differences, remember that a global filter is installed for the entire IIS service and sees requests for all Web sites, whereas a site filter is installed at the site level and sees requests only for the site where it is installed.

**Note**

The only raw data filter that works differently in IIS 6.0 is SF_NOTIFY_READ_RAW_DATA. SF_NOTIFY_SEND_RAW_DATA works as expected and is supported in both application isolation modes.

For IIS 6.0 running in IIS 5.0 isolation mode, the behavior is the same as it was in IIS 5.0. Because IIS must read the host header information to route the request to the correct site, and because the READ_RAW_DATA notification is sent before the host header arrives from the client, it is impossible to know which site must be notified. For this reason, site fiters cannot register for SF_NOTIFY_READ_RAW_DATA notifications. Global filters, however, can register for SF_NOTIFY_READ_RAW_DATA notifications.

IIS 6.0 running in worker process isolation mode does not support SF_NOTIFY_READ_RAW_DATA notifications. Worker process isolation mode is based on application pools, which do not correspond directly to sites. Http.sys routes a request based on server bindings and the URL namespace. Because a READ_RAW_DATA notification must be sent before IIS has received enough information from the client request to determine the server bindings and URL, IIS cannot route a READ_RAW_DATA notification to the correct worker process. This is not an issue in IIS 6.0 running in IIS 5.0 isolation mode, because Inetinfo.exe is always the only worker process.

For information about how the SF_NOTIFY_READ_RAW_DATA notification works with Secure Sockets Layer (SSL), see SSL and SF_NOTIFY_READ_RAW_DATA filters in Managing a Secure IIS 6.0 Solution.

**Applications that require special handling to run in worker process isolation mode**

Applications that you cannot load into multiple processes simultaneously have the following limitations:

- You cannot run them in application pools configured to perform overlapped recycling.
- You cannot run them in application pools configured as Web gardens.

Instead, run this type of application in an application pool that is not configured for overlapped recycling and that is not configured to run as a Web garden. For more information about overlapped recycling, see Features of Worker Process Isolation Mode. For information about configuring overlapped recycling, see Recycling Worker Processes with IIS 6.0.

If the IIS 6.0 WWW service is running in worker process isolation mode (the IIS 6.0 default mode), and you must run applications that require a functionality that is available only in IIS 5.0 isolation mode, change to IIS 5.0 isolation mode until you can correct the incompatibility. When running your server in IIS 5.0 isolation mode, you cannot take advantage of worker process isolation and the other features of worker process isolation mode.

# Application Isolation Mode Defaults

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you install IIS 6.0 on a computer that does not contain an earlier version of IIS, IIS 6.0 automatically sets the application isolation mode to worker process isolation mode. If you upgrade from an earlier version of IIS, IIS 6.0 sets the application isolation mode to IIS 5.0 isolation mode.

Table 2.3 lists the IIS 6.0 default settings for the two application isolation modes.

**Table 2.3 Default IIS 6.0 Installation Settings for Each Application Isolation Mode**

| Type of Installation | Application Isolation Mode |
|---|---|
| New installation of IIS 6.0 (clean install) | Worker process isolation mode |
| Upgrade from an earlier version of IIS 6.0, such as a beta release | No change in isolation mode |
| Upgrade from IIS 5.0 | IIS 5.0 isolation mode |
| Upgrade from IIS 4.0 | IIS 5.0 isolation mode |

Although IIS 5.0 isolation mode is the default application isolation mode when you upgrade from earlier versions of IIS, be sure to test your applications for compatibility issues so that, if possible, you can upgrade to worker process isolation mode.

# Application Isolation Mode Functions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Use Table 2.4 to compare how certain IIS 6.0 functions run in worker process isolation mode with how they run in IIS 5.0 isolation mode. Knowing the host component for each application isolation mode can help you decide which application isolation mode to use. For example, if an application must run in DLLhost.exe, and you cannot change the application to remove this requirement, this table shows you the two available options, which are to run the application in Medium or High isolation in IIS 5.0 isolation mode.

**Subhead**

**Table 2.4 Comparison of IIS 6.0 Functions in the Two Application Isolation Modes**

| IIS 6.0 Function | Worker Process Isolation Mode Host/Component | IIS 5.0 Isolation Mode Host/Component |
|---|---|---|
| Worker process management | Svchost.exe/WWW service | Svchost.exe/WWW service |
| Worker process | W3wp.exe | Inetinfo.exe |
| Running Low-isolation ISAPI applications | W3wp.exe | Inetinfo.exe |
| Running Medium-isolation ISAPI applications | Not applicable (All ISAPI extensions are in-process.) | DLLHost.exe (1) |
| Running High-isolation ISAPI applications | Not applicable (All ISAPI extensions are in-process.) | DLLHost.exe |
| Running ISAPI filters | W3wp.exe | Inetinfo.exe |
| HTTP.sys configuration | Svchost.exe/WWW service | Svchost.exe/WWW service |
| HTTP protocol support | Windows kernel/HTTP.sys | Windows kernel/HTTP.sys |
| HTTP SSL (HTTPFilter) | Lsass.exe | Inetinfo.exe |
| IIS metabase | Inetinfo.exe | Inetinfo.exe |
| FTP | Inetinfo.exe | Inetinfo.exe |
| NNTP | Inetinfo.exe | Inetinfo.exe |
| SMTP | Inetinfo.exe | Inetinfo.exe |

**HTTP SSL (HTTPFilter)**

When HTTP.sys receives requests that are encrypted by using Secure Sockets Layer (SSL), the kernel-mode HTTP service cannot decrypt the requests or encrypt the responses. Instead, HTTP SSL (HTTPFilter), which is a user-mode service, implements SSL for the HTTP service. HTTP SSL runs in the IIS 6.0 isolation modes as follows:

- In worker process isolation mode, Lsass.exe hosts HTTPFilter.
- In IIS 5.0 isolation mode, HTTP filter runs in Inetinfo.exe.

| **Important** |
|---|
| Lsass.exe cannot be stopped except during computer shutdowns — either planned or unexpected. |

**IIS 6.0 Identity vs. IIS 5.0 Identity**

In IIS 6.0, worker processes use a different process identity than in IIS 5.0. *Process identity* is an operating system term used to

denote the account that a process runs under. Every process that is running on a Windows NT operating system has a process identity that is used to control access to resources on the system.

The different process identity used by worker processes in IIS 6.0 can affect applications migrated from IIS 5.0 if the application expects the process identity to run as a specific account, such as IWAM_*ComputerName*. In addition, for Medium-isolation or High-isolation Web applications created in IIS 5.0 or run on IIS 6.0 in IIS 5.0 isolation mode, identity is configured by Component Services; however, when IIS 6.0 is running in worker process isolation mode, identity is configured in IIS Manager.

# Worker Process Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 worker process isolation mode takes the concept of application isolation, which was introduced in IIS 4.0, one step further. In IIS 6.0, you can isolate one application from another so that an error in one application does not affect another application running in a different process. This application isolation mode provides better isolation while not incurring a performance penalty for isolation.

Worker process isolation mode loads application code — for example, ASP and ASP.NET applications — into the worker process only. By isolating application code in the worker process, this application isolation mode ensures a reliable environment for an application server: the WWW service, IIS Admin service, and HTTP.sys can run continuously despite any service interruptions that occur in a worker process. Also, Web sites running in the worker processes are not affected by failures in other worker processes because they are isolated from each other through operating system process boundaries.

Worker process isolation mode uses all of the new IIS 6.0 core components and supports application pooling, recycling, and health monitoring features.

# Benefits of Using Worker Process Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

One benefit of isolating applications or sites into separate worker processes is to simplify management tasks, such as taking an application offline or putting an application back online (independent of all other sites or applications running on the system), changing a component that an application uses, debugging an application, and throttling (limiting) resources that an application uses.

IIS 6.0 worker process isolation mode improves on earlier versions of IIS in the following areas:

- **It is more robust.** Prevents Web applications and Web sites in an application pool from disrupting or harming applications or Web sites in another application pool.

- **It requires fewer or no reboots.** Does not force you to reboot the server or to shut down the WWW service. You can perform common tasks, such as upgrading site content or components, debugging Web applications, or dealing with faulty Web applications, without affecting service to other sites or applications on the server.

- **It is self-healing.** Supports autorestart of failed applications and periodic restart of unstable applications or applications that leak memory.

- **It is more scalable and reliable.** Supports scaling for ISPs, which sometimes run thousands of sites on a server, and offers better multiprocessor scalability.

- **It is application-oriented.** Makes the application the unit of administration and robustness by enabling application isolation and also by enabling resource throttling (limiting the amount of resources that an application can use) and scaling based on the application.

The result is a Web server that is more reliable and always available, even if applications cause their hosting worker processes to terminate.

# Features of Worker Process Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Worker process isolation mode includes several features that you can use to improve IIS robustness, scalability, and reliability without reducing performance. These features include multiple application pools, application pool health monitoring, worker process recycling, and rapid-fail protection. When you run your Web server in worker process isolation mode, you can configure application pools to take advantage of these features, which can only be used when a Web server is running in worker process isolation mode.

**Multiple Application Pools**
In IIS 5.0, applications can be pooled together out-of-process, but only in one application pool (typically referred to as *a pooled out-of-process* in IIS 5.0, rather than an *application pool*). In IIS 6.0, worker process isolation mode allows customers to create multiple application pools, each with a different configuration, such as a unique recycling configuration or a unique process ID. In addition, all HTTP application run-time features, such as the services that support ISAPI extensions, are available in all application pools. This design prevents a malfunctioning Web application or Web site from disrupting other Web applications or Web sites on that server.

**Application Pool Health Monitoring**
You can configure an application pool to monitor not only the health of its worker process, but the health of the entire pool. The WWW service can detect an unhealthy application pool in these situations:

- If a worker process in the application pool terminates abnormally.
- If all of the available IIS threads in the worker process that is assigned to the application pool are blocked.
- If the application notifies IIS that a problem exists.

Monitoring the health of a worker process includes detecting that the worker process is not able to serve requests and taking corrective action. For example, if a worker process does not respond to a ping from the WWW service, the worker process probably does not have threads available for processing incoming requests. When this happens, the WWW service either terminates the worker process or releases the worker process and leaves it running. (You can configure IIS to attach a debugger to an unhealthy worker process when the WWW server releases it.) If requests are waiting in the request queue, the WWW service starts a new worker process to replace the one that was terminated or released.

For more information about configuring IIS for application pool health monitoring, see Configuring Worker Process Health Monitoring in IIS 6.0 Help and Running IIS 6.0 as an Application Server.

**Worker Process Recycling**
Web applications sometimes leak memory, are poorly coded, or have other unidentified problems. In earlier versions of IIS, these faulty applications might force you to restart the Web server. In worker process isolation mode, you can use the recycling feature to periodically restart the worker processes in an application pool in order to manage faulty applications. You can schedule worker processes to restart based on several options, such as elapsed time or the number of requests served.

You can configure the WWW service so that it recycles a worker process in one of two ways:

- By default, the WWW service establishes an *overlapped recycle*, creating a new worker process to handle any new incoming requests *before* signaling the old worker process to finish processing its existing requests and shut down.
- Optionally, the WWW service first signals the old worker process to shut down and, after it shuts down, starts a new worker process.

In both types of recycling, the WWW service allows a configured amount of time for the old worker process to handle the requests that it has already taken from HTTP.sys before it shuts itself down.

In the default configuration, when a worker process requests a recycle, the WWW service initiates an overlapped recycle, creating a new worker process to replace the old process. While the new worker process is starting, the old process continues to serve requests. As soon as the new worker process starts and initializes successfully, the WWW service signals the old worker process to shut down. The old worker process then stops pulling new requests and begins to shut down. The WWW

service gives the old worker process a configured time period in which to finish processing its requests and shut down, and it terminates the worker process if it does not shut down within the specified time.

For more information about worker process recycling, including when to use it and how to configure it, see Recycling Worker Processes with IIS 6.0.

**Rapid-Fail Protection**

Rapid-fail protection stops an application pool when too many of the worker processes assigned to it are found to be unhealthy within a specified period of time. When an application pool is stopped, HTTP.sys either returns an out-of-service message (503: Service Unavailable) or resets a connection based on the configuration of the **LoadBalancerCapabilities** property of the application pool. Also, when an application pool stops automatically, such as when rapid-fail protection engages, you can configure an action (a debugging action, for example) to notify the administrator that the application pool has stopped.

For more information about rapid-fail protection, including how to configure this feature, see Running IIS 6.0 as an Application Server.

**Orphaning Worker Processes**

You can configure worker process isolation mode to orphan a worker process that the WWW service deems to be failing. The WWW service usually terminates a failing worker process and replaces it. If you enable orphaning, the WWW service allows a failing worker process to continue running, but separates it from the application pool (making it an orphan) and starts a new worker process in its place. You can configure the WWW service to run a command on the orphaned worker process — for example, launching a debugger.

For more information about orphaning worker processes, including how to configure this feature, see Running IIS 6.0 as an Application Server in this book and OrphanWorkerProcess Metabase Property metabase property.

**Web Gardens**

*Web gardens* are application pools that are configured to run multiple worker processes. By default, each application pool in IIS 6.0 has only one worker process. However, you can configure an application pool to have a set of equivalent worker processes that share the work, thus creating a *Web garden*. In a Web garden, HTTP.sys distributes the requests among the set of worker processes in the application pool.

| **Note** |
| --- |
| Do not confuse a Web garden with a *Web farm*, which is a Web site or Web hosting service that runs off of more than one server and that uses clustering and load balancing. |

The benefits of Web gardens are that they can handle more load, and that if one worker process stops responding, other worker processes are available to accept and process requests. Hence, Web gardens can enhance performance and reliability of the applications in the application pool.

The **MaxProcesses** metabase property determines the maximum number of worker processes that an application pool allows to service its requests. For more information about Web gardens, including how to create them, see Running IIS 6.0 as an Application Server, and Configuring Web Gardens with IIS 6.0.

**Processor Affinity**

*Processor affinity* is an application pool property that forces worker processes to run on a specific set of microprocessors or CPUs. Processor affinity applies to all worker processes that serve a particular application pool and allows you to take advantage of more frequent CPU caching. If a Web garden is running on a multiprocessor computer, you can use processor affinity to dedicate certain application pools to specific clusters of CPUs.

To set up processor affinity, configure the **SMPAffinitized** and **SMPProcessorAffinityMask** metabase properties. For more information about assigning processor affinity, including how to configure these metabase properties, see Running IIS 6.0 as an Application Server.

**Idle Timeout**

You can configure an application pool to have its worker processes request a shutdown if they are idle for a certain period of time. Configuring idle timeout can help you to free unused resources. New worker processes are started when demand exists for that application pool.

Use either IIS Manager or the **IdleTimeout** metabase property to configure this feature. For information about setting the **IdleTimeout** metabase property, see IdleTimeout in IIS 6.0 Help. For more information about configuring idle timeout for a worker process, see Running IIS 6.0 as an Application Server.

**Application Pool Identity**

*Application pool identity* is the user account that the worker processes servicing the application pool use as their process identity. *Process identity* is the operating system term that is used to denote the account that a process runs under. Every running process on a Windows NT operating system has a process identity that is used to control access to resources on the system.

You can assign a predefined account for the application pool identity or create your own account for this purpose. For security reasons, choose an application pool identity with the minimum permissions that your application requires.

For more information about configuring process identities, see Configuring Worker Process Identities.

# How Application Pools Work

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you run IIS 6.0 in worker process isolation mode, you can separate different Web applications and Web sites into groups known as *application pools*. An *application pool* is a group of one or more URLs that are served by a worker process or set of worker processes. Any Web directory or virtual directory can be assigned to an application pool.

Every application within an application pool shares the same worker process. Because each worker process operates as a separate instance of the worker process executable, W3wp.exe, the worker process that services one application pool is separated from the worker process that services another. Each separate worker process provides a process boundary so that when an application is assigned to one application pool, problems in other application pools do not affect the application. This ensures that if a worker process fails, it does not affect the applications running in other application pools.

Use multiple application pools when you want to help ensure that applications and Web sites are confidential and secure. For example, an enterprise organization might place its human resources Web site and its finance Web site on the same server, but in different application pools. Likewise, an ISP that hosts Web sites and applications for competing companies might run each company's Web services on the same server, but in different application pools. Using different application pools to isolate applications helps prevent one customer from accessing, changing, or using confidential information from another customer's site.

In HTTP.sys, an application pool is represented by a *request queue*, from which the user-mode worker processes that service an application pool collect the requests. Each pool can manage requests for one or more unique Web applications, which you assign to the application pool based on their URLs. Application pools, then, are essentially worker process configurations that service groups of namespaces.

Multiple application pools can operate at the same time. An application, as defined by its URL, can only be served by one application pool at any time. While one application pool is servicing a request, you cannot route the request to another application pool. However, you can assign applications to another application pool while the server is running.

# Request Processing in Worker Process Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Figure 2.3 shows the standard request process for IIS 6.0 when it is running in worker process isolation mode.

The HTTP protocol stack (HTTP.sys), which runs in kernel mode, receives client requests and routes them to the appropriate request queue. Worker processes, which run in user mode, pull the requests directly from their own kernel request queues, eliminating the process hops that occur in IIS 5.0 (and that also occur in IIS 5.0 isolation mode) when the Web server sends a request to a High-isolation, out-of-process application. Because these extra process hops are eliminated in worker process isolation mode, IIS can provide application isolation without sacrificing performance.

| **Note** |
| --- |
| Before routing a request to a queue, HTTP.sys checks to see if the response is located in its kernel-mode cache; if a response is cached, it is returned immediately. |

To see a visual representation of the request process for the two application isolation modes, compare Figure 2.3 (worker process isolation mode) with Figure 2.6 (High isolation in IIS 5.0 isolation mode).

| **Note** |
| --- |
| In Figure2.3, and also in Figure2.4, 2.5, 2.6, and 2.7, the numbered arrows indicate the request process flow. |

When HTTP.sys receives requests that are encrypted by using SSL, the kernel-mode HTTP service cannot decrypt the requests or encrypt the responses. Instead, HTTP SSL (HTTPFilter), which is a user-mode service, implements SSL for the HTTP service. In worker process isolation mode, the default host for HTTPFilter is Lsass.exe.

Figure 2.4 illustrates the process flow for an SSL request when IIS 6.0 is running in worker process isolation mode. The HTTP protocol stack receives the SSL request from the client and places it in the SSL queue. The HTTPFilter listens for requests to enter the queue, picks up any new request, uses SSL to decrypt the request, and then returns the decrypted request to HTTP.sys. HTTP.sys then places the decrypted request in the appropriate request queue. A worker process pulls the request directly from its own kernel request queue.

On the return trip, the worker process returns the response to HTTP.sys, which places it in the appropriate queue from which the HTTPFilter picks it up and performs SSL encryption. After encryption, the HTTPFilter again returns the response to HTTP.sys, which sends the encrypted response back to the client.

Keep in mind that SSL requires more resources than does standard HTTP. If you use SSL, ensure that the information being sent, such as credit card numbers or medical information, is sensitive enough to justify the added performance expense. For example, your home page or a search results page does not necessarily need to be run through SSL. However, you need to make sure that a checkout or purchase page is SSL-secured.

When you use SSL, the initial connection takes significantly longer than reconnecting. Reconnections use security information in the SSL session cache. The default timeout for the SSL session cache is changed to 5 minutes in Windows 2000 (10 hours in Windows 2000 with Service Pack 2) and 10 hours in Windows Server 2003. After cached data is deleted, the client and server must establish a completely new connection. You can change the default timeout by configuring the **ServerCacheTime** registry entry. For more information about configuring this registry setting, see Optimizing IIS 6.0 Performance.

| **Caution** |
|---|
| Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first. |

For more information about balancing performance and security, see Performance and Security in IIS 6.0 Help. For more information about encryption, see About Encryption in IIS 6.0 Help. For more information about the security features available in IIS 6.0, see Managing a Secure IIS 6.0 Solution.

Table 2.5 provides additional details about how worker process isolation mode processes HTTP (standard) and HTTPS (SSL) requests.

**Table 2.5 HTTP and HTTPS Request Processing**

| Step | Request Type | Description |
|---|---|---|

| | | |
|---|---|---|
| I | HTTP & HTTPS | HTTP.sys receives the request from the client and determines the type of request (HTTP or HTTPS). (Corresponds to #1 in Figures 2.3 and 2.4.)<br><br>If the request is an HTTPS request, HTTP.sys places it in the SSL queue. |
| | HTTPS (SSL) only | For an SSL request, the HTTPFilter performs these steps:<br>• Listens for requests to be added to the SSL queue (see #2 in Figure 2.4).<br>• Picks up any requests that are queued.<br>• Uses SSL to decrypt the request.<br>• Returns the decrypted request to HTTP.sys for processing (see #3 in Figure 2.4). |
| II | HTTP & HTTPS | HTTP.sys determines if the request is valid:<br>• If the request is invalid, HTTP.sys sends a 400-class error message for an invalid request back to the client. 1<br>• If the request is valid, HTTP.sys checks to see if the response is located in its kernel-mode cache. |
| III | HTTP & HTTPS | HTTP.sys checks the kernel-mode cache for a response:<br>• If the response is in the kernel-mode cache, HTTP.sys returns the response immediately, without transitioning to user mode.<br>• If the response is not in the cache, HTTP.sys determines the correct request queue and places the request in that queue.<br>• If the target request queue is out of service or if the queue is full, HTTP.sys returns a 503 Service Unavailable message to the client. |
| IV | HTTP & HTTPS | If no worker process is available and listening in the request queue and if HTTP.sys is able to request that a new worker process be started, HTTP.sys signals the WWW service to start a worker process. |
| V | HTTP & HTTPS | The worker process pulls the request from the queue and processes the request. (Corresponds to #2 in Figure 2.3 and #4 in Figure 2.4.) |
| VI | HTTP & HTTPS | The worker process sends the response back to HTTP.sys and instructs HTTP.sys whether to cache the response. (Corresponds to #3 in Figure 2.3 and #5 in Figure 2.4.) |
| VII | HTTP & HTTPS | HTTP.sys determines the type of response (HTTP or HTTPS).<br><br>If the request is an HTTPS response, HTTP.sys places it in the SSL queue. |

| | | |
|---|---|---|
| | HTTPS (SSL) only | For an SSL response, the HTTPFilter performs the following steps:<br>• Listens for responses to enter the SSL queue (see #6 in Figure 2.4).<br>• Picks up any responses that enter the queue.<br>• Uses SSL to encrypt the response.<br>• Returns the encrypted response to HTTP.sys (see #7 in Figure 2.4). |
| VIII | HTTP & HTTPS | HTTP.sys sends the response back to the client and logs the request if logging is enabled. (Corresponds to #4 in Figure 2.3 and #8 in Figure 2.4.) |

For information about 400-class error messages, including keys to the many substatus codes, see Troubleshooting IIS 6.0.

# IIS 5.0 Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 5.0 isolation mode provides as much compatibility as possible for applications that were developed for IIS 5.0. For example, the request processing of IIS 6.0 when it is running in IIS 5.0 isolation mode is nearly identical to the request processing of IIS 5.0. Hence, in IIS 5.0 isolation mode, you can run read raw data filters and can run applications in Inetinfo.exe or in DLLHost.exe — all of which is not accommodated in worker process isolation mode.

Before you decide to run an application in IIS 5.0 isolation mode, carefully evaluate whether you can substitute other filters and applications for the ones that require IIS 5.0 architecture because when a server is running in IIS 5.0 isolation mode, application pools, recycling, and health monitoring features are unavailable.

For more information about evaluating application isolation modes, see Evaluating Application Isolation Modes.

# Application Isolation in IIS 5.0 Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When IIS 6.0 is running in IIS 5.0 isolation mode, your options for isolation, which are similar to your options when you run an application on IIS 5.0, are as follows:

- **Low isolation (in-process).** Applications run in-process (on the Web server) as DLLs in Inetinfo.exe and are not protected from other applications running in-process. The process identity of the application (the account under which the applications process runs) is Local System.

- **Medium isolation (pooled out-of-process).** All pooled applications run as DLLs in one instance of DLLHost.exe and are protected from the effects of applications running in High isolation. However, because all pooled applications run in the same process, they are not protected from each other. The default application identity is IWAM_*ComputerName*.

- **High isolation (out-of-process).** Applications run as DLLs in DLLHost.exe and are protected from the effects of other applications running in Medium or High isolation. In addition, all other applications that run on the same computer are protected from the effects of applications that run in High isolation. The default application identity is IWAM_*ComputerName*.

**Security Considerations**

When IIS 6.0 runs in IIS 5.0, Web applications that are set to Low isolation run with the Local System account. The Local System account has access to all of the resources on the computer. This means that when an attack by a malicious user takes over a Web application that is set to Low isolation, all of the assets of the local computer are open to the attacker.

When you set Web applications to Medium or High isolation, they run with IWAM_*ComputerName* as the default account; however, you can configure these applications to run with other identities.

**Performance Considerations**

When you run IIS 6.0 in IIS 5.0 isolation mode, applications that run in Medium or High isolation incur a performance penalty. The penalty occurs because the Component Object Model (COM) uses a remote procedure call (RPC) during these parts of the cycle:

- When a request is sent to an application that is running in Medium or High isolation and the response is sent back.

- When a Web application that is running in Medium or High isolation communicates with the Web server during the processing of a request.

In contrast, when IIS 6.0 runs in worker process isolation mode, applications are loaded in-process to W3wp.exe. Therefore, no performance penalty occurs.

# Request Processing in IIS 5.0 Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

In IIS 5.0 isolation mode, HTTP.sys is used in almost the same way that it is in worker process isolation mode. The difference is that HTTP.sys routes requests to only a single request queue, which is maintained by the WWW Service Administration and Monitoring component of IIS. Depending on how you configure the IIS 5.0 isolation mode — as in-process or out-of-process — IIS processes the request in either Inetinfo.exe or in DLLHost.exe.

Figure 2.5 illustrates the processing of an SSL request for a Low-isolation application that is running in IIS 5.0 isolation mode. When HTTP.sys receives requests that are encrypted by using SSL, the kernel-mode HTTP service cannot decrypt the requests or encrypt the responses. Instead, HTTP SSL (HTTPFilter), which is a user-mode service, implements SSL for the HTTP service. In IIS 5.0 isolation mode, Inetinfo.exe, rather than Lsass.exe, hosts HTTPFilter.

In Figure 2.5, if you eliminate the decrypting and encrypting steps that are required for SSL requestsand follow only arrows 1, 4, 5, and 8, you see the standard (non-SSL) request process for a Low-isolation application that is running in IIS 5.0 isolation mode. For example, an HTTP request comes in to the HTTP protocol stack from the Internet, enters a single request-processing queue, and is picked up by a worker process that delivers the request to the Low-isolation application and returns it directly to the HTTP protocol stack.

Figure 2.6 illustrates request processing for an HTTP (non-SSL) request when IIS 6.0 is running in IIS 5.0 isolation mode. Note the extra process hops (represented by arrows 3 and 4) that occur when the request hops from the worker process, which is hosted by Inetinfo.exe and managed by the WWW service, to the High-isolation out-of-process application, which is hosted by DLLHost.exe.

If you compare Figure 2.6 with Figure 2.3, you can see the advantage of using worker process isolation mode, in which application isolation occurs without a performance penalty (the additional process hops are not needed) and in which health monitoring and worker process recycling promote the stability of your application server and its applications.

| **Note** |
| --- |
| In IIS5.0 isolation mode, request processing is almost identical for High-isolation and Medium-isolation applications. The only differences between these two isolation methods are that multiple applications can run in the pool for Medium isolation and there can only be one Medium-isolation process; however, only a single application can run in the pool for High isolation and you can have multiple High-isolation applications on one computer. |

Figure 2.7 illustrates the processing of an SSL request for a High-isolation application that is running in IIS 5.0 isolation mode. The HTTP protocol stack receives the SSL request from the client and places it in the SSL queue. The HTTPFilter listens for requests to be added to the SSL queue, picks up any requests that are queued, uses SSL to decrypt the request, and then returns the decrypted request to HTTP.sys. HTTP.sys then places the decrypted request in the worker process request queue (in this application isolation mode, there is only a single request queue), and a worker process pulls the request directly from the queue.

On the return trip, the worker process returns the response to HTTP.sys, which places it in the SSL queue, from which the HTTPFilter picks it up and performs SSL encryption. After encryption, the HTTPFilter returns the response to HTTP.sys, which sends the encrypted response back to the client.

If performance is a concern, and you are running applications in High isolation or Medium isolation on a computer that is running in IIS 5.0 isolation mode, keep in mind that using SSL requires more resources to process a request. In addition, the extra process hops required for High isolation and Medium isolation add to the resource requirements.

For more information about balancing performance and security, see Balancing Performance and Security. For more information about configuring IIS 5.0 isolation mode, see Running IIS 6.0 as an Application Server.

# How ASP.NET Works with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

If you run your ASP.NET applications in IIS 6.0, you obtain a significant advantage over running your ASP.NET applications in IIS 5.0. For example, in IIS 5.0, you cannot isolate individual applications into their own worker processes; hence, if one ASP.NET application fails, it can affect all the other applications. IIS 6.0, however, provides a new architecture that allows you to isolate your ASP.NET applications without incurring a performance penalty.

Before you run ASP.NET applications on IIS 6.0, be sure that you understand how ASP.NET works with the two IIS 6.0 isolation modes. When running in IIS 5.0 isolation mode, ASP.NET uses its own request processing model and configuration settings in the Machine.config file — just as it does when ASP.NET runs on IIS 5.*x*. When running in worker process isolation mode, ASP.NET disables its own request processing model and uses the new worker process architecture of IIS 6.0.

**Important**

The version of ASP.NET that is included with WindowsServer2003 is not available with the Microsoft® Windows® XP 64-Bit Edition and the 64-bit versions of Windows Server 2003. For more information, see Features unavailable on 64-bit versions of the Windows Server 2003 family in Help and Support Center for Windows Server 2003.

**ASP.NET Request Processing Model**

When ASP.NET is enabled on a server running Windows Server 2003, the ASP.NET request processing model depends on the application isolation mode in which IIS 6.0 is running. The preferred application isolation mode for IIS 6.0 is worker process isolation mode, which enables you to use application pools, worker process recycling, and application pool health monitoring. When IIS 6.0 is running in worker process isolation mode, ASP.NET uses the IIS 6.0 request processing model settings.

In almost all situations, if your ASP.NET applications are running on Windows Server 2003, configure them to run in worker process isolation mode. However, if your application has compatibility issues in this mode — for example, if your application depends upon read raw ISAPI data filters — you can change your configuration to run IIS 6.0 in IIS 5.0 isolation mode.

If you configure IIS 6.0 to run in IIS 5.0 isolation mode, ASP.NET runs in its own request processing model, Aspnet_wp.exe, and uses its own configuration settings for process configuration, which are stored in the Machine.config configuration file. When your server is running in IIS 5.0 isolation mode, the ASP.NET ISAPI extension implements a request processing model that is similar to worker process isolation mode and contains worker process management capabilities similar to those provided by the WWW service. ASP.NET also provides recycling, health monitoring, and processor affinity.

When ASP.NET is installed on servers running Windows XP or Windows 2000 Server, ASP.NET runs in IIS 5.1 or IIS 5.0, respectively, and runs in the Aspnet_wp.exe process by default. The ASP.NET request processing model provides process recycling, health detection, and support for affinities between worker processes and particular CPUs on a server with multiple CPUs. For more information about running ASP.NET in its own request processing model, see Using the ASP.NET Process Model.

**When Different Versions of ASP.NET Share the Same Application Pool**

When multiple versions of the .NET Framework are installed on a computer that uses IIS 6.0, you might encounter the following error message in the Application Event log:

**Note**

It is not possible to run different versions of ASP.NET in the same IIS process. Please use the IIS Administration Tool to reconfigure your server to run the application in a separate process.

This error occurs when more than one version of ASP.NET is configured to run in the same process. Different versions of the .NET Framework and run time cannot coexist side by side within the same process. Therefore, an ASP.NET application that uses one version of the run time must not share a process with an application that uses a different version. This error commonly occurs when two or more applications are mapped to different versions of ASP.NET but share the same application pool.

For more information about using ASP.NET with IIS 6.0 application pools, see Configuring an ASP.NET Application for an ASP.NET Version. For more information Deploying ASP.NET Applications, see Deploying ASP.NET Applications in IIS 6.0. For more information about ASP.NET, see About ASP.NET.

# Additional Resources for IIS 6.0 Architecture

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

These resources contain additional information related to this chapter.

# Application Pool Configuration in IIS 6.0

Published: February 19, 2010

Updated: February 19, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This topic provides some best practices recommendations for configuring IIS application pools on your IIS 6.0 Web server. Application pools enable specific configuration settings to be applied to groups of applications, and the worker processes that service those applications. All Web sites and virtual directories must be assigned to an application pool. Configuring application pools appropriately can increase service availability on the server as application pools isolate sites and applications from other sites and applications.

**Planning Application Pool Configuration**

You can configure application pools to optimize performance for your server and organization. The ideal configuration for your environment depends on many factors. These include hardware and network configuration, the number of Web sites that are running on the server, and the applications on those sites. The guidance provided here is intended to highlight points to consider instead of the specific settings for your particular environment. For example, you may want to isolate sites or applications by technology, such as ASP.NET, or by business segment, such as Human Resources or Finance. You may also want to isolate sites and applications by business priority or by specific application. You can configure application pools using one or more of these categories, or define categories to support your specific business needs.

**Application Pools and Service Availability**

How you configure application pools on your server directly affects the availability of the WWW service on your IIS server. For example, if there are two Web sites that are running in a single application pool, the same worker process (W3wp.exe) handles requests for both the sites. If one of the sites experiences a fatal error, the process stops processing requests for both the sites in the application pool. To avoid this, configure a separate application pool for each site so that errors in one are isolated from the other sites on the server.

As a best practice, you should configure application pools to isolate mission critical applications from other applications on the server. This can also result in better performance for critical applications as the computer continues to process requests for the critical application, even if there are problems in other application pools. Requests for other applications or sites are handled by the process in a separate, isolated application pool.

In some cases, administrators prefer to configure each site on the server to run in its own application pool. This is a supported configuration. However, exceeding about 60 application pools that use unique identities on a server requires special configuration, and may cause a decrease in performance because of high utilization of hardware resources. If it is a priority to configure more than 60 application pools but hardware limitations prevent doing this, you could also add another IIS server to your environment and then run some sites and applications on the additional server.

**Advanced Configurations**

If you are configuring your application pools with unique identities, depending on the applications and memory resources on your server, you will reach a limit of about 60 application pools. There are finite limits to some system resources that get allocated with each new logon session. This means that 60 processes can run concurrently as distinct accounts. IIS 6.0 supports running these processes in a single shared workstation and desktop, at a cost of sharing a single encapsulation of a user session among all parties.

To scale beyond 60 application pools and to share a single desktop, change the value of the registry **HKey_Local_Machine\System\CurrentControlSet\Services\W3SVC\Parameters\UseSharedWPDesktop** subkey to **1** (the data type is DWORD). After changing this registry entry, you can scale to hundreds of application pools and hundreds of concurrently running worker processes.

| **Warning** |
| --- |
| Before you change a registry key or subkey, you should export or make a backup copy of the key or subkey. You can save the backup copy to a location that you specify, such as a folder on your hard disk or a removable storage device. If you make changes that you want to undo, you can import the backup copy. |

If IIS starts more worker processes than can be supported, or if the server is running out of resources, you can set a maximum number of concurrent worker processes. By using the IIS 6.0 and HTTP.sys architecture, and with a request load distributed across many application pools, IIS will try to start more worker processes than the server can sustain without running out of memory or CPU resources. The **DemandStartThreshold Metabase** property (also named *concurrent process gating*), when

set to a value less than the default, applies a hard limit to the number of IIS worker processes that can run concurrently. If the hard limit is exceeded, HTTP.sys returns an HTTP 503 error (Service Unavailable).

# Running IIS 6.0 as an Application Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Internet Information Services (IIS) 6.0, running on Microsoft® Windows® Server 2003, helps provide a secure, reliable, and easily managed application server on which you can host sites over an intranet, the Internet, or an extranet. IIS helps you create a platform of dynamic network applications, allowing you to use the latest Web standards to develop, implement, and manage your Web applications.

To match the needs of your applications to your server, IIS offers an adjustable architecture that allows you to isolate applications within a self-contained worker process. The new process model helps prevent one application or Web site from stopping another and reduces the time that you spend restarting services to maintain the health of your server. If health issues arise, IIS helps you manage them, usually without restarting your Web server or affecting your users.

# Introduction to Running an Application Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Establishing an application server begins with configuring the application server role, which includes deciding what Web-related technologies you want to use and then enabling those technologies on your server. Attackers often target unused or unmonitored services; so if you enable only what you need, your IIS 6.0 application server provides a reduced attack surface when it is connected to the Internet.

In IIS 6.0, deciding which request processing model to use is your next decision. Helping you make this decision is IIS 6.0 Architecture, the section that introduces the two IIS 6.0 request processing models, known as *application isolation modes*. Where the earlier section provides architectural diagrams and descriptions of the two application isolation modes, this section offers guidelines for deciding where and when to use each mode and provides procedures for configuring the isolation modes and their features. For information about choosing and configuring an application isolation mode, see Configuring an Application Isolation Mode.

Your application server runs in one of two mutually exclusive application isolation modes: worker process isolation mode or IIS 5.0 isolation mode. Worker process isolation mode, which is the default request processing model, supports new features such as application pools, health monitoring, worker process recycling, and rapid-fail protection. These new features help provide more robust performance. For example, you can recycle faulty applications to prevent service disruption and can use application pools to isolate one application from another without incurring a performance penalty. For more information about using these new features, see Creating Application Pools and Ensuring Application Health in Worker Process Isolation Mode.

Worker process isolation mode also provides better default security for your Web applications — in particular, better balance between security and functionality. To help you evaluate the security differences between the two application isolation modes, see Security Considerations When Choosing an Application Isolation Mode.

Worker process isolation mode provides several features to help you manage system resources, including Web gardens, idle timeout, CPU monitoring, processor affinity, and startup and shutdown limits. For information about configuring these features, see Managing Resources in Worker Process Isolation Mode.

To help you migrate from earlier versions of IIS, IIS 6.0 provides IIS 5.0 isolation mode, which is a processing model that offers compatibility for applications that depend on certain request processing characteristics of IIS 5.0. For example, if an application must run within Inetinfo.exe, it can only run in IIS 5.0 isolation mode unless you modify the application, making it compatible with worker process isolation mode. For information about which applications might require a processing model like IIS 5.0 isolation mode, see Evaluating Application Requirements.

You can configure most IIS 6.0 features either by using a graphical user interface (GUI) or by using a programmatic interface. For the procedures included here, the method that uses the GUI (usually implemented through IIS Manager) appears first, and an optional method for configuring metabase properties programmatically (by using the administrative utility Adsutil.vbs) appears second.

# Configuring an Application Server Role

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can use the Configure Your Server wizard to install or remove many services on a computer running the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; Windows® Server 2003, Datacenter Edition; or Windows® Server 2003, Web Edition operating system. The server roles that you can install by using this wizard include the following: file server, print server, application server (IIS, ASP.NET), terminal server, DNS server, and DHCP server.

The application server role can include IIS 6.0, COM+, ASP.NET, and FrontPage® Server Extensions from Microsoft. Before you install IIS 6.0 on your server, review the technologies offered in the application server role and decide which technologies you want to install and enable during initial installation, and which technologies you will install later as needed. Then prepare for the IIS 6.0 installation by reviewing security considerations.

# Technologies Offered in the Application Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you install IIS 6.0 as an application server by using the Configure Your Server wizard, IIS, COM+, and Microsoft® .NET Framework are automatically installed. To help ensure the security of your system after a default installation, ASP.NET and FrontPage 2002 Server Extensions are installed but not enabled in a default installation; the wizard gives you the option of enabling these services.

Table 3.1 describes the technologies included in the IIS 6.0 application server role, noting which are installed and enabled by default when you use the Configure Your Server wizard to install an application server role on a computer running Windows Server 2003.

**Table 3.1 Technologies That Make Up the Application Server Role**

| Technology | Enabled by Default |
|---|---|
| **Internet Information Services (IIS).** Gives you a full-featured Web server that provides the infrastructure for .NET and existing Web applications and Web services. IIS 6.0 is optimized to run Web applications and XML Web services in a hosting environment. | Yes |
| **COM+ for remote transactions.** Provides an extension to COM. COM+ builds on COMs integrated services and features, making it easier for developers to create and use software components in any language by using any tool. | Yes |
| **Distributed Transaction Coordinator (DTC) for remote access**. Coordinates COM+ transactions across multiple computers. | Yes |
| **ASP.NET.** Offers a unified Web development platform that provides the services necessary for developers to build enterprise-class Web applications.[1] | |
| **FrontPage Server Extensions.** Enables users on a client computer to publish and administer Web sites on a server remotely over a network.[1] | |

[1] To ensure a more secure server during default installations, ASP.NET and FrontPage Server Extensions are automatically installed but in a disabled state. You must enable each of these technologies before you can use them. You can optionally enable either ASP.NET or FrontPage Server Extensions (or both) when using the Configure Your Server wizard by selecting the appropriate check box.

| **Important** |
|---|
| The version of ASP.NET that is included with Windows Server 2003 is not available in the Microsoft® Windows XP 64-Bit Edition and the 64-bit versions of Windows Server 2003. For more information, see Features unavailable on 64-bit versions of the Windows Server 2003 family in Help and Support Center for Windows Server 2003. |

If you are unsure whether you need either of the optional technologies, you can install IIS by using the default installation, which installs them in a disabled state, and then enable the optional technologies when you need them by using **Add or Remove Programs** in Control Panel. For more information about installing IIS 6.0 by using Control Panel, see Installing IIS.

As with every functionality that you enable on your server, use caution and take appropriate steps to secure each new technology that you add. For more information about securing your application server, see Managing a Secure IIS 6.0 Solution.

# Benefits of Enabling ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

ASP.NET is an application environment that provides the services necessary to build and deploy enterprise-class Web applications. ASP.NET is installed but not enabled during a default installation; you must enable it before you can use your application server to host ASP.NET Web pages. ASP.NET is part of the .NET Framework, which simplifies application development in the highly distributed environment of the Internet.

ASP.NET offers several important benefits:

- **Manageability.** ASP.NET uses a text-based, hierarchical configuration system that makes it easier for you to apply settings to your server environment and Web applications. Because ASP.NET stores configuration information as plain text, you can apply new settings without using local administration tools.

- **Security.** ASP.NET provides default authorization and authentication schemes for Web applications. Developers can easily add to, remove, or replace these schemes.

- **Easy deployment.** You can deploy an ASP.NET application to a server by merely copying the necessary files to the server, without restarting the server.

- **Enhanced performance.** ASP.NET is compiled code that runs on the server. ASP.NET takes advantage of early binding, just-in-time (JIT) compilation, native optimization, and caching services out of the box.

- **Flexible output caching.** ASP.NET can cache page data, portions of a page, or entire pages. When ASP.NET is running on Windows Server 2003 with IIS 6.0, ASP.NET can cache entire pages in the high-performance IIS kernel cache.

- **Mobile device support.** ASP.NET supports any browser on any device.

- **Scalability and availability.** ASP.NET includes features specifically designed to improve performance in clustered and multiprocessor environments.

ASP.NET and ASP pages can run compatibly side by side on an IIS application server because they are serviced by different ISAPI extensions that do not interfere with each other. Installing ASP.NET does not corrupt any ASP applications; the ASP engine continues to process files with an .asp extension. You can isolate these two processing environments in separate application pools or run both types of application in the same application pool.

The security configurations for ASP.NET and IIS are complementary and in part interdependent. For example, when IIS is running in worker process isolation mode, the ASP.NET processes are secured by means of restrictions on worker process identities; when IIS is running in IIS 5.0 isolation mode, the ASP.NET processes are secured by means of the identity assigned within the Machine.config file. Additional IIS security features are configured in the IIS metabase, and additional ASP.NET security features are configured in XML-based Web.config files. To secure an ASP.NET Web application, you might need to configure security in both places.

For more information about ASP.NET, see Overview of ASP.NET.

# Benefits of Installing FrontPage Server Extensions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

FrontPage Server Extensions provides Web-based and command-line administration for extending virtual servers. Extending virtual servers with FrontPage Server Extensions enables the site owner to author the site in FrontPage and delegate site ownership and administrative credentials.

If you build and maintain Web sites for customers and coordinate these efforts with multiple authors, the features included in FrontPage Server Extensions can help you accomplish the following tasks:

- Manage Web sites either on the local server or remotely by using HTML Administration pages or a command-line interface.
- Secure Web sites, and grant authoring, browsing, site management, or other user rights to authorized users.
- Analyze site usage to find out which users are visiting the site and how often.
- Monitor the health of FrontPage Server Extensions and detect errors.

FrontPage Server Extensions is typically used on development, test, or staging servers but not on application servers in a production environment. Use appropriate caution if you install a publishing system like FrontPage Server Extensions on a production server.

If you are unsure whether you need FrontPage Server Extensions, you can install them after installing IIS 6.0 by using **Add or Remove Programs** in Control Panel. For more information about installing FrontPage 2002 Server Extensions, see Using FrontPage 2002 Server Extensions with IIS 6.0.

# Preparing to Install IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Before you install IIS and configure it as an application server, review the security considerations outlined in this section:

- Avoid installing IIS on a domain controller.
- Verify that all disk volumes on your application servers use the NTFS file system, not FAT or FAT32 file systems.
- Ensure that your computer has network connectivity and a static or dynamic IP address. For more information, see Before Configuring IIS and Securing Sites with IP Address Restrictions.

**Avoid installing IIS on a domain controller**

Whenever possible, do not install IIS on a domain controller for the following reasons:

- The networking and processor load generated by authentication and other domain controller processes can degrade IIS performance.
- Adding users to a group that can log on locally to the domain controller can increase the attack surface that is exposed by a Web application. If security is compromised on the domain controller, security is compromised on the entire domain.

**Verify that all disk volumes on your application servers use NTFS**

To provide a more secure file system, use NTFS on your application servers. NTFS is a more powerful and secure file system than the FAT or FAT32 file system. When you use NTFS on your application servers, you can limit access to the files and directories on the server and configure the access level that you grant to a particular user or group. An added benefit of NTFS is that it allows larger volume sizes than FAT.

Table 3.2 compares the benefits of using the NTFS and FAT file systems.

**Table 3.2 Comparison of Support Offered by NTFS and FAT File Systems**

| Type of Support | NTFS File System | FAT File System |
|---|---|---|
| Directory and file security | Enables more secure directories and files through the use of NTFS permissions, which you can set at both the file and directory levels. | Does not allow you to secure directories and files. |
| The Active Directory® directory service and domain-based security | Supports Active Directory and domain-based security. | No support. |
| File encryption | Supports file encryption, which enhances file security. | No support. |

To determine the type of file system used by a disk volume, view the properties of the volume (open **My Computer**, right-click the disk volume, and then click **Properties**). Windows provides a conversion utility (Convert.exe) that you can use to convert an existing FAT or FAT32 volume to NTFS without losing data. For more information about converting FAT or FAT32 volumes to NTFS, see "Reformatting or converting a partition to use NTFS" in Help and Support Center for Windows Server 2003.

# Installing IIS 6.0 Technical Reference

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

To help protect the system from malicious users and attackers, IIS is not installed by default when you install Windows Server 2003. In addition, when you initially install IIS, the service is installed in a secure, locked mode.

In Windows Server 2003, you can install IIS by using either Control Panel or the Configure Your Server wizard. These options offer slightly different default installations:

| **Note** |
| --- |
| You can use the Web Platform Installer (Web PI) to easily install IIS, and applications that run on IIS. The Web PI is a free, lightweight tool that lets you install IIS and related technologies such as ASP.NET, SQL Server Express, Visual Web Developer, other popular Web applications, and more. Because the Web PI installs the latest versions of available Web Platform offerings, with just a few simple clicks you can download and install any new tools or updates. To learn more about the Web PI, see Learn more and install the Web PI. |

- If you install IIS by using **Add or Remove Programs** in Control Panel, only IIS is installed and enabled, so the default installation serves only static content. Features such as ASP, ASP.NET, server-side includes (SSI), Web Distributed Authoring and Versioning (WebDAV) publishing, and FrontPage Server Extensions are either not installed or not enabled, and therefore do not work.

- If you install IIS by using the Configure Your Server wizard, ASP.NET and ASP are automatically installed with IIS. In addition, you have the option of enabling ASP.NET and installing FrontPage Server Extensions by using the wizard.

For more information about installing IIS by using **Add or Remove Programs** in Control Panel, or by using the Configure Your Server wizard, see Installing IIS.

If you want to serve dynamic content, you can unlock applications such as ASP.NET, ASP, and FrontPage Server Extensions through the **Web Service Extensions** node in IIS Manager. For more information, see Enabling Dynamic Content.

| **Note** |
| --- |
| When you upgrade from a previous version of IIS, most dynamic content features remain enabled. The installation program notes the exceptions. |

Be sure to install IIS on an NTFS-formatted drive. NTFS is a more powerful and secure file system than FAT or FAT32. For more information about the advantages of using NTFS, see Preparing to Install IIS 6.0.

# Enabling Dynamic Content

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The default installation of IIS 6.0 protects your system from malicious users and attackers by delivering IIS in a locked mode, in which IIS can only serve static HTTP content. After a default installation, the request handlers that process dynamic content are disabled, which means that features like ASP, ASP.NET, SSI, WebDAV publishing, and FrontPage Server Extensions do not work.

You can configure the request handlers (ISAPI extensions or Common Gateway Interface [CGI] programs), known as *Web service extensions*, by using either the **Web Service Extensions** node in IIS Manager or the command-line script Iisext.vbs, which is located in *systemroot*\System32.

Iisext.vbs can be used to perform the same operations that are available in IIS Manager. You can use either tool to administer dynamic content, performing the following tasks:

- Allow or prohibit Web service extensions on the local computer.
- Add new Web service extensions.
- Allow all the Web service extensions that an application requires.
- Prohibit the running of all Web service extensions on the local computer.

For more information about using IIS Manager to administer dynamic content, including instructions for adding new Web service extensions, allowing an application to call a Web service extension, or disabling all Web service extensions, see Enabling and Disabling Dynamic Content in IIS 6.0.

To enable a Web service extension from the command line, use the Iisext.vbs command-line script. Before enabling a Web service extension or application type, obtain a list of all the defined Web service extensions on the computer. (To view a list in IIS Manager, expand the **Web Service Extensions** node.)

**Important** You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /Profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters).

**To view a list of a Web service extensions on the local computer by using Iisext.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.
2. At the command prompt, type:

   **cscript %SystemRoot%\system32\iisext.vbs /listapp**

   This command displays a list of all Web service extensions that are located on the local computer. For example, using the */listapp* parameter might return the following:

   ```
   Connecting to server ...Done.
   Active Server Pages
   Internet Data Connector
   Server Side Includes
   WebDAV
   FrontPage Server Extensions
   ASP.NET v1.1.4322
   ```

If you want to enable ASP pages, type the command-line syntax that is shown in the following procedure. If you want to enable another type of application, replace Active Server Pages with the name of that application. If the application name contains spaces, be sure to enclose the name with quotation marks.

**To enable ASP pages (or other Web service extension)**

1. At the command prompt, type:

   **cscript %systemroot%\system32\iisext.vbs /EnApp "Active Server Pages"**

For more information about using the lisext.vbs command-line script to administer dynamic content, such as enabling, disabling, or listing Web service extensions and their files, see Managing Applications and Web Service Extensions Using Scripts.

# Configuring an Application Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

So that you can match the needs of your server configuration to the requirements of your applications, and to provide more flexibility if you are upgrading from an earlier version of IIS, IIS 6.0 offers an adjustable architecture for isolating your applications. IIS 6.0 can run an application server in one of two process models, called application isolation modes:

- Worker process isolation mode, which is the default application isolation mode for IIS 6.0, isolates key components of the World Wide Web Publishing Service (WWW service) from the effects of defective applications and protects applications from each other by using isolated worker processes.

- IIS 5.0 isolation mode, which processes requests in nearly the same way that IIS 5.0 does, is provided for applications that depend on specific features and behaviors of IIS 5.0 or earlier. Use this isolation mode only if an application has a compatibility problem, which you cannot resolve, when it runs in worker process isolation mode.

Both application isolation modes use the HTTP protocol stack, HTTP.sys, in almost identical ways. The primary difference is that in worker process isolation mode, HTTP.sys can route requests to multiple queues; in IIS 5.0 isolation mode, HTTP.sys routes requests to a single queue. For more information about IIS 6.0 request processing, see IIS 6.0 Architecture.

# Choosing an Application Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

One of the most important decisions that you will make when you configure your application server is which application isolation mode to use. Although worker process isolation mode is recommended if your environment supports it, you must evaluate the relative capabilities of the two application isolation modes, considering their compatibility with the applications that the server will make available, the level of security that your organization requires, and performance requirements.

# Evaluating the Capabilities of the Two Application Isolation Modes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Before you choose an application isolation mode for your application server, review the benefits of each mode and then review your ISAPI (Internet Server API) filters and applications to determine whether any conflicts exist with worker process isolation mode. Keep in mind that when an application server is running in IIS 5.0 isolation mode, many of the benefits of the new request-processing architecture — such as application pools, recycling, and health monitoring — are unavailable. If a filter or application cannot run in worker process isolation mode, evaluate whether you can substitute another filter or application that does not conflict with worker process isolation mode.

Benefits of Worker Process Isolation Mode

In worker process isolation mode, you can isolate an application within its own process, where it does not depend on a central process such as Inetinfo.exe. When you run IIS in this isolation mode, you can group Web applications into *application pools*, through which you can apply specific configuration settings to groups of applications and to the worker processes that service those application groups.

An application pool corresponds to one request routing queue within HTTP.sys and one or more worker processes. Process boundaries separate each application pool from the others so that when an application is routed to one application pool, applications in other application pools do not affect that application. Application pools allow you to run all application code in an isolated environment without incurring a performance penalty.

Worker processes operate independently; if one fails, it does not affect other worker processes. The pooling of applications protects applications from the effects of worker processes that support other application pools. In this way, applications are protected from each other.

In worker process isolation mode, a kernel-mode device driver called the HTTP protocol stack (HTTP.sys) routes HTTP requests directly to a kernel-mode request queue that is assigned to a specific application pool. Worker processes that serve the application pool pull incoming requests directly from the request queue, avoiding the overhead of user-mode process switching.

To protect the WWW service, IIS 6.0 isolates critical components, such as HTTP.sys and WWW Service Administration and Monitoring, from external application code that runs in worker processes. HTTP.sys receives and queues requests for Internet services.

When a worker process enters an unhealthy state and stops processing requests, HTTP.sys continues to queue requests. The WWW service detects that the worker process is unhealthy and shuts it down, starting a new worker process if requests are waiting in the queue or if new requests arrive. Because HTTP.sys continues to accept incoming requests even when worker processes fail, end users are shielded from the failure; the client can still connect to the WWW service while a replacement worker process is initialized.

IIS 6.0 worker process isolation mode delivers the following improvements over earlier versions of IIS:

- **Robust performance.** Isolation prevents Web applications and Web sites in an application pool from disrupting applications or Web sites in other application pools. Restarts of the operating system and WWW service are avoided.
- **Self-healing.** Automated management provides auto-restart of failed applications and periodic restart of unstable applications or applications that leak memory.
- **Scalability.** IIS 6.0 supports hundreds (even thousands) of sites on a server through features such as start on demand and idle timeout for a worker process. In addition, IIS 6.0 offers improved multiprocessor scalability.
- **Processor affinity.** You can bind worker processes to specific processors on multiprocessor servers.
- **Automated debugging.** You can configure debugging tools to start automatically when worker processes fail.
- **CPU monitoring.** You can limit the amount of CPU resources that an application pool can consume within a configured amount of time.

For more information about worker process isolation mode, including architectural diagrams, see IIS 6.0 Architecture. For more information about automated debugging and CPU monitoring, see Enabling Debugging and Enabling CPU Monitoring.

Before you decide which application isolation mode to run on a server, read Evaluating Application Requirements.

Isolation Options in IIS 5.0 Isolation Mode

When IIS 6.0 is running in IIS 5.0 isolation mode, the following options for application isolation, which are similar to those in IIS 5.0, are available:

- **Low isolation (in-process).** Applications run in-process (on the Web server) as DLLs in Inetinfo.exe and are not protected from other applications that run in-process. The process identity (the security context of the process running the application) is LocalSystem.

- **Medium isolation (pooled out-of-process).** All pooled applications run as DLLs in the same single instance of DLLHost.exe and are protected from the effects of applications running in High isolation. However, because all pooled applications run in the same process, they are not protected from each other. The default application identity is IWAM_*ComputerName*.

- **High isolation (out-of-process).** Applications run as DLLs in their own DLLHost.exe and are protected from the effects of other applications running in Medium or High isolation. Also, all other applications that run on the same computer are protected from the effects of applications that run in High isolation. The default application identity is IWAM_*ComputerName*.

| **Note** |
| --- |
| Only the parts of applications that are served by ISAPI extensions can be run out-of-process — that is, in a memory space that is separate from the Web server. Thus, if an ASP page that is set to High-isolation includes static files, those static files are served by Inetinfo.exe. |

For more information about IIS 5.0 isolation mode, including architectural diagrams, see IIS 6.0 Architecture.

# Evaluating Application Requirements

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 cannot run both application isolation modes simultaneously on the same computer. Therefore, on a single computer running IIS 6.0, you cannot run some Web applications in worker process isolation mode and others in IIS 5.0 isolation mode. Applications that require different application isolation modes must be run on separate computers.

**Guidelines for Optimizing Application Performance**

When you are deciding which application isolation mode to use, follow these guidelines:

- Use worker process isolation mode unless you need to use IIS 5.0 isolation mode because of a specific compatibility issue. For example, read raw data filters only work in IIS 5.0 isolation mode.
- Run Web sites that contain static content or simple ASP applications in worker process isolation mode. These Web sites usually require little or no modification to run in worker process isolation mode.
- For applications that run correctly in IIS 5.0, try running them first in worker process isolation mode. If they do not work correctly, attempt to diagnose and resolve any compatibility issues. You can also turn off or scale down some of the features that worker process isolation mode provides. For example, you might turn off recycling or change the recycling settings so that the server does not perform an overlapped recycle.

If a server is running in IIS 5.0 isolation mode and you upgrade the servers applications so that they are compatible with worker process isolation mode, be sure to change the isolation mode on that server to worker process isolation mode. If, after changing the server from IIS 5.0 isolation mode to worker process isolation mode, you find that you cannot easily maintain a healthy server, change back to IIS 5.0 isolation mode while you diagnose and fix the compatibility issues. Then reconfigure the server to run in worker process isolation mode.

| **Important** |
| --- |
| Before you change the application isolation mode, consider that each time you reconfigure a server to use a different mode, you must restart IIS, which temporarily interrupts the service and can cause loss of application state data. |

**Applications That Cannot Run in Worker Process Isolation Mode**

Applications that run in worker process isolation mode can take advantage of all the worker process behaviors, which include multi-instancing, recycling, and configurable process identity. Certain application characteristics conflict with the architecture of worker process isolation mode. Applications with those characteristics must be run in IIS 5.0 isolation mode until you can modify them.

Applications with the following characteristics cannot run in worker process isolation mode:

- **Read raw data filters.** This type of ISAPI filter only works in IIS 5.0 isolation mode.
- **Dependency on Inetinfo.exe.** Applications that must run within an Inetinfo.exe worker process can only run in IIS 5.0 isolation mode.
- **Requires Dllhost.exe.** ISAPI applications that must run in a Dllhost.exe environment can only run in IIS 5.0 isolation mode because Dllhost.exe is not available for ISAPI applications in worker process isolation mode. (Dllhost.exe can still be used to host out-of-process COM+ applications, regardless of the mode in which IIS is running.)

If IIS 6.0 is running in worker process isolation mode (the default mode in IIS 6.0), and you must run applications that require a functionality that is only available in IIS 5.0 isolation mode, reconfigure the server to run in IIS 5.0 isolation mode until you can correct the incompatibility. Running your server in IIS 5.0 isolation mode means that you cannot take advantage of the reliability features in worker process isolation mode.

# Security Considerations When Choosing an Application Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you choose an application isolation mode, keep these security considerations in mind:

- **Worker process isolation mode.** Worker process isolation mode provides better default security for running Web applications than does IIS 5.0 isolation mode. In worker process isolation mode, worker processes run by default as Network Service, which is the account that provides a better balance between security and functionality.

- **IIS 5.0 isolation mode.** Web applications that are set to Low isolation, such as low-isolation ISAPI extensions, run in a process that runs as LocalSystem. The LocalSystem account can read, execute, and change all of the resources on the computer. Thus, if an attack by a malicious user takes over a Web application that runs in Low isolation, many assets of the local computer are open to the attacker. Also, if you set Web applications to Medium or High isolation, they run with IWAM_*ComputerName* as the default identity, which has fewer rights than LocalSystem.

Windows Server 2003 provides the following built-in system accounts, which you can use to provide the security context for worker processes:

- **Local Service.** Has limited rights on the local computer and limited access (Anonymous) to network resources. Use the Local Service account if the worker process does not require authenticated access to network resources.

- **Network Service.** Has limited rights on the local computer and authenticated access (as the computer account) to network resources.

- **LocalSystem.** Has full access to the system because it belongs to the Administrators group.

Table 3.3 provides additional details about the built-in system accounts that are available in IIS 6.0, and Table 3.4 shows the default security account for both application isolation modes**.**

**Table 3.3 Built-in System Accounts in IIS 6.0**

| Built-in Account | Privilege Level | Group or Account Used on the Local Machine | Group or Account Used on the Network |
|---|---|---|---|
| Local Service | Least privileged | Users group | Anonymous access account |
| Network Service | More privileged | Users group | Computer account |
| LocalSystem | Most privileged | Administrator with full access account | Computer account |

**Table 3.4 Default Security Accounts for Each Application Isolation Mode**

| Mode or Options Within a Mode | Default Account |
|---|---|
| Worker process isolation mode | Network Service |
| IIS 5.0 isolation mode | |
| ISAPI extensions set to Low isolation that run in Inetinfo.exe | LocalSystem |
| ISAPI extensions set to Medium-isolation that run in pooled out-of-process application hosts | IWAM_*ComputerName* |
| ISAPI extensions set to High-isolation that run in out-of-process application hosts | IWAM_*ComputerName* |
| ASP.NET worker processes | ASPNET |

For more information about built-in security accounts in IIS 6.0 and Windows Server 2003, including IWAM_*ComputerName*, see Managing a Secure IIS 6.0 Solution and IIS and Built-in Accounts.

# Performance Considerations When Choosing an Application Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you run IIS 6.0 in IIS 5.0 isolation mode, applications that run in Medium or High isolation incur a performance penalty when COM uses a remote procedure call (RPC) during these parts of the request processing cycle:

- When a request is sent to an application that is running in Medium or High isolation and the response is sent back.
- When a Web application that is running in Medium or High isolation communicates with the Web server during the processing of a request.

In contrast, when IIS 6.0 runs in worker process isolation mode, applications are loaded in-process to W3wp.exe and remain there. Therefore, no performance penalty is incurred.

| **Note** |
| --- |
| You cannot run SSI and Internet Database Connector (IDC) applications out-of-process. You need to run these applications in-process. |

For more information about performance issues, see Performance Tuning and Optimizing IIS 6.0 Performance.

# Setting an Application Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

After configuring the IIS application server role and enabling dynamic content, configure the application isolation mode for the server. IIS 6.0 can run in one of two application isolation modes: worker process isolation mode, which is the default mode for IIS 6.0, or IIS 5.0 isolation mode. To configure IIS 6.0 to run in a specific application isolation mode, use either IIS Manager or the Adsutil.vbs administrative utility.

If you are configuring IIS to run in IIS 5.0 isolation mode, after setting the application isolation mode, you must perform the additional task of setting the level of isolation for each application hosted on the server.

For information about choosing the appropriate application isolation mode for your environment, see Choosing an Application Isolation Mode. For more information about configuring the application mode for a server, see Configuring Isolation Modes.

# Setting Isolation for Applications Running in IIS 5.0 Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

If you configured the server to run in IIS 5.0 isolation mode, you must now set the level of application protection, or isolation, for each application that runs on the server. Table 3.5 summarizes the security and performance considerations to take into account when you choose an application isolation mode. If you do not set an isolation level, by default, IIS 5.0 isolation mode runs an application in Medium isolation pooled out-of-process.

**Table 3.5 Isolation Levels in IIS 5.0 Isolation Mode**

| Isolation Level/Host | Protection | Default Security Account | Performance Penalty? |
|---|---|---|---|
| Low/Inetinfo.exe | **In-process.** Not protected from other applications that run in-process. | LocalSystem | |
| Medium/ DLLHost.exe | **Pooled out-of-process.** Protected from the effects of applications that run in High isolation; however, the applications are not protected from each other. | IWAM_*ComputerName* | Yes |
| High/ DLLHost.exe | **Out-of-process.** Protected from the effects of other applications that run in Medium or High isolation; cannot affect other applications running on the same computer. | IWAM_*ComputerName* | Yes |

For more information about the security and performance implications of running applications at each of these application levels, see Security Considerations When Choosing an Application Isolation Mode and Performance Considerations When Choosing an Application Isolation Mode. For more information about setting or changing the level of application protection for applications running in IIS 5.0 isolation mode, see Isolating Applications in IIS 6.0.

# Creating Application Pools

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you run IIS 6.0 in worker process isolation mode, you can isolate different Web applications or Web sites in pools, which are called *application pools*. An application pool is a group of URLs that are routed to one or more worker processes that share the same configuration. The URLs that you assign to an application pool can be for an application, a Web site, a Web directory, or a virtual directory.

In an application pool, process boundaries separate each worker process from other worker processes so that when an application is routed to one application pool, applications in other application pools do not affect that application.

By using an application pool, you can assign specific configuration settings to a worker process (or, in the case of a Web garden, to a set of worker processes) that services a group of applications. For example, you can configure worker process recycling, which offers several configuration options to match the needs of each application. If, for example, you suspect that an application has a memory leak, you might configure the application pools worker process to recycle when its memory use reaches a certain threshold. If another application fails because of the volume of requests that it receives, you can set the application pools worker process to recycle when the application exceeds a specified number of requests.

By creating new application pools and assigning Web sites and applications to them, you can make your server more efficient, reliable, and secure, and ensure that your applications remain available even when a worker process serving an application pool is recycled because of a faulty application.

For more information about the application pool architecture in IIS 6.0, including how application pools work, see IIS 6.0 Architecture. For more information about creating application pools and configuring worker processes, see Configuring Application Pools in IIS 6.0 and Configuring Application Pool Identity with IIS 6.0.

# Guidelines for Creating Application Pools

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Consider the following guidelines when you create application pools:

- To isolate Web applications on a Web site from Web applications on other sites running on the same computer, create an individual application pool for each Web site.

- To improve application security, you can specify a unique user account (process identity) for each application pool. If you specify a unique user account, be sure to add that account to the IIS_WPG group. When you use a built-in account, use Network Service if possible because it offers a better balance between security and functionality.

  | **Note** |
  | --- |
  | If you specify a large number of unique user accounts, your Web server might reach a limit to the number of worker processes you can start under separate identities, in which case, all subsequent application pools fail with a message of Service unavailable. |

  The use of unique user accounts also improves security auditing capabilities, because you can more easily trace security events to the corresponding applications that use the security context — that is, the process identity —of the account listed in the security events. For information about auditing security events, see Auditing in IIS 6.0.

- If you want to configure an application to run with its own unique set of properties, create a unique application pool for that application.

- If you test an application on the same server on which the application is running, create separate application pools and be sure to use different virtual directories for the test and production versions of the application. Using a test application pool for the test virtual directory helps to isolate the test version of the application.

  By running the test version in a separate application pool, you reduce the risk of the test version crashing or corrupting the production version because the applications are separated by process boundaries. However, separation by application pool does not protect any shared resources that both versions use, such as shared COM components or common data sources (for example, flat files, databases, or registry keys). You can improve the isolation of COM components by using side-by-side assemblies, but you must segregate data sources by some other means to completely isolate the applications. For information about using side-by-side assemblies, see Configuring Applications to Use COM+ Services.

# Ensuring Application Health in Worker Process Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Worker process isolation mode provides several features that can help you identify and correct faulty applications in your application pools before they affect your systems or your users. These features often do the work for you, ensuring that you have robust performance and healthy systems:

- **Application pool health monitoring.** Provides the basis for application pool health and health monitoring, including worker process health monitoring and debugging.
- **Recycling worker processes.** Periodically restarts worker processes in an application pool.
- **Rapid-fail protection.** Protects system resources when a worker process that is serving an application pool fails repeatedly within a short period of time.

IIS 5.0 isolation mode does not offer these features.

# Monitoring Application Pool Health

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The WWW service monitors the health of worker processes by periodically pinging them to determine their responsiveness. If a worker process fails to respond to a ping (for example, the worker process might not have available threads to process the incoming request), the WWW service either terminates the worker process and creates another worker process to replace it, or releases the worker process but lets it continue to run. You can configure IIS to perform a specified action when an unhealthy worker process is released — for example, you can specify that IIS attach a debugger to a released worker process.

Additionally, the WWW service maintains a communication channel to each worker process and can detect a drop in the communication channel, which indicates a worker process failure. When a worker process fails of its own accord, the WWW service starts another worker process in its place, provided the application pool does not go into rapid-fail protection.

In addition to monitoring the health of worker processes, the WWW service can detect ongoing problems with the entire application pool by using rapid-fail protection. For example, if worker processes are terminating abnormally every few seconds, the WWW service can determine that the application pool is unhealthy and disable it, preventing the unhealthy application pool from affecting applications in other pools.

The following conditions cause an application pool to start or stop:

- Initiation of rapid-fail protection causes an application pool to stop. For more information about rapid-fail protection, see Configuring Rapid-Fail Protection.

- CPU monitoring shuts down an application pool after it reaches the configured Maximum CPU use limit. When the limit is reached, the application pool shuts down and remains down until the **CPUResetInterval** time limit expires, at which time the application pool restarts. For more information about CPU monitoring, see Enabling CPU Monitoring.

- A configuration error occurs — such as when an incorrect user name or password, or a nonexistent or misconfigured account identity, is used — causing an application pool to stop. For more information about configuring worker process account identities, see Managing a Secure IIS 6.0 Solution and Configuring Worker Process Identities.

- A Windows administrator performs a demand stop or start on an application pool. For more information about performing demand stops and starts on an application pool with the IIsApplicationPool (WMI) class and the IIsApplicationPool (ADSI) class, see the IIS Programmatic Administration Reference in the Platform SDK on MSDN.

You can enable health monitoring for an application pool by using IIS Manager or by using the Adsutil.vbs utility to update metabase properties from the command line. For more information about configuring health monitoring, see Configuring Health Monitoring.

# Using an ISAPI Extension That Declares Itself Unhealthy

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can use an ISAPI extension application that is built to programmatically signal the WWW service that it needs to be recycled. ISAPI developers can configure an ISAPI extension to signal the WWW service by using the **ServerSupportFunction** callback function together with the parameter *HSE_REQ_REPORT_UNHEALTHY*.

The ISAPI extension requires an internal mechanism for determining that it is unhealthy, such as monitoring the status of its internal thread pool. During the ping operation, the WWW service detects whether a worker process is hosting an ISAPI extension that is unhealthy and needs recycling; therefore, for this function to work, you must enable worker process pinging on the application pool that is running the ISAPI extension.

When you use this type of ISAPI extension and pinging is enabled, consider that it will cause a worker process recycle in which the ISAPI extension is running. This affects all applications that are running in that worker process.

The ASP and ASP.NET ISAPI extensions apply logic that takes advantage of this feature as it monitors the status of its internal thread pool. If too many of its threads enter a blocking state, it reports itself as unhealthy, which triggers a worker process recycle if pinging is enabled for the application pool.

For more information about using the **ServerSupportFunction** callback function with *HSE_REQ_REPORT_UNHEALTHY*, see HSE_REQ_REPORT_UNHEALTHY in the IIS Platform SDK on MSDN.

# Enabling Debugging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

By default, when a worker process is determined to be unhealthy, the WWW service terminates the unhealthy process and starts a new worker process to serve new or queued client requests. Optionally, you can allow an application pool to keep the worker process running, but release, or *orphan*, the worker process from the application pool for purposes of debugging while at the same time initializing a new worker process to handle incoming client requests. An orphaned worker process ceases to take new requests from HTTP.sys.

If you enable debugging on an application pool, the WWW service allows an unhealthy worker process to keep running when the WWW service releases the worker process from serving an application pool. When enabling debugging, you can also configure the WWW service to start an executable application or script for a released worker process. For example, the WWW service might start an application that sends you an e-mail notifying you of the failure.

Be sure to closely monitor any worker process that is released from its application pool but continues to run. The worker process can still terminate because the WWW service leaves it running but no longer monitors it, which effectively tells the worker process to shut down without forcing it to do so. If the worker process recovers from its unhealthy state, it detects that it has no relationship to the WWW service and self-terminates. When an orphaned worker process self-terminates, you might find an event log entry stating that a worker process was released but find no evidence of the worker process ever having run.

If you enable debugging on unhealthy worker processes, be sure to monitor these released worker processes, because IIS does not remove them from memory. If you do not correctly handle worker processes that you keep alive for debugging purposes, you can have large numbers of failed worker processes running on your computer. These worker processes can tie up resources needed by other processes. You might need to terminate them quickly to free those resources. In some cases, these worker processes can block metabase access and cause problems with other worker processes or with the WWW service itself.

For more information about setting a metabase property to configure the WWW service to release rather than terminate an unhealthy worker process, see the OrphanWorkerProcess Metabase Property. For more information about configuring IIS to start an executable application or script when a worker process is orphaned, see Troubleshooting IIS 6.0, the OrphanActionParams Metabase Property and the OrphanActionExe Metabase Property.

# Ensuring Application Pool Health

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Health monitoring cannot detect application failures that do not cause the worker process to fail or do not block the available threads in the worker process. For example, an application can return an error response code, such as an HTTP 404 error (Not Found), but still respond normally to a ping from the WWW service. (The exception is an application like a custom ISAPI extension that implements specific code to indicate its unhealthy state.)

At a minimum, monitoring application pool health and taking corrective actions requires that you take the following steps:

- Allow the WWW service to detect unhealthy worker processes by enabling the WWW service to ping worker processes.
- Configure rapid-fail protection to disable application pools when the worker processes assigned to them fail a set number of times within a specified period.

For more information about rapid-fail protection, see Configuring Rapid-Fail Protection.

# Recycling Worker Processes in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

In worker process isolation mode, you can configure IIS to periodically restart worker processes so that you can recycle faulty Web applications. Recycling ensures that applications in those pools remain healthy and that system resources are recovered.

You can configure worker processes to restart based on one of several options, including elapsed time, the number of requests served, scheduled times, and memory usage.

IIS 5.0 isolation mode does not offer these features.

# How Worker Process Recycling Works

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The WWW service can recycle a worker process in one of two ways, both of which do not interrupt service:

- By default, the WWW service establishes an *overlapped recycle*, in which the worker process that is to be shut down is kept running until after a new worker process is started.

- If the applications in an application pool cannot tolerate multi-instancing, you can optionally configure the WWW service to shut down a worker process and then start a new worker process. Use this type of recycling only if the applications in the application pool cannot tolerate multi-instancing. To turn off overlapped recycling, set the **DisallowOverlappingRotation** metabase property to **true**.

When a worker process requests a recycle, the WWW service initiates an overlapped recycle, creating a new worker process to replace the old one. While the new worker process is starting, the old process continues to serve requests. After the new process starts and initializes successfully, the WWW service instructs the old worker process to shut down. At this point, the old worker process stops accepting new requests from HTTP.sys and begins to shut down. The WWW service allows the old worker process a configured time period in which to finish processing its requests before the worker process is shut down. The WWW service terminates the worker process if it fails to shut down within the configured time.

With overlapped recycling, the old worker process remains in communication with HTTP.sys to handle requests until the new worker process is running. HTTP.sys establishes and maintains TCP/IP connections. When the WWW service recycles a worker process, it does not disconnect the existing TCP/IP connection. However, because the shutdown timeout value of a shutdown or startup is configurable, the worker process can be terminated while it is still serving requests if it does not finish servicing existing requests within the time limit.

If the application pool is a Web garden, which uses a set of equivalent worker processes, and you configure worker process recycling based on elapsed time, all the worker processes are recycled during the elapsed time set, but they are not recycled all at once. Worker process recycling in a Web garden is spread over the time set to reduce interruptions of service to client requests and to reduce the impact of restarting all processes at the same time.

Similarly, when you configure a Web garden to recycle applications based on the number of requests processed, recycling takes place at intervals in order to spread out the overhead that is associated with the worker process recycling.

For more information about Web gardens and how to configure them, see Configuring Web Gardens in IIS 6.0. For more information about how you can recycle a Web garden based on length of time, including examples of Web garden recycling, see Deploying ASP.NET Applications in IIS 6.0.

# When and How to Use Worker Process Recycling

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Consider the following guidelines when you decide whether to enable worker process recycling. Worker process recycling is not intended as a replacement for fixing a faulty application; however, recoding is not always an option, especially in cases when other application code is running that cannot be modified.

Consider using recycling in these situations:

- Your Web server hosts faulty applications that you cannot fix.
- Your Web server is experiencing undetermined or intermittent problems.
- Performance monitoring suggests that an application is leaking memory.
- You have implemented a temporary reset solution, such as a scheduled execution of the IISReset utility or a scheduled restart.

You might not need to use recycling in these situations:

- You are hosting a Web site that contains static content only and no custom ISAPI applications.
- You are hosting an application that is thoroughly tested and does not have memory or resource allocation issues.

To effectively use recycling, see Table 3.6, which presents the criteria on which recycling can be based.

**Table 3.6 When to Use Each Recycling Option**

| Recycle Trigger | Timing of Recycling | Conditions for Use |
|---|---|---|
| ISAPI unhealthy request | Recycles based on a request from an ISAPI extension in an application pool. | An ISAPI extension is built to declare itself unhealthy and pinging is enabled. |
| Elapsed time | Recycles after a specified number of minutes. | Applications cannot run for extended time periods. |
| Number of requests | Recycles when the number of HTTP requests exceeds a specified number of requests. | Applications fail because of the quantity of requests that they receive. |
| Scheduled times | Recycles at specified times within a 24-hour period. | Applications cannot run for an extended time period, or you want to periodically refresh applications during times of low use, such as on weekends or during late evening and early morning. |
| Virtual memory | Recycles when the worker process virtual memory (reserved plus used) reaches a specified maximum. | The memory heap becomes fragmented, which is caused by applications reserving memory multiple times. A steady increase in the use of virtual memory can indicate a fragmented memory heap. |
| Used memory | Also called *private memory*. Recycles when the memory that is used by the worker process reaches a specified maximum. | Some applications have memory leaks. |

| | | |
|---|---|---|
| User demand | Recycles when you use IIS Manager to manually recycle all the worker processes in an application pool, or when you run a script that calls the Recycle() method for the application pool. | A single application is causing problems while other sites are running, and you need to act quickly. Consider recycling the application pool instead of resetting the entire WWW service. |

For additional information about configuring worker processes for recycling, see Recycling Worker Processes with IIS 6.0, which provides detailed instructions for recycling worker processes immediately or based on the following criteria: elapsed time, number of processing requests, scheduled time, and maximum memory used.

# Logging Worker Process Recycling Events

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

By setting the metabase property **LogEventOnRecycle**, you can direct the WWW service to log worker process recycling events in the Windows Server 2003 system log. You can use **LogEventOnRecycle** parameters to monitor and log recycle events based on the following criteria:

- Time consumed
- Requests processed
- Scheduled recycles
- On-demand recycles initiated by an administrator
- Memory consumed (both virtual and physical)
- Changes in application pool properties
- ISAPI unhealthy requests

For more information about logging worker process recycling events, see the LogEventOnRecycle Metabase Property.

# Configuring Rapid-Fail Protection

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When a worker process fails, the WWW service detects the failure and takes action, such as logging the event and restarting the process. You can also configure IIS so that if a worker process fails multiple times within a specified time period, its application pool is disabled to protect other application pools that are running on the same computer. This feature, known as *rapid-fail protection*, stops application pools from a continuous cycle of failing and restarting, which uses up system resources.

The WWW service shuts down an application pool whenever a worker process in the application pool fails often enough to equal or exceed the Rapid-Fail Protection (RFP) interval time window (for example: five failures in five minutes). The WWW service detects failure whenever:

- A worker process does not start within the startup time limit.
- A worker process does not shut down within the shutdown time limit.
- A worker process shuts itself down because of a fatal error and sends the WWW service an error code.
- A worker process fails to respond to a ping message.
- The WWW service detects that a worker process is sending non-standard communications (the worker process may have been taken over).

Rapid-fail protection places the disabled application pool in out-of-service mode, and HTTP.sys returns a 503 error (Service Unavailable) message for requests to that portion of the namespace, including requests that have already been queued for the disabled application pool. In addition, you can configure IIS so that when an application pool is stopped automatically, a specified action occurs, such as running a debugger or notifying the administrator that the application pool has stopped.

| **Note** |
| --- |
| Alternatively, HTTP.sys can do a connection reset based on the configuration of the **LoadBalancerCapabilities** property of the application pool. However, if a single computer hosts multiple applications, be sure to configure load balancers or switching hardware to reroute only the traffic intended for a failed application pool. Do not route requests away from healthy application pools, which can still receive and process requests. |

The rapid-fail protection feature is unavailable when IIS 6.0 is running in IIS 5.0 isolation mode. For more information about configuring rapid-fail protection, see Configuring Rapid-Fail Protection in IIS 6.0.

# Managing Resources in Worker Process Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0, when running in worker process isolation mode, offers several features that you can use to better manage your systems resources and to help maintain healthy and robust systems:

- Configure Web gardens.
- Configure idle timeout for a worker process.
- Configure startup and shutdown time limits.
- Enable CPU monitoring.
- Assign processor affinity.

# Configuring Web Gardens in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

In worker process isolation mode, you can configure an application pool to be supported by multiple worker processes. An application pool that uses more than one worker process is called a *Web garden*. (Web gardens are to be distinguished from *Web farms*, which use multiple servers for a Web site.)

| **Important** |
| --- |
| Web gardens can reduce contention for system resources, such as threads, but they can also cause resource contention. For example, if application resources are designed for exclusive access by a single process, such as a flat file used for temporary storage, resource contention can occur between the worker processes within a Web garden. Also, there are documented application characteristics (singletons) for which Web gardens might cause increased contention. |

Creating a Web garden for an application pool enhances performance and reliability in the following ways:

- Robust processing of requests. When a worker process in an application pool is tied up (for example, when a script engine stops responding), other worker processes can accept and process requests for the application pool.

- Reduced contention for resources. When a Web garden reaches a steady state, each new TCP/IP connection is assigned, according to a round-robin scheme, to a worker process in the Web garden. The round-robin scheme smoothes out workloads and reduces contention for resources that are bound to a worker process.

For more information about configuring Web gardens, see Configuring Web Gardens with IIS 6.0.

# Configuring Idle Timeout for a Worker Process

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can conserve system resources by configuring worker processes to shut down after a specified period of inactivity. This feature, known as *idle timeout*, can be used to better manage system resources when the processing load is heavy, when identified worker processes are consistently idle, or when new processing space is not available. If an application pool is shut down due to inactivity and HTTP.sys receives a request for the idle application pool, the WWW service starts a new worker process to replace the one that timed out.

For more information about configuring idle timeout, see Configuring Worker Processes for Idle Timeout.

# Configuring Shutdown and Startup Time Limits

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

For a worker process that has a requested recycle, you can set the maximum time that the worker process continues to process requests before it shuts down. When you set the shutdown time limit (the default is 90 seconds), consider that a worker process shuts down gracefully when the configured shutdown time is long enough to allow it to finish processing its queued requests. Be sure you tune the shutdown time period to fit the load characteristics of the applications that are being processed. If the worker process cannot shut down within the configured time limit, a termination event appears in the event log even when the application shuts down gracefully.

You can also configure a startup time limit (the default is 90 seconds), which specifies how long the WWW service waits for a worker process to start before identifying the worker process as unhealthy and in need of being shut down.

For more information about configuring shutdown and startup time limits, see Configuring Startup and Shutdown Time Limits.

# Enabling CPU Monitoring

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

By using CPU monitoring, you can monitor worker processes for CPU usage and optionally shut down the worker processes that consume large amounts of CPU time. CPU monitoring is only available in worker process isolation mode.

To configure CPU monitoring for individual application pools, choose between two monitoring options: error event logging or the shutdown of all worker processes in the application pool that is consuming more CPU time than the specified limit.

Event logging

When the CPU usage for a specific application pool reaches a set limit, the WWW service writes an error to the Windows Server 2003 system log, which can be viewed in Event Viewer. The entry includes the worker process identifier and the name of the application pool that exceeded the CPU limit.

To view the event log, open Control Panel and access **Event Viewer** through Administrative Tools. Then double-click the system event log.

Shut down the unhealthy application pool (also includes event logging)

When you choose this option, IIS logs an error in the system log and shuts down all worker processes in the application pool. After the application pool shuts down, HTTP.sys returns an out-of-service message (503: Service Unavailable) for any request that is received during the interval when the application pool is stopped. The application pool remains shut down until the CPU reset interval (set by the **CPUResetInterval** metabase property) elapses. IIS then restarts the application pool, and CPU monitoring starts over again.

Obtaining more detailed CPU monitoring

If your Web server is running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, you can use Windows System Resource Manager to obtain more detailed CPU monitoring. Using Windows System Resource Manager, you can control how CPU resources are allocated to applications, services, and processes. For more information, see Windows System Resource Manager Frequently Asked Questions.

Enabling CPU Monitoring

You can enable CPU monitoring by using either IIS Manager or from the command line.

Enabling CPU monitoring from the command line can take as many as three steps:

- Set the **CPULimit** metabase property, which limits the worker processes in a specified application pool to a percentage of CPU time.
- Set the **CPUResetInterval** metabase property, which specifies the time interval for CPU monitoring.
- Set the **CPUAction** metabase property, which specifies the type of action you want IIS to take, such as write to the event log or shut down worker processes that exceed the CPU limit. Table 3.7 lists the possible values for **CPUAction**. Use only one value from the table for each application pool. If you do not set the **CPUAction** metabase property, IIS assigns the default value, which is zero (event logging only).

**Table 3.7 Values for the CPUAction metabase property**

| Value | Description |
|---|---|
| 0 | Writes a warning to the system log in Event Viewer when the worker processes for the application pool exceed the CPU limit, but takes no other action. |
| 1 | Writes a warning to the system log, and shuts down worker processes in the application pool, when the worker processes exceed the CPU limit. |

For more information about enabling CPU monitoring by using IIS Manager and from the command line, see Enabling CPU Monitoring in IIS 6.0.

# Assigning Processor Affinity

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

To efficiently use CPU caches on multiprocessor servers, you can configure application pools to establish affinity between worker processes and the processors, a feature known as *processor affinity*. Processor affinity forces worker processes to run on specific CPUs, and applies to all worker processes serving a particular application pool. You can also use processor affinity with Web gardens that run on multiprocessor computers where specific application pools are dedicated to specific clusters of CPUs.

Processor affinity typically yields the greatest performance benefits when you configure affinity on a computer that has eight or more processors. You can set processor affinity from the command line by using the **set** command with Adsutil.vbs. To set processor affinity, configure the **SMPAffinitized** and **SMPProcessorAffinityMask** metabase properties.

Table 3.8 shows which processors, on a computer with eight processors, are made available to worker processes that serve an application pool when various processor affinity masks are assigned.

**Table 3.8 Sample Processor Affinity Mask Values for Binding an Application Pool to Specific Processors on an Eight-Processor Computer**

| Hexadecimal Mask (Binary Representation) | Processor7 | Processor6 | Processor5 | Processor4 | Processor3 | Processor2 | Processor1 | Processor10 |
|---|---|---|---|---|---|---|---|---|
| 0x2 (0010) | | | | | | | Yes | |
| 0x5 (0101) | | | | | | Yes | | Yes |
| 0xD (1101) | | | | | Yes | Yes | | Yes |
| 0xF (1111) | | | | | Yes | Yes | Yes | Yes |
| 0x11 (00010001) | | | | | Yes | | | Yes |
| 0x1E | | | | Yes | Yes | Yes | Yes | |
| 0xF0 (11110000) | Yes | Yes | Yes | Yes | | | | |
| 0xFE | Yes | Yes | Yes | Yes | Yes | Yes | Yes | |
| 0xFF | Yes | Yes | Yes | Yes | Yes | Yes | Yes | Yes |

[1] Processor numbering begins with 0.

If you extend the table, a hexadecimal value of 0xFFFFFFFF (maximum value) allows all processors up to 32 to be available to worker processes that serve an application pool.

For more information about processor affinity mask settings, see the SMPProcessorAffinityMask Metabase Property and the SMPAffinitized Metabase Property. For more information about using the **set** command with Adsutil.vbs, see Processor Affinity.

# Running Web Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

With IIS 6.0 as your application server, you can use the latest Web application platforms and standards, such as ASP.NET, XML, and Simple Object Access Protocol (SOAP), to develop, implement, and manage your Web applications. While continuing to build on the ISAPI programming model, IIS 6.0 provides several new features, including custom errors, server-side redirection, streamlined file and buffer response, and improved Unicode support.

# Enhancements to ISAPI Support

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 supports both ISAPI extensions and ISAPI filters:

- *ISAPI extensions* are DLLs that handle specific requests.
- *ISAPI filters* are DLLs that you can register with IIS to modify the behavior of the server.

ISAPI extensions and filters load the first time a client requests resources that are processed by the ISAPIs and are kept in memory to handle future requests. ISAPI extensions handle specific requests from the client.

Like ISAPI extensions, ISAPI filters are programs that respond when the application server receives an HTTP request. Unlike ISAPI extensions, ISAPI filters are driven by Web server events instead of client requests. For example, you can write an ISAPI filter to control which files are mapped to a URL, modify the response sent by the server, and perform other actions to modify the behavior of the server.

IIS 6.0 supports these programmatic enhancements to ISAPI extensions:

- **HSE_REQ_EXEC_URL**
- **HSE_REQ_VECTOR_SEND**
- **HSE_REQ_REPORT_UNHEALTHY**
- **HSE_REQ_SEND_CUSTOM_ERROR**

These enhancements are new **ServerSupportFunction** callback functions, known as *support functions*. The **ServerSupportFunction** function, which returns data for several auxiliary functions that are not covered by other callback functions, is supplied in the EXTENSION_CONTROL_BLOCK structure that is associated with HTTP requests. IIS and the ISAPI extensions use the EXTENSION_CONTROL_BLOCK structure to exchange information.

For more information about ISAPI filters and extensions, including the **ServerSupportFunction** callback functions, see the IIS Web Application Technology Reference on MSDN.

Using HSE_REQ_EXEC_URL to Call Other URLS on the Server

The **HSE_REQ_EXEC_URL** support function (also known as **ExecuteURL**) allows ISAPI extensions to rewrite any part of the request, including the entity body, and have IIS reprocess this modified request. As long as the rewritten URL is in the same application pool and uses the same authentication, IIS can successfully reprocess the modified request.

This new support function gives ISAPI developers greater flexibility in transparently rewriting URLs on the server without the clients knowledge, allows an arbitrary number of URLs to be executed in a chain, and supports custom authentication. When used with wildcard application mapping, this support function can replace most read raw data filters by offering easy examination and modification of request entity body prior to request reprocessing. For information about wildcard application mapping, see Setting Application Mappings.

Using HSE_REQ_VECTOR_SEND to Consolidate Multiple Buffers

The **HSE_REQ_VECTOR_SEND** support function (also known as **VectorSend**) allows developers to group and send, in order, a list of buffers and file handles. This list is handed to IIS 6.0 and passed on to HTTP.sys, which compiles all the buffers and file handles within the kernel and then directly sends the group in one kernel-mode transition. This new functionality frees ISAPI from building large memory buffers or making multiple **WriteClient** calls.

In earlier versions of IIS, ISAPI developers have only two possibilities if they have multiple buffers that make up a response: they can either call **WriteClient** multiple times or assemble the response in one big memory buffer. The first approach causes a performance bottleneck because there is one kernel-mode transition for each **WriteClient** function call. The second approach also affects performance and uses additional memory. **VectorSend** is a more all-purpose transmit function for IIS 6.0 customers.

Using HSE_REQ_REPORT_UNHEALTHY to Recycle a Worker Process

The **HSE_REQ_REPORT_UNHEALTHY** support function (also known as **ReportUnhealthy**) allows an ISAPI extension to request that its worker process be recycled. Developers can use this new function to request a recycle if their ISAPI application becomes unstable or enters an unknown state. Note that in order to cause a recycle after an ISAPI calls **ReportUnhealthy**, health monitoring must be enabled for the ISAPI extensions application pool. When calling **ReportUnhealthy**, the developer can also pass in a string representing the reason why the ISAPI extension is calling **ReportUnhealthy**. This string is then added to the event that the worker process writes to the application log, which you can view in Windows Server 2003 Event Viewer.

Using HSE_REQ_SEND_CUSTOM_ERROR to Send Custom Error Messages

The **HSE_REQ_SEND_CUSTOM_ERROR** support function (also known as **SendCustomErrors**) allows ISAPI developers to send the client a specific IIS-configured custom error message, including all sub-error codes. This support function allows an ISAPI extension to better integrate its error messages with a Web sites custom error configuration.

Using the New Unicode ServerSupportFunctions

In addition to the preceding enhancements, IIS 6.0 allows ISAPI extensions to retrieve server variable values that are encoded as Unicode characters. In particular, ISAPI extensions can retrieve the request URL in Unicode, which can benefit international companies that have multilanguage Web sites for which the URL is not in the same code page as the server.

The following are new **ServerSupportFunction** callback functions that support values encoded as Unicode characters:

**HSE_REQ_EXEC_UNICODE_URL**

The **HSE_REQ_EXEC_UNICODE_URL** support function is functionally identical to **HSE_REQ_EXEC_URL** except that it expects the URL to be in Unicode instead of ANSI. This support function, when used with the new Unicode **GetServerVariable**, easily substitutes for **HSE_REQ_EXEC_URL**.

**HSE_REQ_MAP_UNICODE_URL_TO_PATH**

Allows your ISAPI extension to map a logical URL path to a physical path.

**HSE_REQ_MAP_UNICODE_URL_TO_PATH_EX**

Allows your ISAPI extension to map a logical URL path to a physical path, as well as gather several types of attributes that are associated with that physical path, such as access-control or cache-control flags.

# Using ASP in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

ASP is a server-side scripting environment that you can use to create dynamic and interactive Web pages, and powerful Web applications. When the server receives a request for an ASP file, it processes the server-side script code contained in the ASP file to build a Hypertext Transfer Protocol (HTML) Web page, which is sent to the browser.

In addition to server-side script code, ASP files can contain HTML (including related client-side scripts) and calls to COM components that perform a variety of tasks, such as connecting to a database or processing business logic.

Because ASP scripts run on the server rather than on the client, your Web server does all the work involved in generating the HTML pages sent to browsers. Because only the result of the script is returned to the browser, the client cannot access the server-side scripts; therefore, users cannot view the script commands that created the page they are viewing.

For more information about ASP pages, see the IIS Web Development in the IIS Software Development Kit (SDK) on MSDN. For more information about writing server-side scripts with ASP and creating ASP applications, see the MSDN Library.

# Improvements to the ASP Programming Environment

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

In IIS 6.0, you can make use of the following enhancements to the ASP programming environment:

- Improved international and UTF-8 support. UTF-8 support has been expanded to include all ASP built-in object properties and methods. The previous version of ASP supported UTF-8 only for Response.Write.
- Improved POST support. ASP can now read chunked-encoded POST data from a client.
- UNC enhancements. If your ASP scripts reside on a Universal Naming Convention (UNC) share, ASP has improved performance in executing those scripts. For information about configuring IIS 6.0 with remotely stored content on UNC servers, see Deploying and Configuring Internet Information Services (IIS) 6.0 with Remotely Stored Content on UNC Servers and NAS Devices.
- Optional script source access in ASP pages. *Script source access*, which allows access to the source code of scripts in ASP pages and other scripts, is new and is disabled by default. To enable script source access, you must select either Read or Write permission.
- COM+ services in ASP. You can now configure your ASP applications to use the following COM+ services without having to create a COM component:
    - Apartment model selection
    - Side-by-side assemblies
    - COM+ partitions
    - COM+ tracker

**COM+ Services in ASP**

In previous versions of IIS, if you wanted to use COM+ services from an ASP application, you had to create a COM component to call the methods of those services. In IIS 6.0, COM+ services are separate from the components. This separation allows ASP applications to use a set of COM+ services without instantiation by any COM components. Because of this separation, you can configure your ASP application to use the following COM+ services without having to create a COM component.

| **Note** |
| --- |
| Batch Logon is required for COM+ server-activated application identities. COM+ will add this automatically when you enter a new account for the identity of a COM+ application using the UI. Batch Logon gives your application the ability to execute code across servers, but does not allow the account to logon interactively to home server. |

Since only side-by-side assemblies can be enabled using IIS Manager, example code for enabling each service on an ASP application is provided below.

This topic includes the following information:

- Apartment Model Selection
- Side-by-Side Assemblies
- COM+ Partitions
- COM+ Tracker

**Apartment model selection**

ASP is now capable of running all of its threads in a multithreaded apartment (MTA). If your COM components are primarily free-threaded or both-threaded, running the ASP threads as MTA can improve performance significantly.

To enable an ASP application to run in an MTA, set the **AspExecuteInMTA** metabase property at the application level. This enables you to have one application running on ASP MTA threads and a second application running on ASP single-threaded apartment (STA) threads. By default, ASP runs applications in the STA.

| **Important** |
| --- |
| When you switch an ASP application from running in STA to MTA (or from MTA to STA), the impersonation token becomes obsolete, which can cause the application to run with no impersonation. Without impersonation, the application runs with the identity of the process, which might allow access to other resources. If you must switch threading models, disable and unload the application before you make the change. |

The following example sets the Default Web Site application (*W3SVC/1/ROOT*) to execute in MTA:

```
On Error Resume Next
set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
' Get a reference to the ASP application called Default Web Site
set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
WScript.Echo "Before: AspExecuteInMTA = " & IIsWebVirtualDirSettingObj.AspExecuteInMTA
' Set the ASP application to execute in MTA
IIsWebVirtualDirSettingObj.AspExecuteInMTA = 1
IIsWebVirtualDirSettingObj.Put_()
WScript.Echo "After: AspExecuteInMTA = " & IIsWebVirtualDirSettingObj.AspExecuteInMTA
```

**Side-by-side assemblies**

Side-by-side (SxS, in metabase property names) assemblies allow ASP applications to specify which version of a system DLL or shared COM component to use. For example, if your ASP application relies on MSXML version 2.0, you can ensure that your application still uses MSXML 2.0 even if a later version is installed on the computer for use by other applications.

Configuring SxS assemblies requires that you know the path to the DLL, and that the COM+ manifest file exists in every virtual directory that requires the use of the DLL. The COM+ manifest is an XML file that contains information about where a DLL is installed. IIS does not verify that the manifest exists. A manifest looks like the following file excerpt:

```
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>
<assembly xmlns="urn:schemas-microsoft-com:asm.v1" manifestVersion="1.0">
<assemblyIdentity publicKeyToken="75e377300ab7b886" type="win32" name="Test4Dir"
version="1.0.0.0" processorArchitecture="x86"/>
<file name="DirComp.dll" hash="35ca6f27b11ed948ac6e50b75566355f0991d5d9"
hashalg="SHA1">
<comClass clsid="{6C6CC20E-0F85-49C0-A14D-D09102BD7CDC}" progid="DirComp.PathInfo"
threadingModel="apartment"/>
<typelib tlbid="{AA56D6B8-9ADB-415D-9E10-16DD68447319}" version="1.0" helpdir=""/>
</file>
</assembly>
```

You can enable side-by-side assemblies either programmatically or by using IIS Manager. To programmatically enable side-by-side assemblies, set the **AspEnableSxs** flag of the **AspAppServiceFlags** metabase property to **true**. Also, set the **AspSxsName** metabase property to the name of the COM+ manifest. Set both metabase properties at the application level.

| **Important** |
| --- |
| Even though this feature is configurable at the application level, you must not use more than one version of a system DLL in any IIS6.0 application pool. If you load more than one version of a system DLL in an application pool, the application that is loaded first has its version loaded and the other applications are forced to use that DLL until the applications are unloaded. |

The following example enables side-by-side assemblies on the Default Web Site application (*W3SVC/1/ROOT*). Notice that after setting only the **AspEnableTracker** property, the **AspAppServiceFlags** property changes as well:

```
On Error Resume Next
set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
' Get a reference to the ASP application called Default Web Site
set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
```

```
WScript.Echo "Before: AspEnableSxs = " & IIsWebVirtualDirSettingObj.AspEnableSxs
WScript.Echo "        AspSxsName = " & IIsWebVirtualDirSettingObj.AspSxsName
WScript.Echo "        AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
' Set the ASP application to enable COM+ side-by-side assemblies
IIsWebVirtualDirSettingObj.AspEnableSxs = 1
' Set the AspSxsName property
IIsWebVirtualDirSettingObj.AspSxsName = "VersionInfo"
' Save the values to the IIS metabase
IIsWebVirtualDirSettingObj.Put_()
' Get the reference again in order to refresh the AspAppServiceFlags property.
set IIsWebVirtualDirSettingObj = Nothing
set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
WScript.Echo "After: AspEnableSxs = " & IIsWebVirtualDirSettingObj.AspEnableSxs
WScript.Echo "       AspSxsName = " & IIsWebVirtualDirSettingObj.AspSxsName
WScript.Echo "       AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
```

**COM+ partitions**

You can use COM+ partitions to isolate Web applications in their own COM+ partitions. Isolation is useful to prevent one Web application from accessing the private COM+ applications, configuration information, and data of another Web application.

COM+ partitions can hold different versions of your own custom COM components. For example, if you host Web sites for two competing companies that both use COM+ in their Web applications, you can use COM+ partitions to ensure that one company's Web application cannot access the COM+ components in the other company's Web applications. If one of those companies asks you to change certain features in a COM+ application that both companies use, you can isolate the new version of that COM+ application in the partition that is linked to that company's Web application.

To enable COM+ partitions in IIS, set the **AspUsePartition** flag of the **AspAppServiceFlags** metabase property at the application level. The partition is identified by a globally unique identifier (GUID) (created by using the Component Services Manager snap-in), which is set by the **AspPartitionID** metabase property. If no partition is specified, the default system partition is used. For more information, please see "Creating and Configuring COM+ Partitions" in the COM+ SDK or online at COM+ (Component Services).

| **Important** |
| --- |
| Even though you can configure this feature at the application level, use only one version of a COM+ component in any application pool. For example, if application App1 uses version1.0 of a custom COM+ application called Shop.dll, and application App2 uses version2.0 of Shop.dll, App1 and App2 cannot be in the same application pool. If you put them in the same application pool, the application that you load first has its version of Shop.dll loaded, and the other application is forced to use that version until the applications are unloaded. |

The following example enables partitions on the Default Web Site application (*W3SVC/1/ROOT*). Notice that after setting only the **AspEnableTracker** property, the **AspAppServiceFlags** property changes as well.

```
On Error Resume Next
set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
' Get a reference to the ASP application called Default Web Site
set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
WScript.Echo "Before: AspUsePartition = " & IIsWebVirtualDirSettingObj.AspUsePartition
WScript.Echo "        AspPartitionID = " & IIsWebVirtualDirSettingObj.AspPartitionID
WScript.Echo "        AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
' Set the ASP application to enable COM+ partitioning
IIsWebVirtualDirSettingObj.AspUsePartition = 1
' Set the AspPartitionID property to the GUID configured in Component Services Manager
' when you created the COM+ partition
IIsWebVirtualDirSettingObj.AspPartitionID = "{00000000-0000-0000-0000-000000000000}"
' Save the values to the IIS metabase
IIsWebVirtualDirSettingObj.Put_()
' Get the reference again in order to refresh the AspAppServiceFlags property.
set IIsWebVirtualDirSettingObj = Nothing
set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
WScript.Echo "After: AspUsePartition = " & IIsWebVirtualDirSettingObj.AspUsePartition
WScript.Echo "       AspPartitionID = " & IIsWebVirtualDirSettingObj.AspPartitionID
WScript.Echo "       AspAppServiceFlags = " &
```

```
IIsWebVirtualDirSettingObj.AspAppServiceFlags
```

**COM+ tracker**

COM+ tracker allows you to debug ASP applications. For example, if you need to diagnose and fix a faulty Web application, you can enable COM+ tracker to determine when ASP pages are being loaded, when COM components are loaded, and when threads leave a page. After debugging your application, you can disable COM+ tracker to return your application to normal performance speed.

To enable COM+ tracker on the IIS side, set the **AspEnableTracker** flag of the **AspAppServiceFlags** metabase property at the application level.

The following example enables tracking on the Default Web Site application (*W3SVC/1/ROOT*). Notice that after setting only the **AspEnableTracker** property, the **AspAppServiceFlags** property changes as well:

```
On Error Resume Next
set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
' Get a reference to the ASP application called Default Web Site
set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
WScript.Echo "Before: AspEnableTracker = " &
IIsWebVirtualDirSettingObj.AspEnableTracker
WScript.Echo "        AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
' Set the ASP application to enable COM+ tracking
IIsWebVirtualDirSettingObj.AspEnableTracker = 1
IIsWebVirtualDirSettingObj.Put_()
' Get the reference again in order to refresh the AspAppServiceFlags property.
set IIsWebVirtualDirSettingObj = Nothing
set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
WScript.Echo "After: AspEnableTracker = " & IIsWebVirtualDirSettingObj.AspEnableTracker
WScript.Echo "       AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
```

For more information about these enhancements to COM+ services in ASP, including application examples of each, see What's New in ASP.

**New Metabase Properties for ASP**

Table 3.9 describes the metabase properties for ASP that are new in IIS 6.0.

**Table 3.9 New ASP Metabase Properties in IIS 6.0**

| Property | Purpose |
|---|---|
| **AspAppServiceFlags** | Contains the flags that must be set to enable COM+ services on your IIS applications. |
| **AspDiskTemplateCacheDirectory** | Specifies the location of the ASP disk cache. |
| **AspExecuteInMTA** | Enables ASP threads to execute in an MTA. |
| **AspKeepSessionIDSecure** | Sends the ASP session cookie to a browser securely. |
| **AspMaxDiskTemplateCacheFiles** | Specifies the maximum number of compiled ASP templates that can be stored. |
| **AspPartitionID** | Sets the COM+ partition to use for the application. |
| **AspRunOnEndAnonymously** | Enables ASP to run the **Global.asa Application_OnEnd** and **Session_OnEnd** events anonymously. |
| **AspBufferingLimit** | Specifies the buffer size limit. |
| **AspMaxRequestEntityAllowed** | Specifies the maximum number of bytes allowed in the entity body of an ASP request. |
| **AspSxsName** | Allows ASP applications to specify which version of a system DLL or COM component to use. |

For more information about how to use these new metabase properties, see the Metabase Property Reference.

# Security and Performance Enhancements in ASP

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

In IIS 6.0, ASP has undergone several important changes to improve security and performance:

- Default disabling of ASP pages during clean installations of IIS 6.0. In a default installation, the IIS service is installed in a secure mode, and only serves static content. You must enable features such as ASP, ASP.NET, CGI, ISAPI, and WebDAV if you need them. For more information about these features, including how to enable them, see Enabling Dynamic Content.

- Secure ASP built-in functions. All ASP built-in functions always run as the low-privileged account, IUSR_*ComputerName*, or under an authenticated user account if one is selected and has valid credentials.

- Default disabling of parent paths. As a security precaution, the metabase property **AspEnableParentPaths** is now set to zero by default. This new default setting affects Web pages that contain or use the .. notation to refer to a parent directory in the #include SSI directive. Unless you explicitly set this property to **true**, such Web pages do not respond to a client request (they instead generate a Disallowed Parent Path message).

- ASP hang detection. When an IIS Web site is busy, there might be instances when the maximum number of ASP threads are spawned and some of the ASP threads hang, resulting in degraded performance. (Threads are considered to be hung if they do not respond to a timeout.) If sufficient ASP requests hang so that ASP cannot service requests quickly, ASP detects this unhealthy state and requests that the worker process recycle itself.

- Monitoring of disk-based caching. The Active Server Pages performance object now provides the Templates Cached counter to monitor disk-based caching in addition to in-memory caching. This counter counts the number of cached ASP files, both on disk and in memory. A new ASP counter, In Memory Templates Cached, reports the number of ASP pages in the memory cache. The default location of the ASP disk cache is *systemroot*\System32\Inetsrv\ASP Compiled Templates. You can change the cache location by setting the **AspDiskTemplateCacheDirectory** metabase property.

- Anonymous user access for Global.asa events. Earlier versions of ASP executed events in the security context (or user identity) of the host process because during these events there was not necessarily a user context. This sometimes caused access denied errors when writing to a file in the Application_OnEnd or Session_OnEnd event. By default, ASP now runs the Global.asa events, Application_OnEnd and Session_OnEnd, anonymously. Setting the **AspRunOnEndAnonymously** metabase property to **true** allows these global ASP functions to run as anonymous user.

- Performance enhancements. To limit the amount of memory allocated to ASP pages, IIS 6.0 sets the default value of the **AspScriptFileCacheSize** metabase property to 500 ASP pages and the default value of the **AspScriptEngineCacheMax** metabase property to 250 script engines. For sites that include a large set of frequently requested ASP pages, you can increase the number of ASP pages allowed by the **AspScriptFileCacheSize** property, which improves performance because ASP page compilation is substantially slower than retrieving pages from cache. On a site with only a small number of frequently requested ASP pages, you can save memory by setting a smaller value.

ASP Metabase Properties No Longer in Use in IIS 6.0

The following metabase properties are no longer used by ASP, even though they are still in the metabase for compatibility with existing administration scripts:

- **AspAllowOutOfProcComponents**

- **AspTrackThreadingModel**

- **AspExceptionCatchEnable**

In IIS 6.0, all properties that relate to ASP thread gating, such as the **ASPThreadGatingModel** property, were removed from

ASP and the metabase. If you are using scripts to upgrade from IIS 5.0, you might need to make manual adjustments for the properties that were removed.

# Setting Application Mappings

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Because you can choose from many programming and scripting languages when you develop Web applications, IIS uses the file name extension of a requested resource on your Web site to determine which ISAPI or CGI program to run to process a request. For example, a request for a file with an .aspx extension causes the Web server to call the ASP.NET ISAPI (Aspnet_isapi.dll) to process the request. The association of a file name extension with an ISAPI or CGI program is called *application mapping* (or sometimes *script mapping* or *application extension mapping*).

IIS 6.0 is preconfigured to support common application mappings. You can add or remove mappings for all of the applications on a Web site or for an individual application. Use IIS Manager to map a file name extension to an application or remove an application mapping. For more information about setting application mappings, see Setting Application Mappings in IIS 6.0.

Benefits of Using Wildcard Application Mappings Instead of ISAPI Filters

You can configure a Web site or virtual directory to run any number of ISAPI applications at the beginning of every request to that Web site or virtual directory, regardless of the file name extension of the requested file. This type of configuration, which can only be an ISAPI application, is called *wildcard application mapping*.

When an IIS Web server receives a request from a client, the Web server looks at the file name extension for the requested file to determine whether an ISAPI or CGI application handles that file type. For example, if a request comes in for a Web page called Default.asp, IIS knows from its default application mappings that ASP files are handled by the Asp.dll ISAPI extension.

Prior to wildcard application mapping, if you wanted certain tasks to be executed for every client request before the requested page was sent to its mapped application, you had to write an ISAPI filter that intercepted requests as they arrived. Wildcard application mapping offers an alternative to ISAPI filters. Although ISAPI filters are excellent for the functions that they perform, they have a more narrow use than do ISAPI applications.

For example, when you use wildcard application mapping, your ISAPI application:

- Can easily access the entity body of a request.
- Can be configured for virtual directories.
- Can contain long-running operations.
- Offers greater flexibility because the ISAPI extension API, which is used to write ISAPI applications, has more functionality than does the ISAPI filter API.

For more information about ISAPI filters, see Installing ISAPI Filters.

Request Handling with Wildcard Application Mappings

Highly secure Web applications, such as banking applications, require that every user who makes a request be authenticated against a database of user names, passwords, and account numbers. After the user is authenticated, certain rules are applied that specify what information the user can access. If the wildcard application map determines that the user has no rights, it can prevent the request from going any farther, or it can redirect the request to a new Web page.

You can implement a custom authentication and authorization scheme like this in an ISAPI application that you install as a wildcard application mapping, and all users must go through authentication regardless of the file type of their requests. For example, when you install wildcard application mappings, IIS processes a client request in this way:

1. An incoming request is handled by any existing ISAPI filters that are installed at the global and Web site levels. IIS executes the ISAPI filters in priority order from global to Web site.

- The request is sent to any existing wildcard application mappings, which IIS also executes in order.
    - If the incoming request for a Web file triggers wildcard application mappings at multiple levels — such as Web site, virtual directory, or nested virtual directories — IIS only executes the wildcard application mappings installed in the virtual directory closest to the Web file. That is, if wildcard application mappings exist at the Web site and

virtual directory level, a request for a Web file in the virtual directory only triggers the wildcard application mappings for the virtual directory.

- If no custom application mappings are installed in a virtual directory, that virtual directory inherits the effective application mappings, including wildcard application mappings, from its parent.

- The IIS server looks at the application mappings table to determine which ISAPI application or CGI script specifically processes the requested resource.

For information about developing ISAPI extensions, see Creating ISAPI Extensions. For information about developing ISAPI filters, see Creating ISAPI Filters.

For more information about application mapping in general, see Setting Application Mappings in IIS 6.0 and Installing Wildcard Application Mappings.

# Additional Resources for Running IIS 6.0 as an Application Server

# Working with the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The metabase is a hierarchical store of configuration information and schema that are used to configure Internet Information Services (IIS) 6.0. Read this section for an overview of the metabase structure and terminology, as well as detailed information about effectively managing the IIS 6.0 metabase by using the graphical user interface (GUI)–based and command-line utilities that are available with IIS 6.0.

**In This Section**

Overview of the IIS 6.0 Metabase

Metabase Structure in IIS 6.0

Metabase Security and Auditing

Backing Up and Restoring the Metabase

Editing the Metabase

Metabase Import and Export

Additional Resources for the IIS 6.0 Metabase

# Overview of the IIS 6.0 Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The Internet Information Services (IIS) 6.0 metabase comprises two plaintext XML files that store IIS configuration values and schema. The metabase can be edited manually, by using IIS Manager, or it can be edited programmatically. In addition, the IIS 6.0 metabase is extensible in a highly efficient manner — as your IIS deployment grows, so does the metabase. By using an inheritance model, explicit declarations of duplicate values are avoided, which reduces overhead when IIS reads configuration values from the metabase.

The metabase is a hierarchical store of configuration information and schema that are used to configure IIS. The metabase configuration and schema for IIS 4.0 and IIS 5.0 were stored in a single binary file named MetaBase.bin, which was not easy to read or edit. IIS 6.0 replaces MetaBase.bin with two XML files named MetaBase.xml and MBSchema.xml. These files are stored on your computer in the *systemroot*\System32\Inetsrv folder. Only users who are members of the Administrators group can view and modify these files.

The metabase configuration file, MetaBase.xml, stores most of the IIS configuration. Some IIS configuration values are also stored in the Windows registry. If a configuration value is one that you might need to configure or change, or if you can access the setting in the IIS 6.0 user interface, then the setting is typically stored in the IIS metabase.

The MetaBase.xml file is organized in a hierarchical structure, which can vary depending on the choices that are made when IIS is installed and, if needed, reconfigured. When IIS is started or restarted, the configuration settings are read from MetaBase.xml and copied into the IIS cache in-memory, which is referred to as the *in-memory metabase*. When IIS Manager or programmatic interfaces are used to change IIS configuration, the changes are made to the in-memory metabase and persisted to MetaBase.xml after a previously configured number of changes, or according to regular time intervals.

In physical terms, the metabase is a combination of the MetaBase.xml and MBSchema.xml files and the in-memory metabase. The IIS configuration information is stored in the MetaBase.xml file, while the metabase schema is stored in the MBSchema.xml file. When IIS is started, these files are read by the storage layer and then written to the in-memory metabase through Admin Base Objects (ABOs), as shown in Figure 4.1.

The metabase configuration and schema are stored in separate nodes in the in-memory metabase. The in-memory metabase itself resides in the IIS file cache in your computer's RAM. While IIS is running, changes that are made to the in-memory metabase are periodically saved to disk. The in-memory metabase is also saved to disk when IIS is stopped.

# IIS 6.0 Metabase Features

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The IIS 6.0 metabase includes the features described below.

**The metabase schema can be modified by an administrator**
Active Directory® Service Interfaces (ADSI) and Windows Management Instrumentation (WMI) use the metabase schema to enforce which properties can be written at a particular key in the metabase. The schema also enforces the data types that can be used for a particular property attribute. You can modify the metabase schema by using ADSI or WMI to customize this enforcement, or to allow out-of -schema properties to be written in the metabase. For information about extending the metabase schema, see The Metabase Schema.

**The metabase is 100 percent compatible with IIS 5.0 metabase APIs**
Because the XML metabase in IIS 6.0 is fully compatible with IIS 5.0 metabase application programming interfaces (APIs), existing scripts and code will continue to work.

**Metabase performance and scalability are improved**
The IIS 6.0 metabase improves performance and scalability over earlier versions of IIS in the following ways:

- Comparable or better disk footprint size compared to the IIS 5.0 metabase
- Faster read times on Web server startup than the IIS 5.0 binary metabase
- Equivalent write performance to the IIS 5.0 binary metabase

**The metabase incorporates rich functionality**
The metabase incorporates rich functionality with the following features:

- Property inheritance
- Data typing of property values
- Change notification when metabase properties change
- Security
- Simplified backup and restore of your IIS configuration
- Easier import and export of individual nodes to other computers

**Benefits of Plaintext XML Files**
Plaintext XML metabase files offer the benefits described below.

**Metabase files can be edited directly by using common text editors**
The metabase configuration file, MetaBase.xml, can be easily read and edited by using common text editors, such as Notepad, which is provided as part of the Microsoft® Windows® operating system. Editing the metabase configuration file directly will be of interest primarily for administrators who do not want to use scripts or code to administer IIS. In addition, editing the metabase configuration file directly is faster than using IIS Manager when administering IIS over a slow network connection. It is recommended that you become familiar with the structure of MetaBase.xml before you attempt to configure IIS by editing the MetaBase.xml file.

| **Important** |
| --- |
| Editing the MBSchema.xml file directly is not supported. Changes made to the metabase schema must be made programmatically by using the IIS ADSI provider. |

**Improved metabase corruption recovery and troubleshooting**

The metabase makes it easier to diagnose potential metabase corruption because the metabase is stored in a plaintext file, and it can be analyzed by using tools such as the WinDiff utility. The WinDiff utility is located in the Deploy.cab file in the \Support\Tools folder of your Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; Windows® Server 2003, Datacenter Edition; or Windows® Server 2003, Web Edition operating system CD. As the metabase is edited and saved to disk, IIS makes copies of each version of the MetaBase.xml and MBSchema.xml files in the History folder. In other words, the metabase history feature is like an automatic backup mechanism. You can use history files to compare changes that have been made to the MetaBase.xml and MBSchema.xml files.

**Improved metabase backup and restore capabilities**

By using Backup/Restore Configuration, administrators can back up the metabase and encrypt it with any password. If a critical failure occurs, the metabase can be restored on a different computer or on a different installation of the operating system. Additionally, the metabase can be restored by using an earlier version of the MetaBase.xml and MBSchema.xml files from the History folder.

# Metabase Terminology

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

MetaBase.xml is structured by using keys. *Keys* are analogous to file folders in a file system or registry keys in the registry. Each key contains a **Location** attribute, which specifies its hierarchical location in the metabase. Properties, which define the values for configuring IIS, are contained in keys. Because MetaBase.xml is structured hierarchically, a particular property can be configured differently at different keys. Properties contain attributes, such as the **Value** attribute.

Table 4.1 summarizes the metabase terminology that is used to describe the structure of the IIS metabase.

**Table 4.1 Metabase Terminology**

| Term | Description |
|---|---|
| Key | A hierarchical container in MetaBase.xml that is used to contain properties. Each key contains the **Location** attribute within the start tag of the key, specifying the hierarchical position of the key in MetaBase.xml. A metabase key is analogous to a file folder or registry key. |
| Location | Each key contains a **Location** attribute — a sequence of location names separated by one or more forward slashes (/) — that uniquely identifies the hierarchical position of the key in MetaBase.xml. For example /LM is the location of the IIsComputer key, and /LM/W3SVC is the location of the IIsWebService key. The latter is a child key of the LM location. A child key is a key that is contained by another key. |
| Property or Custom Property | A property or custom property defines values that are used to configure IIS. Properties contain attributes; some properties, such as **AccessFlags**, also contain flags. Properties are contained by keys and can be written, in MetaBase.xml, as schema-defined or custom. |
| Attributes | Metabase properties contain several attributes that describe some characteristics of the property. Keys also contain attributes, such as the **Location** attribute or the **DefaultDoc** attribute found within the IIsWebService key.<br>Do not confuse the term *attributes* as used here to describe IIS metabase properties with XML attributes, which describe general XML structure. |
| Flag | A flag is a bit within the DWORD value of a property that contains flags. Each flag within a property is used to configure particular functionality of the property, such as read or write access. The sum of the flag values for a property becomes the sum of the value attribute for that property. |

**Keys and Locations**

Metabase keys are analogous to registry keys or a directory in a file system. Each metabase key is identified by its name and location, which are defined within the start tag of the key. The following example shows two keys, IIsConfigObject and IIsLogModules, each having a unique location as defined by the value of its respective **Location** attribute:

Most key names are the same as the value of the **KeyType** property, also known as the ABO class name, which relates to the type of key. The IIsLogModules key, seen in the example above, is named this way. If you change the **KeyType** value of a metabase key programmatically, the name of the key changes in MetaBase.xml when the in-memory metabase is saved. This **KeyType** value is important because the schema-defined collection that is named by using the same **KeyType** enforces which properties the key can contain.

Keys named IIsConfigObject are special because they are not named by using a **KeyType** value. Because all properties are schema-defined in the IIsConfigObjectcollection, keys in MetaBase.xml that are named IIsConfigObject can contain any property. You can specify a **KeyType** value for a key named IIsConfigObject by writing the **KeyType** property in the key as a custom property. This is not a recommended method, however, because it does not work with ADSI. Preferably, use a real object, not IIsConfigObject.

Some key names describe the type of data at a unique location in the metabase, and thus might appear at multiple locations. For example, because you can have more than one virtual directory, IIsWebVirtualDir is a key that can appear at multiple locations. The **Location** attribute defines the hierarchical position of a key in MetaBase.xml. The value of the **Location** attribute, with only two exceptions, is a sequence of location names separated by one or more forward slashes (/) that uniquely identifies the hierarchical position of the key in MetaBase.xml.

The exceptions are the IIS_Global key, which has the highest hierarchical position in MetaBase.xml (**Location** = .), and the IIS_ROOT key, which has the next-highest hierarchical position in MetaBase.xml (**Location** = /). The next-highest hierarchical position is the IIsComputer key (Location = /LM). All remaining keys in MetaBase.xml are contained by the IIsComputer key; therefore, their location always begins with /LM/*LocationName*, where *LocationName* is the name of the location.

The hierarchical position of any metabase key can be determined by looking at its **Location** attribute. For example. /LM is the location of the IIsComputer key, and /LM/W3SVC is the location of the IIsWebService key. Because the /LM/W3SVC location begins with /LM followed by a forward slash character (/) and another location name (W3SVC), the IIsWebService key at location /LM/W3SVC is a child of the IIsComputer key. A *child key* is a key that is contained by another key. A key that contains another key is also called a *parent key*.

# XML Terminology Related to IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Because MetaBase.xml is an XML file constructed with XML elements, it helps to be familiar with XML terminology and metabase terminology to understand how MetaBase.xml is structured. Table 4.2 identifies and defines the XML terms and relates them to their use in MetaBase.xml.

**Table 4.2 XML Terminology and How It Relates to the IIS Metabase**

| Term | XML Description | Relation to MetaBase.xml |
|---|---|---|
| XML declaration | A processing instruction at the start of an XML document, such as `<?xml version = 1.0?>`, that declares the file to be XML code. | The first line in MetaBase.xml is an XML declaration. |
| Element | A logical unit of information. Elements are surrounded by <*ElementName*> and </*ElementName*> tags, where *ElementName* is the name of the element. Elements can contain attributes. | Keys and custom properties are written by using XML elements. |
| Root element | A single element that contains all the other elements and character data that make up an XML document; also known as a *document element*. | MetaBase.xml contains a root element named <configuration>. |
| Start tag | A tag that marks the start of an element, such as <*ElementName*>, where *ElementName* is the name of the element. | In MetaBase.xml, start tags are used to identify the start of a key or custom property. |
| End tag | A tag that marks the end of an element, such as </*ElementName*>, where *ElementName* is the name of the element. | In MetaBase.xml, end tags are used to identify the end of a key or custom property. |
| Element type | Indicated by the name that occurs in its start tag and end tag. | In MetaBase.xml, the element type for metabase keys is actually the value of the **KeyType** property. For example, IIsWebService is the **KeyType** that is used to identify the World Wide Web Publishing Service (WWW service) key. Custom properties use the name **Custom** as the element type. |
| Attribute | A name and value pair that is associated with an XML element and that provides more information about the content of that element.<br><br>Do not confuse the term **attribute** as used here to describe XML structure with an IIS metabase property attribute that describes an IIS property. | A metabase property contains several attributes that describe the characteristics of the property, such as the data type or value. Keys also contain attributes, such as the **Location** attribute or the **DefaultDoc** attribute found within the IIsWebService key. |
| Comment | Text that is not to be treated as part of the document. Comments are delimited by <!-- and --> tags. | In MetaBase.xml, comments are delimited by <!-- and --> tags, and must be written above the key to which they pertain. If you put a comment inside an XML node, it is removed by IIS. In addition, no comments are allowed above the IIS_Global node. |

# Metabase Structure in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The XML declaration `<?xml version = "1.0"?>` occupies the first line in MetaBase.xml and indicates that the file is formatted as XML. The root element, named <configuration>, contains all other elements.

The IIS_Global key is the highest-level key in the metabase that contains properties. Consider the IIS_Global key to be read-only; do not configure its properties.

The IIS_ROOT key (Location = /) is the highest-level key in which you can configure properties. Properties that are configured at the IIS_ROOT key affect the general operation of IIS.

The IIsComputer key (Location = /LM) contains all remaining metabase locations. Table 4.3 lists, in hierarchical order, child locations that can exist within the namespace of the /LM location. The File Transfer Protocol (FTP), Network News Transfer Protocol (NNTP), and Simple Mail Transfer Protocol (SMTP) components are not installed with IIS by default. Therefore, the /LM/MSFTPSVC, /LM/NNTPSVC, and /LM/SmtpSvc locations do not exist in MetaBase.xml unless their respective components have been installed.

**The Local Machine Namespace**

The local machine (LM) namespace is the parent location in the hierarchical structure of keys where all services and sites are organized. These keys, each of which contains their own unique location, are organized in the following format:

/LM/*Service*/*Site*/*ROOT*/*VirtualDirectory*/*Directory*/*File*

Where the replaceable parameters are:

- *Service* = MSFTPSVC, NNTPSVC, SmtpSvc, or W3SVC
- *Site* = unique number identifier for the FTP, NNTP, SMTP, or Web, site
- *ROOT* = root virtual directory of the site
- *VirtualDirectory* = virtual directory
- *Directory* = physical directory
- *File* = file name

Each site is a server instance, and is referred to by the number used in its namespace. For example, /LM/W3SVC/1 specifies the location of the key that contains the first Web site, and /LM/MSFTPSVC/3 specifies the location of the key that contains the third FTP site.

| **Important** |
| --- |
| Beginning with IIS6.0, the default Web site is numbered 1, and when a new Web site is created, a Web site identification number is randomly generated based on the name of the Web site. You can enable sequential numbering of Web sites, which was the method of generating Web site identification numbers in IIS5.1 and earlier, by setting the IncrementalSiteIDCreation registry key to 1. |

Table 4.3 lists the locations of the parent keys that are contained in the LM namespace. Because their child keys are too numerous, they are not listed here.

**Table 4.3 Local Machine Locations**

| Location | Keys at this location |
| --- | --- |
| /LM/EventManager | Keys at the /LM/EventManager location and its child locations configure Microsoft Exchange Server. You should not configure keys at the /LM/EventManager location or its child keys by editing the MetaBase.xml file. |

| | |
|---|---|
| /LM/IISADMIN | Keys at the /LM/IISADMIN location and its child locations record DCOM extensions to IIS. Because the /LM/IISADMIN location is internally configured by IIS, you should not configure keys at /LM/IISADMIN or its child locations. |
| /LM/Logging | Keys at the /LM/Logging location and its child locations configure IIS logging. |
| /LM/MimeMap | Keys at the /LM/MimeMap location configure the **MimeMap** property. |
| /LM/MSFTPSVC | Keys at the /LM/MSFTPSVC location and its child locations configure the FTP service and sites. |
| /LM/NNTPSVC | Keys at the /LM/NNTPSVC location and its child locations configure the NNTP service and sites. |
| /LM/SmtpSvc | Keys at the /LM/SmtpSvc location and its child locations configure the SMTP service and sites. |
| /LM/W3SVC | Keys at the /LM/W3SVC location configure properties that are global to the WWW service. |
| /LM/W3SVC/1 | Keys at the /LM/W3SVC/1 location and its child locations configure properties that are specific to the first Web site. |
| /LM/W3SVC/AppPools | Keys at the /LM/W3SVC/AppPools location configure properties that are global to all application pools. Keys at child locations, such as /LM/W3SVC/AppPools/DefaultAppPool, configure properties that are specific to a particular application pool. |
| /LM/W3SVC/Filters | Keys at the /LM/W3SVC/Filters location and its child locations configure Internet Server API (ISAPI) filters, and global compression schemes. |
| /LM/W3SVC/Info | Keys at the /LM/W3SVC/Info location configure properties that are global to all Web sites. |
| /LM/W3SVC/Info/Templates | The /LM/W3SVC/Info/Templates location and its child locations were used by the IIS Permissions Wizard in earlier versions of IIS. It remains solely for legacy compatibility. You should not configure keys at the /LM/W3SVC/Info/Templates location by editing the MetaBase.xml file. |

# Property Inheritance in the IIS 6.0 Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Property inheritance configures IIS by using as few property settings as possible. The benefits of using a minimal number of property settings to configure IIS are as follows:

- Faster IIS cache performance
- Reduced memory consumption
- Reduced time required for IIS administration

Metabase properties are used to provide detailed control of IIS functionality. All metabase properties contain attributes, such as the **DefaultValue** attribute, which specify the configuration of the properties. Most metabase properties are inheritable, and they are specified as inheritable in MBSchema.xml by using the string value INHERIT as part of the value of the **Attributes** attribute. The following example shows the default attributes for the **HttpErrors** property in MBSchema.xml:

```
<Property
   InternalName = "HttpErrors"
   ID = "6008"
   Type = "MULTISZ"
   UserType = "IIS_MD_UT_FILE"
   Attributes = "INHERIT"
   MetaFlagsEx = "CACHE_PROPERTY_MODIFIED"
   DefaultValue = ""/
>
```

Hierarchical Relationship of Keys

The metabase is designed so that properties can be set differently at different keys. To understand how property inheritance works, it is necessary to first understand the hierarchical relationship of keys in the MetaBase.xml file. In relation to other keys, a key can be located in MetaBase.xml at a higher level, lower level, or the same level. The **Location** attribute of each key determines the level in which a key exists in the hierarchical structure.

The following example illustrates the relationship between the IIsWebService, IIsWebServer, and IIsWebVirtualDir keys. The example uses indentation to illustrate the hierarchical relationship of the keys.

```
<IIsWebService Location = "/LM/W3SVC"
   <IIsWebServer Location = "/LM/W3SVC/1">
      <IIsWebVirtualDir Location = "/LM/W3SVC/1/ROOT">
   <IIsWebServer Location = "/LM/W3SVC/2">
      <IIsWebVirtualDir Location = "/LM/W3SVC/2/ROOT">
```

In this example, the IIsWebService key is the highest-level key. The IIsWebServer keys are at a lower level than IIsWebService, and the IIsWebVirtualDir keys are at a lower level than the IIsWebServer keys. Keys that are at the same level cannot inherit properties from each other. Therefore, because the IIsWebServer keys are at the same hierarchical level in the metabase, they cannot inherit properties from each other. The IIsWebVirtualDir keys are also at the same level in relation to each other, and therefore they cannot inherit properties from each other.

| **Note** |
| --- |
| The hierarchical structure of the metabase is determined by the **Location** attribute of the keys themselves, not the class name of the keys. |

Inheritance

Inheritable properties that are not explicitly set at a lower-level key are automatically inherited from the key at the next-higher level in which the property is configured. The IIS_ROOT key is the highest key in MetaBase.xml from which a property can be inherited.

The following example illustrates properties that are configured differently in different keys in MetaBase.xml, as well as properties that are inherited.

```
<IIsWebService Location = "/LM/W3SVC"
<!-- The DefaultDoc and ContentIndexed properties are specifically set at this key. -->
= "Default.htm,Default.asp,index.htm,Default.aspx"
ContentIndexed = "TRUE"
   <IIsWebServer Location = "/LM/W3SVC/1">
   <!-- The DefaultDoc property is specifically set at this key. -->
   = "Default.htm,Default.asp,index.htm,iisstart.htm,Default.aspx"
   <!-- The ContentIndexed property is inherited from the IIsWebService key and
   does not appear here -->
   </IIsWebServer>

<IIsWebVirtualDir Location = "/LM/W3SVC/1/ROOT"
<!-- The DefaultDoc and ContentIndexed properties are inherited from the /LM/W3SVC/1
location and do not appear here. -->
</IIsWebVirtualDir>
>
   <IIsWebServer Location = "/LM/W3SVC/2"
   <!-- The DefaultDoc and ContentIndexed properties are inherited from the
   IIsWebService key. -->
   </IIsWebServer>
   >
   <IIsWebVirtualDir Location = "/LM/W3SVC/2/ROOT"
   <!-- The DefaultDoc property is inherited from the /LM/W3SVC/2 location. -->
   <!-- The ContentIndexed property is specifically set at this key. -->
   ContentIndexed = "TRUE"
   >
</IIsWebVirtualDir>
</IIsWebService>
```

# The Metabase Schema

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The metabase schema defines what properties can exist in the metabase configuration file. The metabase schema also enforces which properties can be set at which keys. The metabase schema provides this enforcement only for *schema-defined* properties, which are properties written to the metabase configuration file that adhere to the rules of metabase schema. Properties that are not schema-defined can be written in the metabase configuration file as *custom properties*. Custom properties can be used in the metabase configuration file to override schema enforcement or to configure a property with values other than the default values that are defined by the schema.

# Metabase Schema Collections

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The metabase schema is organized into containers called *collections*. Collections are defined in MBSchema.xml by using <Collection> start and end tags, and they are written in the following format:

```
<Collection InternalName = "CollectionName" MetaFlagName = "MetaFlagValue" >
   <Property PropertyName = "PropertyValue" >
      <Flag FlagName = "FlagValue" >
   .
   .
</Collection>
```

In the example above, *CollectionName* is the name of the entire collection. *MetaFlagName* and its associated *MetaFlagValue* apply to the entire collection. *PropertyName* and its associated *PropertyValue* are individual settings within the collection. *FlagName* and its associated *FlagValue* are individual settings within a property.

All collections exist at the same hierarchical level in MBSchema.xml. Therefore, no collection is a parent of another. Reading the MBSchema.xml file from top to bottom, the first collection, named **MetabaseBaseClass**, defines global settings in the schema.

The following code example is taken from the metabase schema file to illustrate how collections are defined.

```
<Collection InternalName = "IIsConfigObject" MetaFlagsEx = "NOTABLESCHEMAHEAPENTRY"
MetaFlags = "HASUNKNOWNSIZES | HIDDEN">
   <Property InternalName = "AccessFlags" ID = "6016" Type = "DWORD"
   UserType = "IIS_MD_UT_FILE" Attributes = "INHERIT"
   MetaFlagsEx = "CACHE_PROPERTY_MODIFIED" DefaultValue = "AccessRead"
   EndingNumber = "0">
      <Flag InternalName = "AccessExecute" Value = "4" ID = "6209"/>
</Collection>
```

The collection directly below **MetabaseBaseClass** is named **IIsConfigObject**. The **IIsConfigObject** collection is unique, because it is where all properties are defined. Only properties that are defined in the **IIsConfigObject** collection can be written to the metabase configuration as schema-defined properties.

# Metabase Schema Properties

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

*Properties* are configuration objects that are associated with IIS Admin Objects and their corresponding ABOs. All properties that are defined in the **IIsConfigObject** collection contain attributes. The default values of these attributes for each property are also defined.

| **Note** |
| --- |
| The default values that are assigned to property attributes in the **IIsConfigObject** collection are not necessarily the values that are written to the metabase configuration when IIS is installed. The default values of attributes, which are defined by the **IIsConfigObject** collection, are used when you write a schema-defined property to the metabase configuration file after IIS is installed. |

Each property that is defined in the **IIsConfigObject** collection contains the following attributes: **ID**, **Type**, **UserType**, **Attributes**, **InternalName**, and **DefaultValue**. Some properties also contain the following attributes: **MetaFlags**, **MetaFlagsEx**, **StartingNumber**, and **EndingNumber**. Property attributes are contained in the <Property> start tag. The following example from the **IIsConfigObject** collection illustrates how a property is defined.

```
<Property
   InternalName = "ServerComment"
   ID = "1015"
   Type = "STRING"
   UserType = "IIS_MD_UT_SERVER"
   Attributes = "INHERIT"
   MetaFlagsEx = "CACHE_PROPERTY_MODIFIED | WAS_NOTIFICATION"
   DefaultValue = ""/>
```

# Flags

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

In addition to attributes, some properties also contain *flags*. Each flag configures a unique functionality of the property, such as read or write access. Each flag is identified by the ABO that uses the unique *bitmask identifier* of the flag.

Flags contain attributes named **Value** and **ID**. Flags are defined in the property's start and end tags, and they are identified by using <Flag> tags. The sum value of all flags that are set for a property determines the value of the property's **DefaultValue** attribute, which is also called the default value of the property. The following example illustrates a property that contains flags.

```
<Property InternalName = "PasswordChangeFlags"
   ID = "2068"
   Type = "DWORD"
   UserType = "IIS_MD_UT_SERVER"
   Attributes = "INHERIT"
   MetaFlagsEx = "CACHE_PROPERTY_MODIFIED"
   DefaultValue = "0"
   EndingNumber = "0">
      <Flag InternalName = "AuthChangeUnsecure" Value = "1" ID = "6292"/>
      <Flag InternalName = "AuthChangeDisable" Value = "2" ID = "6293"/>
      <Flag InternalName = "AuthAdvNotifyDisable" Value = "4" ID = "6294"/>
</Property>
```

| **Note** |
| --- |
| Flags and their attributes are written in the start and end tags of a property. A property that does not contain a flag is encapsulated in the start tag of the property, and it does not use end tags. |

# Remaining Collections

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

All remaining collections, which are below the **IIsConfigObject** collection, are organized by key type. These collections enforce at which keys in the metabase configuration a schema-defined property can be written. For example, if a collection named **IIsWebServer** contains the **ServerComment** property, IIS allows the **ServerComment** property to be written to any key in the metabase configuration that uses the IIsWebServer key type. Therefore, only properties that are contained in these remaining collections can be written (as schema-defined properties) in a metabase key of the same key type in MetaBase.xml.

The exception to this rule is the IIsConfigObject key type, described earlier. Because all properties are contained in the **IIsConfigObject** collection, all properties can be written to any key in the metabase configuration of the IIsConfigObject key type.

Properties are written in these remaining collections in the following format:

```
<Property InheritsPropertiesFrom = "IIsConfigObject:PropertyName"/>
```

where *PropertyName* is the name of the property.

All of the properties that are contained by these remaining collections inherit their default values from the **IIsConfigObject** collection, because the **IIsConfigObject** collection is where all properties are defined.

You cannot use ADSI or WMI, which are not defined in metabase schema, to update properties in the metabase configuration. Changes written directly to the MetaBase.xml file that do not comply with metabase schema rules might not be written to the in-memory metabase. If this occurs, an error or warning is sent to the event log.

# Metabase Security and Auditing

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

A default installation of IIS 6.0 ensures metabase security by setting strict access control entries (ACEs) on the metabase files and by encrypting sensitive data within the files. If you maintain this level of security, perform regular backups, use a strong administrator password, and limit the number of users who have administrative credentials, you are taking the proper precautions to protect your metabase files.

# File-Level Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

As described in Table 4.4, IIS installs the metabase files with strict ACEs set to prevent anyone but administrators from viewing your configuration data. An access control list (ACL) is a container for ACEs.

**Table 4.4 Metabase files, purpose, and permissions**

| File | Purpose | ACL |
|---|---|---|
| *systemroot*\System32\Inetsrv\MetaBase.xml | Stores configuration data for the IIS services. | NT AUTHORITY\SYSTEM : Full control<br>BUILTIN\Administrators : Full control |
| *systemroot*\System32\Inetsrv\MBSchema.xml | Stores the schema for the configuration file. The schema defines what IIS properties can be set at certain metabase keys. | NT AUTHORITY\SYSTEM : Full control<br>BUILTIN\Administrators : Full control |
| *systemroot*\System32\Inetsrv\ History*HistoryFile* | Stores the metabase history files that are created automatically by IIS. | NT AUTHORITY\SYSTEM : Full control<br>BUILTIN\Administrators : Full control |
| *systemroot*\System32\Inetsrv\MetaBack*BackupFile* | Stores the metabase backup files that are created on demand by using Backup/Restore Configuration. | NT AUTHORITY\SYSTEM : Full control<br>BUILTIN\Administrators : Full control |

# Encrypted Properties

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS encrypts sensitive data in the metabase configuration file, MetaBase.xml, so that it cannot be viewed even if an unauthorized user gains access to the file.

| **Important** |
| --- |
| Do not manually change encrypted properties in MetaBase.xml. There is no way to encrypt your data before inserting it by using Notepad or another text editor. Only WMI, ADSI, or ABOs can be used to change the data in encrypted properties. |

Metabase properties are marked for encryption by an attribute that is set on the property in the metabase schema file. The following example from the metabase schema file shows how the **AnonymousUserPass** property is marked for encryption with a **SECURE** attribute:

```
<Property InternalName = "AnonymousUserPass" ID = "6021" Type = "STRING" UserType =
"IIS_MD_UT_FILE"
   Attributes = "INHERIT|SECURE" MetaFlagsEx = "CACHE_PROPERTY_MODIFIED"
   DefaultValue = ""/>
```

| **Caution** |
| --- |
| You cannot use WMI, ADSI, or ABOs to add an attribute to an existing property in the metabase schema. For example, you cannot add the **SECURE** attribute to an existing property. If you attempt to use WMI, ADSI, or ABOs to remove a property in the metabase schema and then create it again with the **SECURE** attribute, the metabase configuration data for that property is lost. You can, however, use ADSI to create new properties in the metabase schema with the **SECURE** attribute. Manual changes made to the metabase schema are not supported and might cause an error. |

The following metabase properties are encrypted:

- **ADConnectionsPassword**
- **AdminACL**
- **AdminACLBin**
- **AnonymousUserPass**
- **ImapDsPassword**
- **LogOdbcPassword**
- **Pop3DsPassword**
- **RoutePassword**
- **SmtpDsPassword**
- **UNCPassword**
- **FeedPassword**
- **WAMUserPass**

# Checklist: Metabase Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Table 4.5 is a list of recommended steps to ensure the security of the metabase.

**Table 4.5 Steps to ensure metabase security**

| Complete | Step | Reference |
|---|---|---|
| | Make sure that the passwords for all accounts on your computer are strong and not written anywhere near the computer or within view. | See "Passwords" in Help and Support Center for Windows Server 2003. |
| | Maintain strict access control permissions on the metabase files that are listed in Table 4.4. Only the LocalSystem account and the Administrators group should be listed in the ACLs as having full control of the metabase files, including the history files and backups. IIS sets this access control by default. | See "Access control" in Help and Support Center for Windows Server 2003. |
| | Employ the concept of *least privilege* on your computer. Allow only one person to know the Administrator password, and limit the number of people whose accounts are in the Administrators group. Set ACLs on all folders and files so that the fewest users have the lowest-level privileges needed to run required tasks. Set IIS security on all IIS applications and virtual directories so that the least permission necessary exists to allow the appropriate clients to view your content. | See "Access control" and "Security" in Help and Support Center for Windows Server 2003. |
| | Do not run the **cipher** command or use Encrypting File System (EFS) on the metabase files. Sensitive data, such as passwords that are stored in MetaBase.xml, is already encrypted. Encrypting the entire MetaBase.xml file slows the performance of your IIS server and might cause errors. | See the "Cipher" and "Encrypting File System" topics in Help and Support Center for Windows Server 2003. |
| | When you edit the MetaBase.xml file manually, copy the MetaBase.xml file first, and then work on the copy. When you have checked your changes, replace MetaBase.xml with your copy. | See Editing the MetaBase.xml File While IIS Is Running. |
| | Create backups of your metabase files using Backup/Restore Configuration whenever you make a significant change in the metabase. If you allow other people to configure the metabase, make it a policy that they create a backup with their name in the title whenever they make a change. IIS periodically makes its own backup files, called history files, but history files might not be created for every change to the metabase. | See Backing Up the Metabase |
| | Do not use the metabase import and export feature to create regular backup files. This feature is meant to transport sections of the metabase to other computers. However, it is recommended that you create an export file for your entire metabase periodically in the event that your computer hardware fails and you must move your Web sites to another computer. | See Metabase Import and Export. |

| | | |
|---|---|---|
| | Remember that backing up or exporting the metabase does not back up your content (for example, .htm files, .asp files, and components). The metabase holds only configuration data, such as the location where your content is stored. To back up your content, use Windows Backup. | See "Backing up and restoring data" in Help and Support Center for Windows Server 2003. |
| | Monitor your event log for IIS event messages. For example, if you attempt to make changes to the metabase when there is a write-lock on the in-memory database, a metabase history file is created and an error is written to the event log. If you successfully create an FTP virtual directory, but IIS cannot enumerate the physical directory, an error is written to the event log. | See "Event Viewer" in Help and Support Center for Windows Server 2003. |
| | Set up file auditing on the various files that affect the metabase. This way, if the metabase becomes corrupted, you can identify the account of the last user who made a change. Select your auditing choices carefully for the files listed below, and monitor the audit logs for a period of time to determine if the settings are meeting your needs.<br>`Systemroot\System32\Inetsrv\MetaBas.xml….`<br>If you choose to audit the MetaBase.xml file, only users who edit the metabase manually are identified in the audit logs by their own account name. Users who edit the metabase by using IIS Manager or other tools are logged as accessing the metabase under the LocalSystem account. Because IIS itself is constantly accessing the metabase, audit logs can grow very quickly unless you limit auditing to specific users, such as the local Administrators group, and specific access attempts, such as writing to a file. Auditing MetaBase.xml is still valuable for determining when changes were made, but you might have to audit the other files listed here to find the exact identity of the user.<br>Custom tools and script files that use WMI, ADSI, or ABOs to edit the metabase:<br>Auditing should be set on these tools to identify who executes them. If you audit MetaBase.xml and want to find out who made a change at 3:01 P.M. on a certain day, you can look in the audit logs for your scripts and tools to see if someone ran one of them at 3:01 P.M.<br>`Systemroot\System32\Inetsrv\Inetmgr.exe….`<br>Audit this file for the same reason you audit custom tools and script files, above. | See "Auditing overview" in Help and Support Center for Windows Server 2003. |

# Metabase Auditing

Updated: August 22, 2005

Applies To: Windows Server 2003 with SP1

Beginning with the Windows Server 2003 Service Pack 1 (SP1) release, IIS 6.0 includes a metabase auditing feature that allows tracking of each change that is made to the metabase. Metabase auditing is enabled by enabling an audit access control entry (ACE) on a node in the metabase. After ACE is enabled, whenever a metabase change takes place on that node, an audit event is published in the NT Security event log.

The following information is recorded in the NT Security event log:

- What was changed (metabase node, property, and old and new values).
- When the change was made (date and time).
- Who made the change (domain and user name).
- Success or failure of the change attempt (HRESULT).
- When a change is made remotely (client IP number).

Without metabase auditing, you cannot determine who made changes to the metabase and when those changes were made. IIS 6.0 does feature a metabase history, with up to 10 (configurable) Metabase.xml files stored in the Inetsrv\History folder. However, history files do not reveal what changed, who made the change, and when the change was made.

The auditing requirements for changes to metabase properties differ from changes to metabase keys. For a change to a key, it is necessary to log only the key data, because changes to a key affect everything beneath it (child operations are not audited). Changing a property requires more information, including both the key and the property name.

The following list specifies the audit event content for operations on both metabase keys and metabase properties:

- Delete key: name of node being deleted
- Delete property: name of key and name of property being deleted
- Move key: old node location and new node location
- Copy key: source node location and new node location
- Add key: name of node being added
- Add property: name of key, name of property, and value of property
- Rename key: names of old node and new node
- Change property: name of key, name of property, old and new values of property

| **Note** |
| --- |
| To avoid disclosing sensitive information, such as passwords, values of secure properties will not appear in audit event log entries. |

**Enabling and Disabling Metabase Auditing**

Metabase auditing is enabled when the following conditions are met:

- In the Windows Group Policy Editor (gpedit.msc), audit-object access is enabled and auditing is turned on for both

successes and failures.

- ACEs are enabled on the metabase nodes that you want to audit.
- The command script iiscnfg.vbs was used to enable auditing.

Metabase auditing is disabled when the following conditions are met:

- In the Windows Group Policy Editor (gpedit.msc), audit-object access is disabled.
- ACEs are disabled on the metabase nodes that you no longer want to audit.
- The command script iiscnfg.vbs was used to disable auditing.

For information about metabase audit event log messages, see Metabase Auditing Event Messages.

# Backing Up and Restoring the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Creating backups of the metabase is a vital part of maintaining metabase reliability. The ability to create backup files and to restore the metabase by using backup files has been enhanced in IIS 6.0. You can now restore the backup on other computers if portable backup has been chosen. History file copies of the metabase are created automatically by IIS, and an IIS administrator using IIS Manager can create them on demand. All backups, regardless of how they were created, are stored together and displayed together in IIS Manager.

Restoring a backup from an earlier version of IIS is not supported. After you install or upgrade to IIS 6.0, it is recommended that you perform a metabase backup as soon as possible to preserve your configuration data.

Backing up the metabase should be supplemented with proper metabase security practices. For more information about metabase security, see Metabase Security and Auditing.

# Backing Up the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Using Backup/Restore Configuration, you can create complete backup copies of the IIS metabase. The backup files are either portable or nonportable copies of both the metabase configuration file (MetaBase.xml) and the matching metabase schema file (MBSchema.xml). Metabase backup files provide a way to restore your metabase configuration and schema data in the event that the metabase becomes corrupted. Portable backup files can be restored either to the computer on which the backup was made or to other installations of Windows Server 2003, while non-portable backup files can only be restored to the same system from which it was made.

When a backup is created, a set of two files is created and named in the following way:

```
Name.mdx and Name.scx
```

In the syntax above, *Name* is the name that the administrator uses to name the backup set, and *x* is the version number of the backup set, starting with 0 (zero). The version number is increased by one for each backup set that uses the same name, up to 999. For example, if you use the name *MyBackup* as the name of your backup set twice, MyBackup.md0 and MyBackup.sc0 are created on the first backup; on the second backup, the files are named MyBackup.md1 and MyBackup.sc1. By default, backup files are stored in the *systemroot*\System32\Inetsrv\MetaBack folder.

Backup files contain only configuration data; they do not include your content. To back up your content, use Windows Backup. For more information about using Windows Backup, see "Backing up and restoring data" in Help and Support Center for Microsoft® Windows® Server 2003.

| **Note** |
| --- |
| The metabase is locked while the backup is in progress. |

**Portable Backup**

When creating a portable backup, the administrator provides a password that is used by IIS to encrypt the backup files. The password is encrypted and stored in the header of the backup file. Only the administrator password and secure properties within the backup files are encrypted; all other information within the backup files is plain text. After the backup file is encrypted, the password within the backup file cannot be changed.

**Non-portable Backup**

When creating a non-portable backup, the administrator does not supply a password. Therefore, non-portable backup files are encrypted with a blank password, which allows any member of the Administrators group to restore the metabase. Only the blank password and secure properties are encrypted; all other information within the backup file is plain text.

# The Metabase History Feature

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS automatically maintains a record of metabase changes in history files that are saved to disk. You can also configure the number of metabase history files to save. By using the metabase history feature, you can revert the metabase through any number of changes to restore a particular configuration, or to see what has changed between revisions.

By marking each new metabase file with a unique version number and saving a copy of the file in the History folder, the metabase history feature automatically keeps track of metabase changes that are saved to disk. Each history file is then available for restoring the MetaBase.xml and MBSchema.xml files from the History folder, editing the MetaBase.xml file while IIS is running, and troubleshooting event log errors. The metabase history feature is enabled by default.

**History Folder**

The History folder stores versioned copies of the MetaBase.xml and MBSchema.xml files. These copies can only be viewed by members of the Administrators group. The location of the History folder is *systemroot*\System32\Inetsrv\History.

A *history file pair* consists of a MetaBase.xml and MBSchema.xml file of the same major and minor version numbers. The default setting allows for a maximum of 10 versioned history file pairs to be stored in the History folder, but you can configure this number. However, before increasing the number of versioned sets of files stored in the History folder, you should ensure that you have adequate hard disk space on the drive volume where the History folder is located. (You can estimate the amount of hard disk space that is required by multiplying the average combined file size of MetaBase.xml and MBSchema.xml files by the number of versions that you want to store in the History folder.) You should not decrease the value of the **MaxHistoryFiles** property to below 10.

When the in-memory metabase is written to disk, IIS checks to determine whether the number of history file pairs that are contained in the History folder exceeds the value of the **MaxHistoryFiles** property. If the number of history file pairs exceeds the value of the **MaxHistoryFiles** property, the oldest history file pair is deleted.

For information about backing up your entire operating system, including special steps that must be performed to include IIS in that backup, see Backing up and restoring data in Help and Support Center for Windows Server 2003. For information about the event log, see Event log in Help and Support Center for Windows Server 2003.

# Configuring the Metabase History Feature

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

By default, the metabase history feature is enabled and the number of history file pairs that are saved within the History folder is defined by the default value of the **MaxHistoryFiles** property. A history file pair is the combination of a copy of a MetaBase.xml file and an MBSchema.xml file of the same version in the History folder. If the **EnableHistory** property is not written in the MetaBase.xml file, IIS interprets the absence of the property to mean that the history feature is enabled, and the **MaxHistoryFiles** property is set to the default value.

**To change the metabase history default settings**

1. Add the **EnableHistory** and **MaxHistoryFiles** metabase properties to the /LM level of the metabase.

**To disable metabase history**

1. Set the value of the **EnableHistory** property to **0** (zero).

**To enable metabase history**

1. Set the value of the **EnableHistory** property to **1**.

**To change the number of history files that are stored in the History folder**

1. Change the value of the **MaxHistoryFiles**property.

| ⚠**Caution** |
| --- |
| Disabling history files can have serious consequences if the metabase becomes corrupted by improper editing. Without backup files, the IIS server might have to be reconfigured from an empty state. However, keeping backup files can also be a security risk if you do not ensure that the files are protected by ACLs. By default, only members of the Administrators group can view the history files, but if you copy history files to a new location, you must duplicate those settings. For information about configuring ACLs, see "Access control" in Help and Support Center for Windows Server 2003. |

# Naming the Metabase History Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

To keep track of metabase history, IIS uses the following versioning scheme to enumerate the copies of MetaBase.xml that are stored in the History folder.

**Metabase Version Numbers**

The value of the **HistoryMajorVersionNumber** metabase property, also referred to as the major version number, increases when the in-memory metabase is written to disk.

The minor version number increases when the edit-while-running feature is enabled and an administrator changes and saves the MetaBase.xml file directly with an application such as Notepad.

**HistoryMajorVersionNumber Property**

The **HistoryMajorVersionNumber** property is located under the IIS_Global node in the metabase, as shown in the following example:

```
<?xml version = "1.0"?>
<configuration xmlns = "urn:microsoft-catalog:XML_Metabase_V54_0">
<MBProperty>
<IIS_Global Location = "."
   BINSchemaTimeStamp = "9676376defb8c201"
   ChangeNumber = "1023"
   HistoryMajorVersionNumber = "154"
   SessionKey = "4585thge754u4509853743hg0948054ug6t095"
   XMLSchemaTimeStamp = "444e436defb8c201"
   >
</IIS_Global>
```

| **Important** |
| --- |
| IIS uses the **HistoryMajorVersionNumber** property to track the versions of the metabase. Thus, manually changing the value of the **HistoryMajorVersionNumber** property is not recommended. |

**Minor Version Number**

The minor version number is not a property that is stored in the metabase. IIS calculates the minor version number when the MetaBase.xml file is edited and saved directly, and if edit-while-running is enabled, as follows:

IIS looks in the History folder to determine the last minor version number that was used for a history file with the same HistoryMajorVersionNumber number as MetaBase.xml. IIS then uses the next sequential minor version number when naming the new history file.

When a history file is created because the in-memory metabase is written to disk, either through the regular timed history algorithm, or by the user explicitly saving the current configuration to disk, the major version number is incremented by 1, and the minor version number is reset to zero.

**Naming the History Files**

When a copy of MetaBase.xml is written to the History folder, the value of the **HistoryMajorVersionNumber** property is incremented and added to the names of the file pair. If edit-while-running is enabled, and the user makes a manual change to the metabase, the minor version number is incremented and added to the names of the file pair.

The file names of versioned MetaBase.xml files and MBSchema.xml files are created in the following format, respectively, where both the value of the **HistoryMajorVersionNumber** property and the minor version number are 10-digit numbers:

```
MetaBase_HistoryMajorVersionNumber_MinorVersionNumber.xml
MBSchema_HistoryMajorVersionNumber_MinorVersionNumber.xml
```

When either the HistoryMajorVersionNumber or the minor version number value is less than 10 digits, the number is padded with zeros in the file name to create a 10-digit number. This keeps the file names aligned and in numerical order when you sort by file name, making the contents of the History folder easier to read.

The following is an example of file names in the History folder:

```
MetaBase_0000000001_0000000000.xml
MetaBase_0000000001_0000000001.xml
MetaBase_0000000002_0000000000.xml
MetaBase_0000000002_0000000001.xml
MetaBase_0000000002_0000000002.xml
MetaBaseError_0000000000.xml
MetaBaseError_0000000001.xml
MBSchema_0000000001_0000000000.xml
MBSchema_0000000001_0000000001.xml
MBSchema_0000000002_0000000000.xml
MBSchema_0000000002_0000000001.xml
MBSchema_0000000002_0000000002.xml
```

For each instance of a MetaBase_*MajorVersion_MinorVersion*.xml file within the History folder, there is an MBSchema_*MajorVersion_MinorVersion*.xml file of the same version that is used with the metabase configuration.

# Metabase Error Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

File names that contain the word *error* are created in the History folder under the following circumstances:

- Edit-while-running is enabled.
- You edit MetaBase.xml directly by using an application, such as Notepad.
- An error, such as (but not limited to) the following occurs:
    - An XML tag is omitted in MetaBase.xml.
    - A property name is misspelled in MetaBase.xml.
    - The corresponding history file with the same HistoryMajorVersionNumber value as MetaBase.xml is not found.

Error files are named in the following format, where *TenDigitNumber* is the version number of the error file, starting with version number 0000000000:

```
MetaBaseError_TenDigitNumber.xml
```

The version number increases by one for each additional error file that is created.

# Restoring the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Restoring the metabase from history files is similar to restoring it from backup files. For a comparison of the two methods of restoring the metabase, see Table 4.6.

**Table 4.6 Comparison of Metabase Restore Methods**

| Using Backup Files | Using History Files |
|---|---|
| If a password is provided by the user to encrypt secure properties, the metabase can be restored to a different installation of Windows, even on a different computer. | The metabase can be restored only on the same installation of Windows from which the history files were created. This is because data is encrypted with the machine key in the backups. |
| Backup files can be created on demand, scheduled, or created by using a programmatic administration script. | History files can be created automatically (when the IIS history feature is enabled) or by using a programmatic administration script. |
| Backup files can be restored from IIS Manager, by using APIs or by using programmatic administration scripts. | History files can be restored manually or by using IIS Manager. |

# Restoring the Metabase from History Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can use automatically generated history files to restore your IIS configuration from IIS Manager. However, you may find it necessary to restore the metabase without using IIS Manager. For example, suppose a configuration change is made incorrectly, or if it is made using incorrect XML syntax. In this case, IIS Manager would be unable to enumerate the metabase.

For more information about restoring the metabase from history files, with or without IIS Manager, see Restoring the Metabase with History Files.

# Restoring the Metabase from Backup Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can restore a metabase backup to the same computer on which the backup was made or, if the backup was created with a password, onto a different computer. Because a metabase backup does not include content files, if you restore a metabase backup to a different server you must copy your content files as well. The content files must exist in the same location and on the same drive used on the original server. Restoring a backup from an earlier version of IIS is not supported.

For more information about restoring the IIS metabase from backup files, see Restoring the Metabase with Backup Files.

**SSL Certificates**

If you use a Secure Sockets Layer (SSL) certificate on your Web server and you restore the metabase backup to a different installation of the operating system, an error occurs if the certificate is not available or installed. If a site's SSL certificate is missing, connections are dropped, and the browser displays a page unavailable message. The solution is to reinstall the certificate into the same certificate store as on the original computer, and restart IIS.

# Restoring a Section of the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can make fixes to specific sections of the metabase in two ways:

- You can use the import feature without the merge option to import metabase elements over damaged data.
- If the damaged section prevents IIS from loading the metabase, you can manually edit the MetaBase.xml file in any text editor by copying sections from an export or backup file and pasting them into the MetaBase.xml file.

  For information about importing and exporting metabase elements, see Metabase Import and Export.

You can be prepared to make fixes to the metabase by creating a template of your entire metabase, as well as by creating export files of new sections of your metabase file at various stages of its life, so that you have something to work from if a section becomes corrupted.

To create a template of your entire metabase, first create a backup file. Remove any machine-specific and system-specific information from your backup file, and then remove extraneous information and configuration information that is specific to applications, sites, and virtual directories.

What you are left with is a template of top-level configuration information that might not be recoverable using metabase import/export. Together with the export files of specific sections that you created, you are prepared for any loss of data or corruption. One way to identify where XML syntax corruption exists is to open the MetaBase.xml file with Internet Explorer. Internet Explorer will identify the line at which it encountered invalid xml syntax.

# Editing the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Editing the MetaBase.xml file directly by using common text-editing tools is an efficient way to configure the metabase over low-bandwidth connections. Editing MetaBase.xml with Notepad is more efficient than using IIS Manager, because IIS Manager is relatively slow over low-bandwidth lines, such as a 56 KB modem. Additionally, editing the metabase file directly is faster than through user interfaces (UIs), such as IIS Manager, when hundreds or thousands of sites are running on the same computer. Editing the MetaBase.xml file directly is particularly useful for administrators who do not want to use programmatic methods to administer IIS but want an alternative to the UI methods. Editing the Metabase directly over a remote connection is not recommended because a dropped connection can leave the Metabase in an indeterminate state.

You can make changes to the MetaBase.xml file while IIS is running only if the edit-while-running feature is enabled. If edit-while-running is not enabled, you must stop IIS before you edit the MetaBase.xml file. This is inefficient and not a recommended practice.

# Best Practices for Maintaining Metabase Integrity

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The following practices can greatly reduce the chance that the metabase will become corrupted.

- Enable edit-while-running. This ensures that changes made to the metabase configuration while IIS is running are written to the on-disk metabase.
- Always back up the metabase before making configuration changes. Make the right kind of backup. A password-protected backup is cleanly transportable to other systems, while a backup made without a password is tied to the system on which the backup was made.
- When editing the metabase with a text editor, use a text editor that write-locks the open file. This prevents the possibility of more than one person editing the metabase at a time.
- After editing the metabase, open the file in Internet Explorer 6 or above. Any errors in the XML syntax will be displayed when Internet Explorer opens the file.
- Never allow changes to the metabase by more than one entity at a time. For example, do not edit the metabase by hand at the same time an administrative script that changes metabase settings is running.
- If you make changes to the metabase and it does not load properly, use a file comparison tool to compare the backup you made before editing the metabase with the edited metabase. This can help pinpoint any unintended changes.

Note the following about editing the metabase:

- Recoverable metabase schema errors occur when text editing yields well-formed XML but one or more properties are invalid, according the metabase schema.
- Editing the metabase schema is not supported.
- If the metabase contains incorrectly formatted XML, IIS cannot read the metabase and will not run. You can restore the last good history file to correct this problem.
- If an invalid configuration is created in MetaBase.xml, the error cannot read property is logged to Event Viewer, but the rest of IIS keeps running.

# Configuring the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The IIS metabase is a plaintext XML file containing most IIS configuration values. The metabase can be configured manually, by using IIS Manager or a text editor, or programmatically, using the IIS WMI and ADSI providers. Deciding the method you use to configure the metabase depends on the task you want to accomplish. For a one-time, one-step configuration task, editing the metabase file directly in a text editor might be easiest; for repetitive tasks that require a number of steps, a programmatic approach is most efficient. Another important aspect of configuring the metabase is knowing how to back up and restore the metabase if changes result in an error.

IIS includes several methods for changing values in the metabase. As shown in Figure 4,2, you can set or view metabase values programmatically by using any of the following resources:

- IIS Manager. The user interface (UI) that you can use to update the in-memory metabase. This is the safest way to update the metabase. However, it does not expose all available metabase properties.
- IIS ADSI provider. A set of scripting interfaces that you can run from a script.
- IIS WMI provider. A set of scripting interfaces that you can run from a script.
- Admin Base Objects (ABOs). A set of binary COM interfaces.

All configuration settings are written to the metabase through ABOs, as illustrated in Figure 4.2.

**About the IIS ABOs**

As shown in Figure 4.2, the ABOs are central to updating the in-memory metabase. An ABO is a set of binary COM objects that are used to write IIS configuration values that are stored in the IIS metabase. Each object has properties, and each property is stored in the metabase. You can manipulate IIS configuration by using ABOs to add new virtual directories, new Web sites, and so forth.

IIS Manager and the other resources in the illustration that are used to update the in-memory metabase write directly to the ABOs. The ABOs then write the changes to the in-memory metabase. You can also access ABOs directly by using C or Microsoft® Visual C++® development system, Microsoft® Visual Basic® development system, Delphi, or any COM-compliant language to programmatically update the in-memory metabase. You cannot use scripting language code to programmatically update the in-memory metabase.

**Metabase Storage Layer**

The in-memory metabase is periodically written to disk through the metabase storage layer. The metabase storage layer is the part of IIS that reads the metabase files into the in-memory metabase and also writes the in-memory metabase to the metabase files. The storage layer writes the in-memory metabase directly to the metabase files when a write-to-disk event occurs or when IIS is shut down.

| **Important** |
| --- |
| You cannot edit the MBSchema.xml file directly by using edit-while-running. Changes to MBSchema.xml must be made programmatically by using ADSI. |

**Adding Comments to the Metabase**

A metabase comment must be stored in the in-memory metabase in the correct XML format and associated with a particular node within the metabase, so the context of the comment is preserved during subsequent writes of the metabase to disk. Put node-specific comments right above the node. If you delete the node, the comments about the node are deleted as well.

When loading the metabase, the configuration system loads comments as a generic property into the metabase, along with other metabase data. Any comments found at the bottom of the file (below all nodes) will always be preserved at the bottom of the file.

Comments are added in the following format:

```
<!-- your comment goes here -->
```

The following is a list of rules concerning metabase comments:

- Comments that are added above the MBProperty node are not picked up by edit-while-running.
- Comments that are added between the MBProperty node and the IIS_Globalnode cause an error file to be created.
- Comments that are added between IIS_Global and IIS_ROOT are picked up by edit-while-running.
- Adding comments between start and end XML tags results in an error file and the in-memory metabase being flushed to disk.

# Editing Metabase Properties

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can write metabase properties in MetaBase.xml as either schema-defined or custom properties. Writing schema-defined properties results in an efficient use of the IIS cache, which is where the in-memory metabase and schema are stored, because the attributes are inherited from the schema rather than rewritten for each instance of a property. Using custom properties is not recommended, because they might not show up in the UI and ADSI cannot access them after they have been created.

A schema-defined property is contained in the start tag of a key, and only the property name and value are defined. Attributes for a schema-defined property come from the metabase schema. In the following example, the **EnableEditWhileRunning** property is a schema-defined property with a value of zero, and it is written in the IIs_Computer key:

```
<IIs_Computer Location = "/LM"
   EnableEditWhileRunning = "0">
```

A custom property defines some or all of the attributes of a property. Unlike a schema-defined property, a custom property is written between the XML start tag and the end tag of a metabase key. Custom properties are easy to identify because the name of the element that contains the custom property is **Custom**. The name and attributes of a custom property are contained in an XML element named **Custom**.

At a minimum, the **Name** and **ID** attributes must be defined in a custom property. Other than the name of the property and the **ID** attribute, all remaining attributes for a custom property come from the schema, if they are undefined. You need to define the other attributes only when you want them to contain a different value than the schema-defined attribute values. In the following example, the **Win32Error** property is defined as a custom property with a value of zero, and it is written within the IIsFtpVirtualDir key.

```
<IIsFtpVirtualDir Location = "/LM/MSFTPSVC/1/ROOT">
   <Custom
      Name = "Win32Error"
      ID = "1099"
      Value = "0"
      Attributes = "INHERIT"/>
</IIsFtpVirtualDir>
```

| **Important** |
| --- |
| Each property that is defined in the schema (MBSchema.xml) has a unique **ID** attribute. When you define a known property as a custom property, you must specify the unique ID number for that property. |

#### General Notes for Editing the Metabase

Keep the following points in mind when editing the metabase:

- Properties with the **SECURE** attribute set are stored encrypted.
- All text in MetaBase.xml is case sensitive.
- The **KeyType** property contained in a node is used to determine the element or node type that is applied to the metabase path.
- Nodes that do not contain a **KeyType** property are stored as the generic object IISConfigObject, which can contain any property, and any node can be contained within any other node.
- Custom properties are allowed for any node type.
- The IIS_Global node must not be edited.
- A schema-defined property that violates the schema — for example, a misspelled property name — is logged and the property is ignored.

- Custom properties require a metabase **ID** attribute.
- The **Multi-SZ** attribute is replaced with the multistring value.
- Flags contain bitmask identifiers.
- The internal metabase implementation is Unicode. To support international and non-ASCII characters, the MetaBase.xml file is encoded in UTF-8 text format.

**Changing Schema-Defined or Out-of-Schema Properties**
You can use custom properties for the following purposes:

- To use properties that are not schema-defined.
- To use properties with different attribute values than what is available in the schema-defined properties.

When you write a property by using different attribute values than what is schema-defined, you must write the property as a custom property. Only the attributes that are different from the schema should be defined in MetaBase.xml.

The following example shows a schema-defined property:

```
AccessFlags = AccessWrite
```

The following example shows a custom property:

```
<Custom Name = "AccessFlags"
   ID = "6016"
   Type = "DWORD"
   Value = "1"
   UserType = "IIS_MD_UT_FILE"
   Attributes = "INHERIT"/>
```

**Starting or Stopping IIS**
When IIS is started or restarted, the metabase configuration that is stored in MetaBase.xml and the schema information that is stored in MBSchema.xml is read by the storage layer and then written to the in-memory metabase through ABOs, as shown in Figure 4.2.

If the MetaBase.xml file cannot be parsed when IIS is started or restarted, an error is sent to the event log and IIS does not start. The reasons that MetaBase.xml might not be parsed correctly include — but are not limited to — missing XML tags, misspelled property names, or corruption of the MetaBase.xml file. To determine the cause of failure, you can use the last history file to determine what has changed in the MetaBase.xml file. If the metabase cannot be parsed, you can also restore it to an earlier version by using the last manual backup or an automatically generated history file.

When IIS is stopped, it checks to determine whether the configuration node or the schema node have changed in the in-memory metabase since the last time the in-memory metabase was written to disk. The configuration node contains the metabase configuration, which is stored in the MetaBase.xml file. The schema node contains the metabase schema, which is stored in the MBSchema.xml file.

To minimize the amount of time that is required to stop IIS, the MetaBase.xml file is not written to disk if the configuration node in the in-memory metabase has not changed. If the configuration node in the in-memory metabase has changed since the last time the in-memory metabase was saved to disk, the MetaBase.xml file is overwritten with the contents of the configuration node, and a new history file is created. For more information about history files, see Naming the Metabase History Files.

# Editing the MetaBase.xml File While IIS Is Running

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

This section contains information about the metabase edit-while-running feature, which is also known as Direct Metabase Edit. The ability to edit the metabase while IIS is running makes administration simpler and avoids site down time, because you do not have to stop IIS when you need to change the metabase configuration.

# The Edit-While-Running Process

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS uses Windows file change notification to determine when the MetaBase.xml file has been saved. When IIS detects that the metabase configuration file has been saved, a series of checks are made, as illustrated in Figure 4.3. Several possible scenarios are presented, based on the results of the steps shown in the illustration, to demonstrate the behavior of edit-while-running.

| **Important** |
| --- |
| The MBSchema.xml file cannot be edited directly by using edit-while-running. Changes made to metabase schema must be made programmatically. |

**Explanation of the Edit-While-Running Process**

**Step 1: IIS receives a file change notification that MetaBase.xml has been saved.**
IIS receives a file change notification from Windows when the metabase configuration file is saved. If MetaBase.xml is write-locked and you attempt to save MetaBase.xml directly with an application such as Notepad, an error is generated and a file change notification does not occur.

**Step 2: IIS looks in MetaBase.xml for the HistoryMajorVersionNumber value.**
IIS reads the value of the **HistoryMajorVersionNumber** property in MetaBase.xml to determine the major version number.

**Step 3: IIS looks in the History folder for the corresponding history file.**
The corresponding history file is named with the highest minor version number with the same HistoryMajorVersionNumber value found in MetaBase.xml in step 2. If the corresponding history file is found, IIS proceeds to step 4.

**Step 4: Parse MetaBase.xml.**
IIS parses MetaBase.xml to determine whether there are fatal XML errors, such as missing XML end tags. If MetaBase.xml can be parsed successfully, IIS proceeds to step 5.

**Step 5: Compare MetaBase.xml to the corresponding history file.**
IIS compares MetaBase.xml to the corresponding history file of the same major version within the History folder. IIS determines the differences between the two files and does one of the following:

- If no changes were made to MetaBase.xml, a history file is not created and no further action is taken.
- If changes were made to MetaBase.xml, IIS proceeds to step 6.

**Step 6: Check that the level exists in the in-memory metabase that changes were made to in MetaBase.xml.**
IIS determines whether the level/node exists within the in-memory metabase that changes were made to in the MetaBase.xml file. If the level/key exists within the in-memory metabase, IIS proceeds to step 7.

**Step 7: Write the changes to the in-memory metabase through ABO.**
The changes are written to the in-memory metabase through ABOs.

A change that was made to MetaBase.xml might not be sent to the in-memory metabase for any of the following reasons:

- The change violates metabase schema; for example, a property name is misspelled.
- The in-memory metabase is write-locked by someone making a simultaneous change by using ADSI, ABO, or WMI to modify the same metabase node or property.
- The key in the in-memory metabase that changes were made to in MetaBase.xml does not exist. This could occur if an administrator deletes the key in the in-memory metabase, by using a programmatic interface or IIS Manager, before MetaBase.xml is changed and saved to disk.

If a change is not written to the in-memory metabase for any of the reasons listed above, an error or warning is sent to the event log.

**Step 8: IIS creates a new history file that contains the contents of the corresponding history file and the changes that were written to the in-memory metabase.**
A history file is created in the History folder. This new file includes the combination of contents of the corresponding history file plus the changes that were written to the in-memory metabase in step 7. The new history file is named with the major version number that was found within MetaBase.xml (the value of the **HistoryMajorVersionNumber** property that was determined in step 2) and the next highest minor version number. IIS looks within the History folder to find the highest minor version number that was used for the same major version number, and it uses the next sequential minor version number to name the new history file. This naming convention permits succeeding edits to the same major version of the file to work correctly.

# Simultaneous Updates

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS supports simultaneous updates between programmatic interfaces such as ADSI and WMI. However, under some circumstances, errors can occur as described in step 7 above. The rule is that the last write always wins.

IIS does not support simultaneous updates between the programmatic interfaces and an administrator who directly edits MetaBase.xml. Simultaneous writes to the same metabase node or property can result in an error because of the resulting race condition. You can protect against this type of error by allowing only one administrator to edit the metabase at a time.

# Enabling Edit-While-Running

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Edit-while-running can be enabled by using either IIS Manager or a command prompt. Before you can enable edit-while-running, the metabase history feature must be enabled and set to a value of at least 10 (the default metabase history setting).

| **Important** |
| --- |
| All text within MetaBase.xml is case sensitive. |

For more information about enabling edit-while-running from IIS Manager or a command prompt, see Enabling Edit-While-Running in IIS 6.0.

# Writing the In-Memory Metabase and Schema to Disk

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The metabase is written to disk either when MetaBase.xml is edited directly and manually saved to disk, or when the in-memory metabase is saved to disk.

| **Important** |
| --- |
| MetaBase.xml can be edited by hand and saved to disk only when edit-while-running is enabled or when the IIS Admin service is stopped before the MetaBase.xml file is edited and saved. |

The in-memory metabase is written to disk only under the following circumstances:

- When the IIS Admin service is stopped, and there are changes pending in the in-memory metabase.
- The in-memory metabase is written to disk 60 seconds after a change is made to the metabase; however, if more than 30 changes occur during those 60 seconds, the write-to-disk event is postponed for another 60 seconds. The in-memory metabase write-to-disk event is postponed a maximum of five times, after which it is written to disk.
- When saved programmatically, as when using a resource such as ADSI, WMI, or ABO.

Figure 4.4 and the following discussion describe how the in-memory metabase is written to disk. The verification checks can influence how IIS saves the in-memory metabase to disk, as illustrated by the possible scenarios.

# Writing the In-Memory Metabase to Disk

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Figure 4.4 shows the process IIS uses to determine when to write the in-memory metabase to disk.

Step 0: A change is made to the metabase, which schedules a write-to-disk event 60 seconds in the future.

**Explanation of How the In-Memory-Metabase Is Written to Disk**

**Step 1: Are there changes pending in the in-memory metabase?**

When a write-to-disk event occurs, IIS first checks for pending changes that occurred after the first change in the in-memory metabase. Changes that are written to the MetaBase.xml file when edit-while-running is enabled are counted as pending changes in the in-memory metabase. If there are no pending changes in the in-memory metabase, no further action is taken and the in-memory metabase is written to disk; otherwise, IIS proceeds to step 2.

**Step 2: IIS locks the in-memory metabase to prevent external writes.**

The in-memory metabase is write-locked, meaning that no writes can occur but the metabase can still be read; this prevents writes while the in-memory metabase is written to disk and ensures that a valid copy of the in-memory metabase is saved.

**Step 3: IIS determines the major version number.**
IIS increases the value of the **HistoryMajorVersionNumber** property in the in-memory metabase by one. IIS then verifies whether a file in the History folder is named with the same major version number. If a file that uses the same major version number exists in the History folder, IIS increases the value of the **HistoryMajorVersionNumber** property in the in-memory metabase again by one, and checks the History folder to determine whether the major version number is available. This process is repeated until an available major version number is found.

This method of determining the major version number prevents the possibility of overwriting a file in the History folder. Although unlikely under normal circumstances, the possibility exists that a file in the History folder has a nonsequential version number for one of the following reasons:

- An administrator changes the value of the **HistoryMajorVersionNumber** property, which causes the value of the **HistoryMajorVersionNumber** property to roll over to 1 or to the lowest available major version number.

- An administrator copies an old history file into the History folder.

**Step 4: IIS creates a temporary file that contains the in-memory metabase configuration.**
When the major version number is determined, a temporary file named Xml.tmp is created in the same folder as MetaBase.xml. The major version number that was determined in step 3 is written in the temporary file.

**Step 5: IIS unlocks the in-memory metabase to allow writes.**
After the temporary file is created, the in-memory metabase is unlocked to allow writes through ABOs.

**Step 6: IIS copies the temporary file to the History folder and renames the history file by using the major and minor version numbers.**
The temporary file is copied to the History folder and renamed in the following format, where *HistoryMajorVersionNumber*is the major version number that was determined in step 3 and the minor version number is reset to 0.

MetaBase_*HistoryMajorVersionNumber_MinorVersionNumber*.xml

**Step 7: Is MetaBase.xml write-locked?**
The MetaBase.xml file can become write-locked if edit-while-running is not enabled and an administrator uses an application to open MetaBase.xml for editing, and the editing application enforces a write-lock. An application that enforces a write-lock releases the lock when the file is closed. However, in most circumstances, MetaBase.xml is not write-locked.

If MetaBase.xml is write-locked by an application, IIS cannot write changes to the file. Instead, a history file is created and an error is sent to the event log.

**Step 8: Is MetaBase.xml newer than the temporary file?**
IIS checks to determine whether the MetaBase.xml file is newer than the temporary file. The MetaBase.xml file can be newer than the temporary file when the in-memory metabase is written to disk at about the same time that an administrator saves changes to the MetaBase.xml file when edit-while-running is enabled.

If the MetaBase.xml file is newer than the temporary file, the MetaBase.xml file is not overwritten with the temporary file. Instead, an error is sent to the event log.

**Step 9: The temporary file copies over MetaBase.xml, and is then deleted.**
If all verification tests are passed, the MetaBase.xml file is overwritten with the temporary file and the temporary file is deleted.

**Step 10: Delete oldest history file?**
IIS checks to determine whether the number of history file pairs in the History folder exceeds the value of the **MaxHistoryFiles** property. (A history file pair is a MetaBase.xml file and an MBSchema.xml history file that are named by using the same major and minor version numbers.) If the number of history file pairs exceeds the value of the **MaxHistoryFiles** property, the oldest history file pair is deleted.

# Writing the In-Memory Schema to Disk

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS can distinguish changes that are made to the in-memory metabase schema separately from changes that are made to the in-memory metabase configuration. The process of writing the in-memory metabase schema to disk is similar to writing the in-memory metabase configuration to disk, as follows:

- If there are no pending changes within the in-memory metabase schema when a write-to-disk event occurs, the in-memory metabase schema node is not written to disk. Instead, the MBSchema.xml file is copied to the History folder and renamed with the same major and minor version numbers that are used to name the metabase configuration history file in step 6 above.

- If changes are made to the in-memory metabase schema, the following occurs:

    - The MBSchema.xml file is renamed to a temporary schema file.

    - The in-memory schema is written to MBSchema.xml.

    - The temporary schema file is copied to the History folder and renamed with the same major and minor version numbers that are used in step 6 above.

# Metabase Import and Export

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The metabase import and export feature enables administrators to create an export file, named MetaBase.xml by default, which contains specifically selected elements of a metabase configuration file. This export file can later be imported into the metabase configuration file of the same computer, or to another computer running Windows Server 2003. For more information about procedures for performing metabase import and export, see Metabase Import and Export in IIS 6.0.

Additionally, you can use the metabase export feature to create a metabase template, which can be used to configure multiple computers with the same IIS configuration settings, excluding machine-specific and system-specific information. For more information about metabase templates, see Restoring a Section of the Metabase.

Metabase export does not replace the functionality of metabase backup. You use metabase backup to create a backup file of the entire metabase configuration and schema, which can be restored only in its entirety (including encrypted properties). Metabase export does not export the metabase schema.

| **Note** |
| --- |
| Neither metabase backup nor export can be used to save or copy content files, scripts, or binaries. To back up your entire server — including content files, scripts, and binaries — use Windows Backup. To simply copy these files to a new location, use Windows Explorer or the Windows **xcopy** command. Remember to reregister any components that you copy to a new computer. |

**Specifying Metabase Elements for Import or Export**

You can import and export the following metabase elements:

- All Web site configurations or a single site configuration
- All FTP site configurations or a single FTP site configuration
- All SMTP site configurations or a single SMTP site configuration
- All NNTP site configurations or a single NNTP site configuration
- An IIS application configuration
- A directory, virtual directory, or file configuration properties
- All application pool configurations or a single application pool configuration

**Importing and Exporting a Metabase Element**

To import or export a metabase element, you can use any of the following:

- IIS Manager
- The Iiscnfg.vbs tool that is included with IIS
- A custom script that uses the **Export** method of the WMI provider for IIS or the **Export** method of the ADSI provider for IIS
- A custom application that uses ABO

Regardless of whether you use a programmatic interface, a script, or IIS Manager to import and export metabase elements, there are specific choices you must make. The following list outlines both the required and optional steps needed to import and export a metabase element. The inheritance and merge options are discussed after the list. When a metabase element is

exported, IIS creates an XML file that contains the exported element.

**Before exporting a metabase element**

1. Select a metabase element to export.
2. Specify the name and location of the XML file to contain the exported element.
3. Optionally choose to export inherited properties.
4. Optionally choose to export lower-level child keys recursively (recommended).
5. Optionally encrypt the export file with a password that you provide (recommended).

**Before importing a metabase element**

1. Specify a metabase export file to import.
2. Specify an element within the export file to import.
3. Optionally choose to import inherited properties.
4. The export file must contain inherited properties for this option to be available.
5. Optionally choose to import lower-level child keys recursively.
6. The export file must contain lower-level child keys for this option to be available.
7. Specify the password, if any, that was used to encrypt the export file.
8. Optionally choose to merge the settings from the export file into the metabase configuration.
9. If you intend to import a metabase element to another computer, you must first change the machine-specific and system-specific information in the export file.

**Setting Inherit and Merge Flags**

If you set the inherit flag during a metabase export, inheritable properties that are applicable to the metabase element are saved as part of the export file. If the inherit flag is set during an import operation, these inheritable properties are imported into the metabase.

The behavior of importing inheritable properties differs, depending on whether the merge flag is used along with the inherit flag.

For example:

- If you import a metabase element by using the inherit flag without the merge flag, inheritable properties are imported into the metabase, unless the property already exists at the same location in MetaBase.xml. (If the value of an imported property differs between the export file and the MetaBase.xml file, the value of the property in the MetaBase.xml file remains unchanged.)
- If you import a metabase element by using the inherit flag with the merge flag, inherited properties are imported into the metabase and the value of the properties that already exist at the same location in MetaBase.xml are overwritten. (If the value of an imported property differs between the export file and the MetaBase.xml file, the value of the property in the MetaBase.xml file is overwritten with the value from the export file.)

**Important**

Inherited properties in the destination metabase affect the configuration of all sites. Use caution when you import a metabase element without using the inherit flag. To avoid unintended changes to other sites, import to a unique location that has no child nodes.

**Exporting Lower-Level Child keys**

When specifying a metabase element to export, you can optionally export lower-level child keys. If an element is exported by using this option, you can optionally import the element and all recursive child keys.

# Importing and Exporting Metabase Elements with IIS Manager

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can use the metabase import/export feature to create an export file that contains specifically selected elements of a metabase configuration file. This exported file can later be imported into the metabase configuration file on the same computer or another computer running Windows Server 2003.

The simplest way to use the metabase import/export feature is through IIS Manager. However, if you need to use this feature on numerous machines quickly, you can use one of the following:

- The Iiscnfg.vbs tool that is included with IIS 6.0
- A custom script that uses the **Export** method of the WMI provider for IIS or the **Export** method of the ADSI provider for IIS
- A custom application that uses ABO

For more information about importing and exporting metabase elements using IIS Manager, see Exporting Metabase Elements with IIS Manager and Importing Metabase Elements with IIS Manager.

# Moving Sites and Applications to Another Computer

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can use the metabase export feature to configure multiple computers with the same basic IIS configuration settings. The procedure below illustrates how to create a metabase template for the WWW service — though any service, site, virtual directory, or application can be moved.

For more information about moving sites and applications to other computers, see Moving Sites and Applications to Another Computer in IIS 6.0.

# Metabase Import/Export Behavior

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When using the metabase import/export feature, you need to be aware of the following behaviors with which the feature operates:

- If you attempt to import a property to a computer whose metabase schema file does not include the property, the import process continues, but errors are logged in Event Viewer. If you are using a script or application to perform the import, the script or application issues a warning.
- If the key type of any imported metabase element does not match the destination element, an error occurs.
- If you use a script or application that uses the inherited option, inherited settings are imported and applied to the top element. If you do not use the inherited option, only the elements that are explicitly set are imported.
- If you import configuration data by using a script or application and you use the merge flag, existing elements are not overwritten, and new ones are added. If you do not use the merge flag, existing elements are deleted or overwritten.

# Machine-Specific and System-Specific Information

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When importing a metabase element to another computer, you must change or remove machine-specific and system-specific information in the import file before you use it; otherwise IIS cannot use these values.

| **Important** |
| --- |
| Never include password properties in import files. If you use an import file with a blank password property, the new computer subsequently stores encrypted properties as plain text. |

Metabase properties that contain paths to resources in the file system might not match the paths on other computers. For example, the following properties might be written in the import file in the following way:

```
LogFileDirectory = ""
Path = "c:\inetpub\ftproot"
HttpErrors = "400,*,FILE,
   more HTTP errors
InProcessIsapiApps = "
   more ISAPI applications
ScriptMaps = ".asp,,1,GET,HEAD,POST,TRACE
   more script maps
```

Change the paths in bold above to the path used by the computer to which you want to import the metabase element. Search for other paths in your import file before using it.

Metabase properties that specify the IWAM and IUSR accounts might not match the user accounts used by other computers. If your import file contains these properties, delete or alter them so that their values do not overwrite the existing valid properties. These properties might be written in the import file in the following way:

```
<IIsWebService
   Location = "/LM/MSFTPSVC"
   WAMUserName = "AccountName"
   AnonymousUserName = "AccountName">
```

The **ServerBindings** property, which is used to configure the port number for a site, might not be set the same way on another computer. However, you might want to import these settings to the new computer so that the computers will be configured the same way. The **ServerBindings**property is set at the site level, and can be written in the import file in the following way:

```
<IIsFtpServer
   Location = "/LM/MSFTPSVC/1"
   ServerBindings = ":21:" >
<IIsWebServer
   Location = "/LM/W3SVC/1"
   ServerBindings = ":80:">
```

Metabase properties that contain ACLs cannot be moved to another computer. If your import file contains these properties, delete them so that their values do not overwrite the existing valid properties. These properties might be written in the import file in the following way:

```
AdminACL = "LongNumber"
```

Metabase properties that contain passwords cannot be moved to another computer. If your import file contains properties with passwords, delete them so that their values do not overwrite the existing valid properties. These properties might be written in the import file in the following way:

```
<IIsWebService
   Location = "/LM/W3SVC"
   WAMUserPass = "LongNumber"
   AnonymousUserPass = "LongNumber"
   LogOdbcPassword = "LongNumber">
```

# Additional Resources for the IIS 6.0 Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

These resources contain additional information and tools related to the IIS 6.0 metabase.

**Related Information**

- Common IIS 6.0 Administrative Tasks for step-by-step instructions to help you complete many metabase-related tasks.
- IIS 6.0 Architecture for information about the role of the metabase in the overall architecture of IIS 6.0.

**Related topics in the IIS 6.0 Operations Guide**

- IIS 6.0 Registry Reference for information about the IncrementalSiteIDCreation registry key.
- Metabase Property Reference for information about the IIS 6.0 metabase properties.
- The Metabase Schema for information about the IIS 6.0 metabase schema.

**Related Windows Server 2003 Help Topics**
For best results in identifying Help topics by title, in Help and Support Center, under the **Search** box, click **Set search options**. Under **Help Topics**, select the**Search in title only** check box.

- "Access control" in Help and Support Center for Windows Server 2003 for information about how to configure ACLs.
- "Backing up and restoring data" in Help and Support Center for Windows Server 2003 for information about how to back up your entire operating system that include special steps that must be performed to include IIS in that backup.
- "Passwords" in Help and Support Center for Windows Server 2003 for information about strong passwords.

**Related Tools**

- The IIS MetaEdit 2.2 Utility

  MetaEdit is a metabase editing tool available for download from Microsoft. For information about how to obtain MetaEdit, see Knowledge Base article 232068.

# Managing a Secure IIS 6.0 Solution

Updated: August 22, 2005

Applies To: Windows Server 2003 with SP1

Appropriate security safeguards on your Web server can help reduce or eliminate various security threats. These threats can come from malicious users as well as from well-intentioned users who accidentally gain access to restricted information or inadvertently alter important files. Internet Information Services (IIS) 6.0 provides the elements for a secure IIS solution, including a new approach to server configuration that emphasizes installing only the services that you know you will run on your server.

**In This Section**

Security Changes in IIS 6.0

# Security Changes in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

To improve the security of your Web server, many aspects of IIS 6.0, including default behavior and settings, function differently than in earlier versions of IIS. Some of the most notable changes were made to take a more proactive stance against malicious users and attackers. A significant change is that IIS is not installed by default on Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems, and many services and features of IIS are not installed or enabled by default when you install IIS. Other security changes in IIS 6.0 affect components of Active Server Pages (ASP), authentication, and access control methods. As a result of these changes, some existing applications and sites might require you to enable services, change settings, or make other adjustments before they run as expected. However, if you change default settings, you should do so carefully to maintain the most secure solution possible.

The most significant security-related changes are as follows:

- IIS installs in a locked-down mode.
- Restrictive Multipurpose Internet Mail Extensions (MIME) types reduce the attack surface of IIS.
- Multiple worker processes affect Internet Server API (ISAPI) filter status display.
- ASP and ASP.NET functionality are disabled by default.
- Parent paths are disabled by default.
- Global.asa events are run as anonymous user.
- Anonymous password synchronization is disabled by default.
- Advanced Digest authentication requires Windows Server 2003.
- Microsoft® .NET Passport authentication requires LocalSystem user account rights.
- Kerberos authentication requires service principal names (SPNs) for multiple worker processes.
- Access is restricted for executables.
- Access is restricted for non-default identities for Common Gateway Interface (CGI) processes.

The following sections describe the security-related changes and provide information about how to customize your IIS work environment.

# IIS Installs in a Locked-Down Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you install IIS 6.0, it is locked down — only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on by default, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and Web Distributed Authoring and Versioning (WebDAV). This locked-down state minimizes the attack surface that is available to intruders, who sometimes target computers by attacking services that are running but that are unused. These attacks can happen if, for example, an administrator forgets to turn off an unused service, and then to maintain it with current hotfixes, service packs, and security updates. Over time, the service might become increasingly vulnerable to attackers.

IIS 6.0 installation and service-enabling features simplify administration and management of IIS services for security purposes. For example:

- You can install and enable services when you need them.
- If you need additional services, you can enable them through the Web Service Extensions node in IIS Manager.
- When enabled features are no longer required, you can disable them through the Web Service Extensions node in IIS Manager.

| **Important** |
| --- |
| It is possible to use the Web Service Extensions node to allow all unknown ISAPI and CGI extensions, but this presents a security risk and is not recommended. This option is available for use in development and test environments, but it should never be enabled on a production server. |

**IIS Lockdown Tool Capabilities Are Built-in**

You cannot install the IIS Lockdown Tool in IIS 6.0. However, to prevent the WWW service from being disabled after an upgrade, you can run the IIS Lockdown Tool prior to upgrading from an earlier version of IIS. When you upgrade from a server running Microsoft Windows® 2000 Server and IIS 5.0, IIS 6.0 runs in IIS 5.0 isolation mode by default, and IIS implements the following security measures:

- UrlScan functionality is left unchanged. UrlScan is a tool that reduces the attack surface of Web servers running earlier versions of IIS. By default, IIS 6.0 has features that significantly improve security by reducing the attack surface of the Web server. UrlScan provides flexible configuration for advanced administrators, while maintaining the improved security in IIS 6.0. When you need this flexibility in configuring your Web server, you can run UrlScan on IIS 6.0.
- Web service extensions that are mapped to 404.dll are mapped to their original location and added to the Web service extensions list with a prohibited status.
- Access control lists (ACLs) for WebDAV are reset correctly, and WebDAV is added to the Web service extensions list with a prohibited status.
- Indexing Service is left disabled, and existing ACLs are unchanged.

# Restrictive MIME Types Reduce the Attack Surface of IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

To help prevent attackers from sending files that could compromise the security of your Web server, the IIS static file handler serves only the files that are explicitly listed in the list of Multipurpose Internet Mail Extensions (MIME) types. IIS is preconfigured to recognize a default set of global MIME types that are recognized by all of the Web sites that you create with IIS.

If the default list of registered MIME types is too restrictive and you want to allow IIS to serve other file types, you can add allowable MIME types on a global basis or for a specific Web site or directory.

For more information about MIME types, see Working with MIME Types.

**Allowing All Extensions**

In IIS 5.0, if a request fell through the static file handler, IIS served the file, regardless of its extension. IIS 6.0 does not automatically serve file requests that fall through the static file handler. Although it is not generally recommended as a best security practice, you might want to allow all file extensions in some scenarios — for example, if you want to serve files that have ascending extensions such as .001, .002, and so on. If you want to serve all files, you can add a wildcard character (*) to the MIME types list. Files that do not have extensions can be served only if the wildcard character is added to the list.

You can add a wildcard character through IIS Manager, or you can add one programmatically by using the Adsutil.vbs command-line script. For information about adding a wildcard character through IIS Manager, see Creating Global MIME Types and Creating MIME Types for a Web site or directory.

To add a wildcard programmatically by using Adsutil.vbs, use the customizable text file provided in Listing 5.1.

**Important** You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters).

**Listing 5.1 Sample Script for Adding Wildcards**

```
c:\inetpub\adminscripts\adsutil.vbs set /w3svc/MimeMap ".*,common/type"
Sample
' VBScript source code
Const ADS_PROPERTY_UPDATE = 2
Set MimeMapObj = GetObject("IIS://LocalHost/MimeMap")
aMimeMap = MimeMapObj.GetEx("MimeMap")
' Add a new mapping.
i = UBound(aMimeMap) + 1
Redim Preserve aMimeMap(i)
Set aMimeMap(i) = CreateObject("MimeMap")
aMimeMap(i).Extension = ".*"
aMimeMap(i).MimeType = "common/type"
MimeMapObj.PutEx ADS_PROPERTY_UPDATE, "MimeMap", aMimeMap
MimeMapObj.SetInfo
```

For more information about using adsutil.vbs, see Using the Adsutil.vbs Administration Script.

# Multiple Worker Processes Affect ISAPI Filter Status Display

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

As a routine security practice, you should monitor the status of your ISAPI filters to ensure that they are functioning correctly. In IIS 6.0, you can use IIS Manager to check the ISAPI filter status. Because multiple worker processes are supported in IIS 6.0, be careful when you interpret the status as it is displayed. For example, if a red arrow appears, that indicates that the last ISAPI filter failed to load; it does not indicate that all of the ISAPI filters for all of the worker processes failed.

For more information about checking the status of ISAPI filters, see Checking ISAPI Filter Status.

# ASP-Related Security Changes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

There are several important changes to the way IIS interacts with ASP that improve security and reduce the attack surface of IIS.

**ASP and ASP.NET Are Disabled by Default**
In IIS 6.0, ASP and ASP.NET are disabled by default. If you want to serve ASP or ASP.NET content from IIS 6.0, you must first enable ASP or ASP.NET in the Web Service Extensions node.

| **Note** |
| --- |
| If your content requires ISAPI, CGI, WebDAV, or other extensions, you must enable those extensions as well. |

For more information about enabling ASP or ASP.NET, see Enabling ASP Pages in IIS 6.0 and Enabling ASP.NET.

**Parent Paths Are Disabled by Default**
When parent paths are enabled, ASP pages allow you to include files with paths that are relative to the current directory (using the ..\ notation). This constitutes a potential security risk because a server-side include (SSI) path can provide access to critical or confidential files that are outside the root directory of the application. When parent paths are enabled, a Web server is more susceptible to *traversal attacks*, which allow a malicious user to execute commands or view data that is outside the intended target path.

In IIS 6.0, because parent paths are disabled by default, an existing application that has a Web page that contains the #include SSI directive and uses ..\ notation to refer to a parent directory will not work unless you enable parent paths. The parent paths correspond to the **AspEnableParentPaths** metabase property. For more information about enabling parent paths, see Configuring ASP Applications. For more information about SSI directives, see Using Server-Side Include Directives.

**Global.asa Events Are Run As Anonymous User**
In earlier versions of IIS, ASP executes events in the security context (or user identity) of the host process because during ASP-executed events there is no user context. Global.asa executes events in earlier versions of IIS as follows:

- **Application_OnStart** Impersonated user
- **Application_OnEnd** Host identity
- **Session_OnStart** Impersonated user
- **Session_OnEnd** Host identity

In IIS 6.0, ASP executes the Global.asa events **Application_OnEnd** and **Session_OnEnd** anonymously by default. This change prevents user code from running as the base identity of the worker process. For example, if **Application_OnEnd** and **Session_OnEnd** run under the host identity context, and an Internet service provider (ISP) allows users to upload Global.asa files, a malicious user might be able to use the **FileSystemObject** to access files that are otherwise inaccessible in the anonymous context.

If you want to change this default setting, use the **AspRunOnEndAnonymously** metabase property. For more information about this setting, see the AspRunOnEndAnonymously Metabase Property.

# Security-Related Changes in Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 introduces a number of changes to user authentication. These changes include new default settings and requirements for different authentication methods.

**Anonymous Password Synchronization is Disabled by Default**

- Anonymous password synchronization requires the IIS subauthentication component, Iissuba.dll, which was installed by default in earlier versions of IIS. The subauthentication component allows IIS to authenticate an anonymous user even if the password in the IIS metabase does not match the password in the Windows local account database. Because this involves a security risk, the subauthentication component is not installed by default in IIS 6.0. However, some administrators need to use anonymous password synchronization, in, for example, large ISP settings where thousands of anonymous IIS accounts are used to isolate Web sites.

- For more information about enabling subauthentication and anonymous password synchronization, see Configuring Subauthentication on a New Installation of IIS 6.0.

**Advanced Digest Authentication Requires Windows Server 2003**
To use Advanced Digest authentication, the domain infrastructure and the server running IIS must both be running Windows Server 2003. If you upgraded to IIS 6.0, the default digest authentication is Digest authentication. If you performed a clean installation of IIS 6.0, the default digest authentication is Advanced Digest authentication. For more information about Advanced Digest authentication, see Advanced Digest Authentication.

**Intermediate Certificates Are Not Downloaded to Complete a Certificate Chain**
When IIS receives an incoming SSL request from a client, IIS attempts to build its certificate chain before sending its certificate information back to the client. In IIS 6.0, missing intermediate certificates are not automatically downloaded by default, which was the behavior for previous versions of IIS. To ensure that client requests for SSL-enabled content can be served, you must manually add the intermediate certificate to the Intermediate Certification Authorities folder on the local computer. In addition, every time a certificate in the external chain is renewed or modified, you must manually update the certificate store. For information about manually updating the certificate store, see Client receives 403.16 error when IIS cannot process a complete certificate chain.

This change affects the following scenarios:

- IIS servers in workgroups, because no Group Policy is available to populate the cache.

- Cross Certificates, because the certificates might not be published into the Directory Service so Group Policy can populate the cache.

- IIS servers that are set to explicitly trust a foreign Certification Authority (CA).

**.NET Passport Authentication Requires LocalSystem User Account Rights**
Microsoft .NET Passport authentication works only when the account that is used for the IIS worker process has *trusted computing base*(TCB) rights, which means that the account acts as part of the operating system. Only the LocalSystem user account has TCB rights by default. You can add TCB rights to an account by using the Local Security Settings snap-in. However, because a worker process running with TCB rights acts as part of the operating system, this account has a very high level of access, which presents a security risk.

**Kerberos Authentication Requires SPNs for Multiple Worker Processes**
You can isolate Web sites that are in different worker processes and running under different identities; however, unexpected IIS behavior might occur if you use Integrated Windows authentication. Integrated Windows authentication attempts to use Kerberos authentication, which might not work, depending upon the identity of the worker process. To use Kerberos authentication, a service must register its Service Principal Name (SPN) in the account in the Microsoft Active Directory® directory service under which the service is running. By default, Active Directory registers the NetBIOS name or computer name and allows the Network Service or LocalSystem user accounts to use Kerberos. However, for Kerberos to work with the following configurations, you must first register an SPN:

- If your site is referenced by a Windows Internet Name Service (WINS) or Domain Name System (DNS) name that is different from the computer name of the server running IIS (a Web farm, for example), authentication defaults to NTLM (which is also known as Microsoft Windows NT® Challenge/Response authentication).

- If you configure the worker process for the Web site to run as a domain account, and you did not use a WINS or DNS name, authentication will fail. This is because the SPN can be found, but it is registered for the Network Service and LocalSystem user accounts, not for the domain account under which the worker process is running.

You can use the Setspn.exe command-line tool to register an SPN on the account under which the worker process is running. You must be a domain administrator to set an SPN. The Setspn.exe tool is included in Resource Kit Tools for Windows Server 2003, available on the *Windows Server 2003 Deployment Kit* companion CD, or on the Web at http://www.microsoft.com/reskit.

**Forcing NTLM**

When you isolate Web sites on a virtual directory level by configuring worker process identities as different domain accounts, Kerberos fails. If you are using Integrated Windows authentication, are not using a WINS or DNS name for the server running IIS, and you want to use a local user account or the Local Service user account as a worker process identity, Kerberos authentication fails because Active Directory does not trust the accounts.

To work around these issues, you can force IIS to use NTLM authentication by setting the NTAuthenticationProviders Metabase Property to NTLM.

# Security-Related Changes in Access Control

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 improves security by changing access control requirements for executables and CGI processes. These changes can affect existing applications that might require less restrictive permissions.

**Access Is Restricted for Executables**
Windows Server 2003 requires a user to be a member of the Administrators group to run most command-line executables in the System folder, so remote access is limited to administrators. This might affect you if your application uses command-line tools from a Web page. To work around this issue, change the ACL for the executable by using an ACL editing tool, such as the **cacls** command. For more information about ACLs and ACL editing tools, see Access Control in IIS 6.0.

**Access Is Restricted for Nondefault Identities for CGI Processes**
IIS 6.0 worker processes use the **CreateProcessAsUser** API to start CGI processes. The **CreateProcessAsUser** API must have the SE_ASSIGNPRIMARYTOKEN_NAME and SE_INCREASE_QUOTA_NAME user rights to succeed. The Network Service, Local Service, and LocalSystem user accounts have these user rights. If you change the identity of a worker process and want to run CGI processes, ensure that the new identity has these two user rights. You can assign user rights using the Local Security Settings snap-in in Windows Server 2003.

For more information about configuring user rights for identities that run CGI processes, see Configuring User Rights for Nondefault Identities to Run CGI Processes.

# Automatic Installation of Security Updates

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

As a security best practice, keep IIS up-to-date with the current security updates that Microsoft releases. With Windows Server 2003 Automatic Updates, you can install updates automatically so that the most critical code is updated on your computer, based on a schedule that you specify. You do not need to be logged on to the computer for the installation to occur. By minimizing the time that you spend logged on to your computer as a member of the Administrators group, your computer is less vulnerable to attack.

The only IIS updates that are available for scheduled automatic installation are critical security-related hotfixes. Because these hotfixes might require restarting the operating system, you can delay or change the time of the scheduled installation. You must be logged on as an administrator to change the scheduled installation time.

When an update is available for automatic installation, two events occur:

- At the scheduled installation time, the Priority 0 Critical security hotfix is installed.
- After the scheduled installation takes place, an event is logged notifying you that the hotfix has been installed successfully.

For information about scheduling automatic updates, see To schedule automatic updates in Microsoft Windows Server 2003 documentation.

# Authentication Methods Supported in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Using authentication with IIS is critical if your Web server contains resources that are not meant for anonymous or public access, but approved users must be able to access the Web server over the Internet. For example, if you run Microsoft® Outlook® Web Access (OWA) or the Microsoft Terminal Services Advanced Client on your Web server, you must configure an appropriate authentication method to control access to those applications. You can require users to confirm their identity by providing a valid Microsoft® Windows® name and password before they access any information on your Web server. This identification process is called *authentication*, and, like many features of IIS, authentication can be set at the Web site, directory, or file level.

IIS 6.0 supports the following authentication methods:

- Anonymous authentication. This authentication method allows everyone access to the public areas of your Web sites, without asking for a user name or password.
- Basic authentication. This authentication method prompts the user for a user name and a password, also called *credentials*, which are sent unencrypted over the network.
- Digest authentication. This authentication method operates much like Basic authentication, except that passwords are sent across the network as a hash value for additional security. Digest authentication is available only on domains with domain controllers running Windows server operating systems.
- Advanced Digest authentication. This authentication method is identical to Digest authentication, except Advanced Digest authentication stores the client credentials as a Message Digest (MD5) hash in Active Directory on your domain controller running Windows Server 2003.
- Integrated Windows authentication. This authentication method uses hashing technology to scramble user names and passwords before sending them over the network.
- UNC authentication. This authentication method passes users' credentials through to the computer with the Universal Naming Convention (UNC) share.
- .NET Passport Authentication. This authentication method is a user-authentication service that lets Web site users create a single sign-in name and password for access to all .NET Passport–enabled Web sites and services. .NET Passport–enabled sites rely on the .NET Passport central server to authenticate users; .NET Passport–enabled sites do not host and maintain their own proprietary authentication systems.
- Certificate authentication. This authentication method uses Secure Sockets Layer (SSL) certificates to authenticate servers and clients.

Table 5.2 compares the Web site authentication methods that are discussed in this chapter.

**Table 5.3 Comparison of Web Site Authentication Methods**

| Method | Security Level | How Passwords Are Sent | Crosses Proxy Servers and Firewalls | Client Requirements |
|---|---|---|---|---|
| Anonymous authentication | None | N/A | Yes | Any browser |
| Basic authentication | Low | Base64 encoded clear text | Yes, but sending passwords across a proxy server or firewall in clear text is a security risk because Base64 encoded clear text is not encrypted. | Most browsers |

| | | | | |
|---|---|---|---|---|
| Digest authentication | Medium | Hashed | Yes | Internet Explorer 5 or later |
| Advanced Digest authentication | Medium | Hashed | Yes | Internet Explorer 5 or later |
| Integrated Windows authentication | High | Hashed when NTLM is used; Kerberos ticket when Kerberos is used. | No, unless used over a PPTP connection | Internet Explorer 2.0 or later for NTLM; Windows 2000 or later with internet Explorer 5 or later for Kerberos |
| Certificate authentication | High | N/A | Yes, using an SSL connection | Internet Explorer and Netscape |
| .NET Passport authentication | High | Encrypted | Yes, using an SSL connection | Internet Explorer and Netscape |

If you configure multiple authentication methods, IIS attempts to negotiate the most restrictive method first, and then it works down the list of available authentication protocols until finding an authentication method that is supported by both the client and the server.

You can also provide security for FTP sites by using one of the following authentication methods:

- Anonymous FTP authentication. This authentication method gives users access to the public areas of your Web site without prompting them for a user name and password.

- Basic FTP authentication. This authentication method requires users to log on with a user name and password corresponding to a valid Windows user account.

You can use these authentication methods to grant access to public areas of your site while minimizing the risk of unauthorized access to your private files and directories. Each authentication method is covered in detail in the following sections.

# Anonymous Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Anonymous authentication gives users access to the public areas of your Web or File Transfer Protocol (FTP) site without prompting the users for a user name or password. When a user attempts to connect to your public Web or FTP site, your Web server assigns the connection to the Windows user account that is specified for anonymous connections. By default, this account is named IUSR_*ComputerName*, where *ComputerName* is the name of the computer on which IIS is running, and it is included in the Windows user group, Guests. This group has security restrictions, which are imposed by NTFS file system permissions, that designate the level of access and the type of content that is available to public users.

| **Important** |
| --- |
| Do not confuse the anonymous user context that Windows Server2003 provides with the anonymous user account that IIS provides. The IIS anonymous user account is configurable; the default is IUSR_*ComputerName*. The operating system also provides a notion of anonymous access across the network. |

When you use Anonymous authentication, the IUSR_*ComputerName* account is added to the Guests group on the computer running IIS during setup. When IIS receives a request, it impersonates the IUSR_*ComputerName* account before executing any code. IIS can impersonate the IUSR_*ComputerName* account because it recognizes the user name and password for this account. Before returning a page to the client, IIS checks NTFS and directory permissions to see whether the IUSR_*ComputerName* account is allowed access to the file. If access is allowed, the access process, which is also called authorization, completes, and the resources are made available to the user. If access is not allowed, IIS returns a 401.3 error message to the client.

You can change the account that is used for Anonymous authentication in IIS Manager, either at the Web server service level or for individual virtual directories and files. However, be aware that when you change the IUSR_*ComputerName* account, the changes affect every anonymous HTTP request that a Web server services, so use caution if you modify this account.

If you enable Anonymous authentication, IIS always attempts to authenticate the user with Anonymous authentication first, even if you enable additional authentication methods. If the anonymous user account does not have permission to access a specific file or resource, your Web server will not establish an anonymous connection for that resource.

In IIS 6.0, NETWORK_CLEARTEXT is the default logon type for Anonymous authentication. As a result, Anonymous authentication no longer requires the Allow log on locallyuser right. For more information about the NETWORK_CLEARTEXT logon type, see Basic Authentication.

# Sub-Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

In earlier versions of IIS, sub-authentication was enabled by default. The sub-authentication component, Iissuba.dll, enables IIS to manage passwords on anonymous accounts. Because using this component involves a security risk, sub-authentication is not enabled by default when you install Windows Server 2003 with IIS 6.0. However, you can use sub-authentication to manage passwords for anonymous accounts by meeting the following requirements:

- For applications you grant anonymous access, the worker process runs as LocalSystem.
- The sub-authentication component, Iissuba.dll, is registered.
- The AnonymousPasswordSync Metabase Property is enabled (set to **true**).

The actions taken to meet the above requirements are different for clean installs of IIS 6.0 and upgrades to IIS 6.0 from installations of IIS with sub-authentication configured.

**Configuring Sub-Authentication on a New Installation of IIS 6.0**
By default, on a new installation, IIS 6.0 runs in worker process isolation mode, and sub-authentication is disabled (**AnonymousPasswordSync** is set to **false**).

If after a new installation of IIS 6.0, you switch to IIS 5.0 isolation mode, then by default, the worker process assigned to in-process applications will run as LocalSystem.

**Configuring Sub-Authentication on an Upgrade to IIS 6.0**
When you upgrade a server to IIS 6.0 from an earlier version of IIS that uses sub-authentication to manage passwords on anonymous accounts, sub-authentication is enabled by default (**AnonymousPasswordSync** is set to **true**). However, sub-authentication will not work because two configuration tasks have not been accomplished: Iissuba.dll is not registered and the worker processes using Anonymous authentication are not running as LocalSystem. Your event log should have entries on this.

# Basic Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The Basic authentication method is a widely used industry-standard method for collecting user name and password information. When you use Basic authentication, the browser displays a dialog box into which users are required to enter a previously assigned Windows account user name — which includes a Windows domain name, for example, Domain1\User1 — and password, which are also known as *credentials*. The browser then attempts to establish a connection to a server using the user's credentials. The plaintext password is Base64-encoded before it is sent over the network.

One advantage of Basic authentication is that it is part of the HTTP specification and is supported by most browsers. However, Base64 encoding is not encryption. Web browsers that use Basic authentication transmit passwords in an unencrypted form. If a Base64-encoded password is intercepted over the network by a network sniffer, unauthorized users can easily decode and reuse the password. Therefore, Basic authentication is not recommended unless you are confident that the connection between the user and your Web server has been secured, for example, with a dedicated line or an SSL connection. For more information about SSL, see SSL and Certificates.

If a user's credentials do not correspond to a valid Windows user account, Internet Explorer displays a dialog box into which the user re-enters his or her credentials. Internet Explorer — not IIS — allows the user three connection attempts before it terminates the connection and reports an error to the user. If a user's credentials correspond to a valid Windows user account, a connection is established.

Basic authentication does not automatically configure your Web server to authenticate users; to require authentication, you must also disable anonymous access. As a security best practice, you should create Windows user accounts with NTFS permissions correctly set. For step-by-step instructions for configuring Basic authentication, see Basic Authentication in IIS 6.0.

**Logon Types**

In IIS 6.0, the default logon type for Basic authentication (and Anonymous authentication) is NETWORK_CLEARTEXT. This is a change from earlier versions of IIS, in which the default logon type is INTERACTIVE. As a result of this change, when you use the default logon type for Basic authentication, users no longer need interactive logon rights. Basic authentication works with domain controllers, and the NETWORK and NETWORK_CLEARTEXT settings no longer require logon rights. Table 5.4 lists the logon types that are available for Basic authentication and Anonymous authentication.

**Table 5.4 Logon Types for Basic Authentication and Anonymous Authentication**

| Logon Type | LogonMethod Setting | Logon Right Required | Security Identifier (SID) Added to Access Token | Outbound Credentials |
|---|---|---|---|---|
| NETWORK_ CLEARTEXT (default) | 3 - MD_LOGON_NETWORK_ CLEARTEXT | Network | NT AUTHORITY\NETWORK_ CLEARTEXT | Yes |
| NETWORK | 2 - MD_LOGON_NETWORK | Network | NT AUTHORITY\NETWORK | No |
| BATCH | 1 - MD_LOGON_BATCH | Batch | NT AUTHORITY\BATCH | Yes |
| Interactive | 0 - MD_LOGON_INTERACTIVE | Interactive | NT AUTHORITY\INTERACTIVE | Yes |

For more information, see the LogonMethod Metabase Property.

**Token Cache Security Considerations**

When you use Basic authentication, user tokens are cached in the token cache. By default, tokens remain in the cache for 15 minutes. If you log on using Basic authentication with an account that has a high level of user logon rights, a successful attacker could use the account to gain access to the resources on your computer. There are several ways to help minimize this threat:

- Do not log on, or allow anyone to log on, using Basic authentication with an account that has a high level of user logon rights.
- Disable user token caching by setting the global registry entry, UserTokenTTL, to zero (0).

**Caution**

Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Registry Reference.

- Change UserTokenTTL to less than the default of 15 minutes. Note that time is expressed in seconds for this metabase property. For more information about the UserTokenTTL global registry entry, see Global Registry Entries.

**Note**

If you use Basic authentication and disable the token cache, IIS must log on for every request made — potentially thousands for a requested Web page. This will have a negative effect on performance. For more information, see Balancing Performance and Security.

**Related Topics**

For information about editing the registry, see the Registry Reference.

# Digest Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Digest authentication offers the same functionality as Basic authentication; however, Digest authentication provides a security improvement because a user's credentials are not sent across the network in plaintext. Digest authentication sends credentials across the network as a Message Digest 5 (MD5) hash, which is also known as the MD5 message digest, in which the credentials cannot be deciphered from the hash.

If your server is running an earlier version of IIS with Digest authentication enabled and you upgrade to IIS 6.0, Digest authentication remains the default authentication method. In all other instances, you must enable Digest authentication.

**Client Authentication Process for Digest Authentication**

Figure 5.1 shows how a client is authenticated using Digest authentication. The steps that follow the figure describe the process in more detail.

1. The client requests a file from the server running IIS.
2. The server running IIS denies the request and sends the client the following information:
   a. Digest authentication is being used.
   b. The realm name.
3. Internet Explorer prompts the user for credentials (user name and password). Internet Explorer then combines these credentials with the name of the realm to create an MD5 hash and resubmits the request for the file from the server running IIS, this time sending the MD5 hash.
4. The server running IIS receives the hash and sends the client's hash to the domain controller for verification.
5. The domain controller informs the server running IIS of the authentication results.
6. If the client is authenticated, IIS sends the requested document or data to the client.

| **Important** |
| --- |
| Digest authentication completes only if the domain controller has a reversibly encrypted (clear text) copy of the requesting user's password stored in Active Directory. To allow passwords to be stored in clear text, you need to activate the **Store password using reversible encryption** setting on the **Account** tab of the user in Active Directory. Alternatively, you can set a Group Policy to enable this capability. After making this setting you need to set a new password to activate this feature because the old password cannot be determined. For more information about setting user properties in Active Directory, see Help and Support Center for Windows Server 2003. |

**Requirements for Digest Authentication**

You do not need to install additional client software to use Digest authentication, but Digest authentication relies on the

HTTP 1.1 protocol, as defined in RFC 2617 HTTP Authentication: Basic and Digest Access Authentication, and not all browsers support that protocol. If a non–HTTP 1.1–compliant browser requests a file from a server that uses Digest authentication, the server requests that the client provide Digest authentication credentials. The non–HTTP 1.1–compliant browser rejects the request because the client cannot support Digest authentication. For more information about HTTP authentication, see RFC 2617, HTTP Authentication: Basic and Digest Access Authentication on the Internet Engineering Task Force Web site.

Before you enable Digest authentication on your server, ensure that:

- All of the clients that need access to a resource that is secured with Digest authentication are using Internet Explorer 5.*x* or Internet Explorer 6.
- The user and the server running IIS are members of, or are trusted by, the same domain.
- Users have a valid Windows user account that is stored in Active Directory on the domain controller, with reversible encryption enabled.
- The domain has a domain controller running the Microsoft® Windows® 2000 Server operating system or Windows Server 2003.

  **Important**

  If the authenticating domain controller is on a computer running Windows2000 Server, IIS6.0 requires subauthentication for Digest authentication to work. For more information about subauthentication, see Using Sub-Authentication with Digest Authentication later in this topic.

- The server running IIS 6.0 is running Windows 2000 Server or Windows Server 2003.
- If the server operates in worker process isolation mode, the application pool that contains an application that uses Digest authentication must run with LocalSystem as the worker process identity. This requirement applies because a user password is not stored outside the hash that the client sends to IIS, and a worker process that is associated with the application cannot impersonate the user by using the user name and password.
- The Iissuba.dll file is registered on the server running IIS.

**Note**

Only domain administrators can verify that the domain controller requirements are met. Check with your domain administrator if you are unsure about whether your domain controller meets the preceding requirements.

Enabling Digest authentication on a server running IIS requires the following two tasks:

- Enabling Digest authentication for Windows domain servers. For more information about enabling Digest authentication for Windows domain servers, see Help and Support Center for Windows Server 2003.
- Configuring the realm name at any level of the metabase by using IIS Manager or by scripting.

**Note**

If Basic authentication is enabled for the site, virtual directory, or folder you are configuring, the **Default domain** box will also be available. However, only **Realm** is meaningful to Digest authentication.

**Configuring the Realm Name**

Table 5.4 lists and describes the levels of the metabase where the realm name can be configured. If a child key is not specifically configured, it inherits its configuration from the next configured level up.

**Table 5.5 Metabase Levels Where the Realm Name Can Be Configured**

| Metabase Level | Description |
|---|---|

| | |
|---|---|
| W3SVC | The W3SVC level, also known as the **IISWebService** level, is the highest level in the metabase where Digest authentication can be configured. Configurations set at this level are inherited by lower levels that do not have specific configuration settings. |
| W3SVC/*n* | The W3SVC/*n* level, also known as the **IISWebService** level, is a specific Web site, where *n* is the number of the site. Sites are numbered starting at 1. The default Web site is 1. |
| W3SVC/*n*/root | The W3SVC/*n*/Root level, known as the **IISWebVirtualDir** level, is the starting point for a Web Site, where *n* is the number of the site. |
| W3SVC/*n*/root/vdir | The W3SVC/*n*/ROOT/WebVirtualDir level, known as the **IISWebVirtualDir** level, is a virtual directory within a Web Site, where *n* is the number of the site. |
| W3SVC/*n*/root/vdir/webdir | The W3SVC/*n*/Root/WebVirtualDir/WebDir level, also known as the **IISWebDirectory** level, is a physical directory within a virtual directory within a Web site, where *n* is the number of the site. |
| W3SVC/*n*/root/vdir/file | The W3SVC/*n*/root/vdir/file level is an individual file within the W3SVC/*n*/ROOT/WebVirtualDir level, where *n* is the number of the site. |
| W3SVC/*n*/root/webdir/file | The W3SVC/*n*/root/vdir/file level is an individual file within the W3SVC/*n*/Root/WebVirtualDir/WebDir level, where *n* is the number of the site. |

You can configure one or multiple realm names on a server running IIS. For example, you might want to configure multiple realm names to allow members of Domain1 to access the Sales directory, and members of Domain2 to access the Engineering directory. This is particularly useful if no trust relationship exists between Domain1 and Domain2. If you configure multiple realm names, they must be configured at different levels of the metabase. For more information about domains, see Help and Support Center for Windows Server 2003.

If a child key in the metabase is not configured with a realm name, that child key inherits the realm name from the next parent key that has the realm name configured. If the realm name is not configured, IIS sends its own computer name as the realm name. If IIS sends its own name as the realm name and IIS is not running on a Windows Server 2003 domain controller with Active Directory, Digest authentication will fail.

For step-by-step instructions for configuring Digest authentication, see Digest Authentication in IIS 6.0.

**Using Sub-Authentication with Digest Authentication**

To use Digest authentication in IIS 6.0 when the domain controller is running Windows 2000 Server, you must enable sub-authentication. The sub-authentication file, Iissuba.dll, is automatically copied to the %Windir%\System32 folder when you install Windows 2000 Server and Windows Server 2003. However, by default, sub-authentication is not enabled in IIS 6.0. To enable sub-authentication, you must perform the following tasks:

- Install the sub-authentication component, iisuba.dll.
- Set the **UseDigestSSP** metabase property to false.

| **Note** |
|---|
| The W3SVC service must be restarted before changes to this property take effect. |

- Set the identity of the application pool to LocalSystem.

For more information about how to configure sub-authentication, see Configuring Subauthentication.

Logging on with a user principal name (UPN) in the form username@domain.com will still fail at this point, even though your IIS 6.0 server is a member of a Windows 2000 domain and is correctly configured for Digest authentication as well as subauthentication.. This failure occurs because Digest authentication accepts only domain logons in one of the following formats:

- If a user logs on to a server in the same domain where the user's account resides, the username alone is sufficient for authentication.

- For logons with a user account from another domain, use the domain\username format.

**Understanding the MD5 Hash**

An MD5 hash is used for sending encrypted user credentials across a network within an HTTP header. An MD5 hash, also known as the MD5 message-digest, is created by an HTTP 1.1–compliant browser such as Internet Explorer 5 and above, using the MD5 message-digest algorithm as defined in RFC 1321, The MD5 Message-Digest Algorithm.

| **Note** |
| --- |
| The MD5 hash is a security improvement over base64 encoded clear text passwords. An unauthorized person can easily intercept base64 encoded passwords by using a network sniffer, and decoding the passwords is a trivial matter. A user name and password that is encrypted using the MD5 message-digest algorithm cannot feasibly be decrypted from the hash. |

An MD5 hash contains a user name, password, and the name of the realm. The realm is the domain that will authenticate or reject the users credential. The users credential is the password that is encrypted within the MD5 hash.

**MD5 Hash Properties**

An MD5 hash consists of a small amount of binary data, typically no more than 160 bits, and is sent by across the network within an HTTP header. All hash values share the following properties:

- **Hash length.** The length of the hash value is determined by the type of algorithm used, and its length does not vary with the size of the message. The most common hash value lengths are either 128 or 160 bits.

- **Non-discoverability.** Every pair of nonidentical messages will translate into a completely different hash value, even if the two messages differ only by a single bit. Using today's technology, it is not feasible to discover a pair of messages that translate to the same hash value.

- **Repeatability.** Each time a particular message is hashed using the same algorithm, the exact same hash value will be produced.

- **Irreversibility.** All hashing algorithms are one-way. Given a hash value, it is not feasible to discover the password. In fact, none of the properties of the original message can be determined given the hash value alone.

For more information about the MD5 message-digest algorithm, see RFC 1321, The MD5 Message-Digest Algorithm, on the Internet Engineering Task Force Web site.

# Advanced Digest Authentication

Updated: August 14, 2013

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Advanced Digest authentication is available only on Windows Server 2003. When Advanced Digest authentication is enabled, user credentials are stored on the domain controller as an MD5 hash. Advanced Digest authentication does not require that credentials are stored using reversible encryption. Instead, Advanced Digest authentication stores a few precalculated hashes in Active Directory, so user passwords cannot feasibly be discovered by anyone with access to the domain controller, including the domain administrator.

When you perform a clean installation of IIS 6.0, Advanced Digest authentication is enabled as the default authentication method, and it is recommended over Digest authentication for the following reasons:

- Subauthentication is not required for Advanced Digest authentication, because Advanced Digest authentication uses the Windows Security Support Provider Interface (SSPI) traditional implementation for security.
- Reversible password encryption is not required for Advanced Digest authentication. In Windows Server 2003, the Active Directory extended schema properties ensure that every newly created user account automatically has the Advanced Digest authentication hashed and stored as a field in the AltSecId property of the user object.
- A worker process with an application that uses Advanced Digest authentication does not have to run with LocalSystem as the process identity, because subauthentication is not required.

**Client Authentication Process for Advanced Digest Authentication**

Figure 5.2 shows how a client is authenticated using Advanced Digest authentication, and the steps that follow describe the process in more detail.

1. The client browser requests a file from the server running IIS.
2. The server running IIS denies the initial request and sends the client the following information:
   - Digest authentication is being used, because the same Digest authentication algorithm is used between the server running IIS and the client for both Digest and Advanced Digest authentication.
   - The realm name.
3. Internet Explorer prompts the user for credentials (user name and password). Internet Explorer then combines these credentials with the name of the realm to create an MD5 hash and resubmits the request for the file to the server running IIS, this time also sending the MD5 hash in the header of the HTTP request.
4. The server running IIS receives the client's hash and sends it to the domain controller for verification.
5. The domain controller compares the client's hash to the copy stored in Active Directory. If the hash values match, the domain controller informs the server running IIS that the client is authenticated.

6. The server running IIS sends the requested file to the client.

**Requirements for Advanced Digest Authentication**

As with Digest authentication, you do not need to install additional client software to use Advanced Digest authentication. Because Advanced Digest authentication relies on the HTTP 1.1 protocol as defined the RFC 2617, HTTP Authentication: Basic and Digest Access Authentication, your browsers should be HTTP 1.1 compliant. If a non-HTTP 1.1–compliant browser requests a file from a server using Advanced Digest authentication, the server will request the client to provide Advanced Digest authentication credentials. The non-HTTP 1.1–compliant client rejects the request because Advanced Digest authentication is not supported by the client.

Advanced Digest authentication, like Digest authentication, will not work unless the following minimum requirements are met:

- All of the clients that need access to a resource that is secured with Advanced Digest authentication are using Internet Explorer 5 or Internet Explorer 6.
- The user and the server running IIS are members of the same domain, or the user is a member of a trusted domain within the same forest.
- Users have a valid Windows user account that is stored in Active Directory on the domain controller.
- The domain controller and the server running IIS are both running Windows Server 2003. If either your domain controller or the server running IIS is running Windows 2000 Server or earlier, IIS defaults to Digest authentication and does not notify you of this action.

| **Note** |
| --- |
| Only domain administrators can verify that the domain controller requirements are met. Check with your domain administrator if you are unsure about whether your domain controller meets these requirements. |

**Configuring Advanced Digest Authentication**

Enabling Advanced Digest authentication on the server running IIS requires the following three tasks:

- Enable Digest authentication for Windows domain servers. For more information about enabling Digest authentication for Windows domain servers, see Configuring Digest Authentication in IIS 6.0.
- Configure the realm name. For more information about configuring the realm name, see "Configuring the Realm Name" in Configuring Digest Authentication.
- Set the UseDigestSSP Metabase Property to **true**. The W3SVC service must be restarted before changes to this property take effect.

| **Important** |
| --- |
| If you follow the first two procedures but do not configure the **UseDigestSSP** metabase key, you will be using Digest authentication, not Advanced Digest authentication. |

Advanced Digest authentication uses the **UseDigestSSP** metabase property to switch between Digest and Advanced Digest security support provider interface (SSPI) code. If this property is set to **false**, Digest authentication is used. In all other cases (true, empty, or not set), IIS uses Advanced Digest authentication. If you configure **UseDigestSSP** at the W3SVC level of the metabase, all child keys inherit their configuration from that level.

| **Important** |
| --- |
| If you use Digest authentication and select worker process isolation mode, you must use the LocalSystem user account as the application pool identity. |

Additionally, IIS has two registry keys that specify timeout periods for Advanced Digest authentication: DigestPartialContextCacheTTL and DigestContextCacheTTL. These keys are not present by default, but you can add them to the

registry and configure them if the default values used by IIS are not sufficient.

The value of DigestPartialContextCacheTTL specifies the timeout period for partially-formed security contexts, during which a user is initially challenged for credentials to authenticate. IIS uses a default value of 30 seconds if the registry key is not present on the Web server.

| **Important** |
| --- |
| If you choose to configure this key, understand that keeping the value low will minimize the risk of Denial of Service (DoS) attacks. |

The value of DigestContextCacheTTL specifies the timeout period for fully-formed security contexts, during which a user remains authenticated after providing valid credentials on the initial challenge response. IIS uses a default value of 300 seconds if the registry key is not present on the Web server.

For more information about DigestPartialContextCacheTTL and DigestContextCacheTTL, see Global Registry Entries.

# Integrated Windows Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003 with SP1

With Integrated Windows authentication (formerly called NTLM, and also known as Windows NT Challenge/Response authentication), the user name and password (credentials) are hashed before being sent across the network. When you enable Integrated Windows authentication, the client browser proves its knowledge of the password through a cryptographic exchange with your Web server, involving hashing.

| **Important** |
| --- |
| Integrated Windows authentication is disabled by default if you install Windows Server 2003 Service Pack 1 (SP1) as part of a slipstream installation of a Windows Server 2003 operating system. If you install Windows Server 2003 SP1 by itself, as an upgrade to a Windows Server 2003 operating system, the setting for Integrated Windows authentication is unchanged from its Windows Server 2003 setting. Integrated Windows authentication is enabled by default for Windows Server 2003 operating systems. |

Integrated Windows authentication uses Kerberos v5 authentication and NTLM authentication. Kerberos is an industry-standard authentication protocol that is used to verify user or host identity. If Active Directory is installed on a domain controller running Windows 2000 Server or Windows Server 2003, and the client browser supports the Kerberos v5 authentication protocol, Kerberos v5 authentication is used; otherwise, NTLM authentication is used.

Integrated Windows authentication includes the Negotiate, Kerberos, and NTLM authentication methods. Negotiate, a wrapper for Kerberos v5 and NTLM, allows the client application to select the most appropriate security support provider for the situation. Kerberos v5 and NTLM have the following restrictions:

- NTLM can get past a firewall, but is generally stopped by proxies because NTLM is connection-based, and proxies do not necessarily keep connections established.
- Kerberos v5 requires that the client have a direct connection to Active Directory, which is generally not the case in Internet scenarios.
- Kerberos v5 requires that both the client and the server have a trusted connection to a Key Distribution Center (KDC) and be Active Directory–compatible.
- Kerberos v5 requires SPNs for multiple worker processes. If your Web site uses multiple worker processes, you can use Kerberos authentication, but you must manually register service names. For more information about Kerberos and service registration, see Kerberos and service registration later in this topic.

Integrated Windows authentication has the following limitations:

- Integrated Windows authentication is supported by only Internet Explorer 2 and later.
- Integrated Windows authentication does not work over HTTP proxy connections.

Therefore, Integrated Windows authentication is best suited for an intranet environment, where both user and Web server computers are in the same domain and where administrators can ensure that every user has Internet Explorer 2 or later.

**Client Authentication Process**

Unlike Basic authentication, Integrated Windows authentication does not initially prompt for a user name and password. The current Windows user information that is on the client is used for Integrated Windows authentication. If the authentication exchange initially fails to authorize the user, Internet Explorer prompts the user for a Windows account user name and password, which it processes using Integrated Windows authentication. Internet Explorer prompts the user for the correct user name and password up to three times. If, however, the user has logged on to the local computer as a domain user, then no authentication is required when the user accesses a network computer in that domain.

| **Note** |
| --- |

Microsoft Internet Explorer versions 4.0 and later can be configured to initially prompt for user name and password. For more information, see Internet Explorer Help.

**Kerberos and Service Registration**

Kerberos is the default method of network authentication for services in Windows Server 2003. A service can use Kerberos only if that service first registers a service principal name (SPN) in Active Directory. By default, Active Directory registers the NetBIOS, or computer, name of the server, but if the SPN is different, you must manually register the service. Before Kerberos can authenticate a service, the service must be registered on only one account object. If the logon account name of a service instance changes, the service must be reregistered under the new account. Therefore, only one application pool that has the service registered can authenticate with Kerberos.

IIS uses the NTAuthenticationProviders Metabase Property to pass the Negotiate header when Integrated Windows authentication is used to authenticate client requests. The Negotiate header permits clients to choose either Kerberos or NTLM. Negotiate uses Kerberos, unless Kerberos cannot be used by one of the systems involved in the authentication, or unless the calling application does not provide sufficient information to use Kerberos.

By default, Active Directory allows the Network Service and Local System accounts to use Kerberos. If **NtAuthenticationProviders** is set to **Negotiate,NTLM** for an application pool, Kerberos works correctly with Network Service as the worker process identity, because this is the default worker process identity for IIS 6.0 in worker process isolation mode. However, suppose you isolate applications on a Web site by configuring each application to run in a separate application pool under a separate process identity that is a domain account. If you attempt to use Integrated Windows authentication with the isolated applications, because you want to use Kerberos authentication, Kerberos fails.

Unless Kerberos authentication is configured correctly, it fails with a 401.1 error in the following situations:

- The Fully Qualified Domain Name (FQDN) is different from the NetBIOS name. For example, the IIS server might host a Web site called www.contoso.com on a server named web01.
- The process—for example, Dllhost.exe or W3wp.exe—that is performing the underlying authentication runs under an identity other than System, and no SPN is registered for that identity.
- Applications are hosted across multiple servers that use the same computer name. Only one user can be registered per computer name.
- If all servers in a Web farm use one computer name, but load balancing distributes requests to multiple servers, and no server in the Web farm has a unique SPN.

For Kerberos authentication to work correctly, you must configure isolation at the site level, not at the application pool level. All application pools in your Web site that use Kerberos must run with the same application pool process identity. You must then register that process identity as an SPN with Kerberos by using the Setspn.exe command-line tool. The Setspn.exe tool is included in Resource Kit Tools for Windows Server 2003 Deployment Kit companion CD, or on the Web at http://www.microsoft.com/reskit. You must be a domain administrator to set an SPN. For more information about registering a service principal name by using Setspn.exe, see Configuring Constrained Delegation for Kerberos.

For more information about this limitation and using Setspn.exe, see Security-Related Changes in Authentication.

# UNC Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

The UNC authentication method, which is also known as UNC Passthrough authentication, determines the credentials to use for gaining access to a UNC share on a remote computer. UNC Passthrough authentication works only with authentication methods that can perform delegation, for example, Basic authentication and Kerberos authentication. If you use IIS Manager to create a Web site or virtual directory and you specify a UNC path for the content, IIS Manager prompts you to type a user name and a password for the network resource. The user name must be specified as *domain\username*. If you specify a user name and password, both the UNCUserName Metabase Propertyy and the UNCPassword Metabase Property are set.

In IIS 6.0, UNC authentication works by looking at the requesting user and the credentials that are stored in the **UNCUserName** and **UNCPassword** properties of the metabase to determine the credentials to pass through to the computer with the UNC share. If **UNCUserName**is specified (not empty) and **UNCPassword** is valid, the metabase user credentials are sent as the user identity for access to the remote share. If **UNCUserName** is specified (not empty) and **UNCPassword** is not valid, a "500 Internal Server Error: Invalid User Name or Password" message is sent to the client. If **UNCUserName** is empty, the credentials of the request user, which can be either an authenticated set of credentials for authenticated requests or IUSR_*computername* credentials for anonymous requests, are sent as the user identity for access to the remote share.

Table 5.6 shows the behavior resulting from the values of **UNCUserName** and **UNCPassword**.

**Table 5.6 Values and Behavior of UNC Passthrough Properties in the IIS Metabase**

| UNCUserName Value | UNCPassword Value | Resulting Behavior |
|---|---|---|
| Specified (not empty) | Valid value | Metabase user credentials are sent as the user identity for access to the remote share. |
| Specified (not empty) | Invalid value | 500 Internal Server Error: Invalid Username or Password message is sent to the client. |
| Empty | Not applicable | Credentials of the request user — either an authenticated set of credentials for authenticated requests or IUSR_*computername* credentials for anonymous requests — are sent as the user identity for access to the remote share. |

| **Note** |
|---|
| The **UNCAuthenticationPassthrough** metabase property is no longer used for UNC authentication. |

**Constrained Delegation**

*Delegation* is the act of allowing a service to impersonate a user account or computer account to access resources throughout the network. When a service is trusted for delegation, that service can impersonate a user to use other network services. *Constrained delegation* is a new option for Windows Server 2003 that allows you to specify the SPNs to which an account can delegate. A service can be trusted for delegation, but the domain administrator can limit that trust to a select group of explicitly specified services. By allowing delegation only to specific services, you can control the specific network resources the service or computer can use.

Constrained delegation is particularly useful in scenarios in which a site that requires authentication — a site that does not allow anonymous access — contains content that is housed on a remote UNC file server. With constrained delegation, you can enable Integrated Windows authentication, which can use NTLM authentication or send credentials across the network as a Kerberos token. For more information about Integrated Windows authentication, see Integrated Windows Authentication.

Figure 5.3 shows how constrained delegation works in a simple configuration.

**Deciding Whether to Use Constrained Delegation**

Constrained delegation is best implemented in a Windows Server 2003 domain. Although you can use constrained delegation in a Windows 2000 Server mixed domain, there are significant limitations. In a Windows 2000 Server mixed domain, constrained delegation works only for users that are authenticated using Basic or Kerberos authentication. In addition, you cannot restrict delegation to a specific set of services on a computer running Windows 2000 Server, which makes it difficult to implement this feature and reduce the attack surface of your server.

If you do not use constrained delegation but you enable Integrated Windows authentication, the token that the Web server obtains from the security infrastructure of Windows does not have sufficient permissions to access another computer, such as your file server. However, with constrained delegation and Integrated Windows authentication, the token received by the Web server from the security infrastructure of Windows is a Kerberos-based token with permission to access other computers, including the file server. Essentially, constrained delegation allows an NTLM-based token to be upgraded to a Kerberos-based token.

If you use Basic authentication, you probably do not need constrained delegation because the tokens cached by Basic authentication have sufficient permissions to access other computers in the domain, including the file server. However, in some situations you do not need to allow clients to authenticate with Integrated Windows authentication, but you might need constrained delegation. For example, you might have applications that need to access a file server using computer accounts, such as an enterprise intranet application that impersonates the client to gain access to information on various servers in the enterprise and then presents the consolidated data to the client over HTTP.

If you are running IIS 6.0 in IIS 5.0 isolation mode and you have an out-of-process application, this process normally runs as the local IWAM_*computername* account, which prevents constrained delegation from working correctly. One example of an application that might fail to perform as expected in this scenario is an ASP application that accesses a remote computer running Microsoft® SQL Server™ on which you intend for the authenticated users credentials to be used. To fix this, switch IIS to run in worker process isolation mode.

# .NET Passport Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Microsoft .NET Passport is a user-authentication service and a component of the Microsoft .NET Framework. The .NET Passport single sign-in service and express purchase service enable organizations to deliver a fast and convenient way for consumers to sign in and make transactions on a Web site. With the .NET Passport single sign-in service, you can map sign-in names to information in your databases, which enables you to offer .NET Passport members a personal Web experience through targeted content, advertisements, and promotions. The .NET Passport single sign-in service is similar to the forms-based authentication model that is commonly used on the Web today. The .NET Passport network extends this model in the following ways:

- The sign-in, sign-out, and registration pages are centrally hosted rather than being specific to each individual site.
- .NET Passport can be extensively co-branded to match the look and feel of your site. Co-branding material is served directly from your site and is included in the centrally hosted pages when those pages are displayed on a client browser.
- Centrally hosted pages that require additional security to exchange credentials or other information are always served using SSL.
- All .NET Passport sign-in and core profile cookies are strongly encrypted. Each participating Web site receives a unique encryption key that ensures information privacy.
- The central .NET Passport servers return encrypted sign-in and profile information to your site, which can then be used to write local cookies and thus avoid redirects back to the central .NET Passport servers on subsequent page views.
- Members do not need to retype their sign-in name and password when moving from site to site. .NET Passport–enabled sites issue a set of encrypted cookies in the .NET Passport central servers' domain to facilitate silent and seamless sign-in across sites. However, sites might still choose to always force members to be redirected to .NET Passport sign-in and to authenticate upon first viewing of their site.
- Participating Web sites never receive a member's password. The authentication cookie is actually a pair of encrypted time stamps asserting when the member signed in. When members choose to sign out by clicking the .NET Passport sign-out link, they are redirected to a central page that enables deletion of all .NET Passport cookies from all of the sites that the member visited during the session.
- There is no real-time, server-to-server communication between participating Web sites and the central .NET Passport servers. All information exchange occurs through the client's browser using HTTP redirects, encrypted information on the query string, and cookies. Server-to-server communication occurs only when a centrally hosted XML configuration file is periodically downloaded and cached locally by .NET Passport's server-side object (supplied in the .NET Passport SDK); this XML file contains current URLs for all the .NET Passport servers and the current profile schema.

Microsoft .NET Passport uses standard Web technologies, such as SSL, HTTP redirects, cookies, Microsoft® JScript® development software, and strong symmetric key encryption to deliver the single sign-in service. In addition, .NET Passport is compatible with Internet Explorer 4 and later, Netscape Navigator version 4.0 and later, and some versions of UNIX.

.NET Passport–enabled sites rely on the .NET Passport central server to authenticate users. However, the .NET Passport central server does not authorize or deny the access of a user to individual .NET Passport–enabled sites. It is the responsibility of the Web site to control user access rights.

After .NET Passport authentication is verified, a Windows Server 2003 Passport user can be mapped to a user of Active Directory through the users Windows Server 2003 Passport identification, if such a mapping exists. A token is created by the Local Security Authority (LSA) for the user, and is set by IIS for the HTTP request. Application developers and Web site administrators can use this security model for authorization based on users of Active Directory. You can also delegate these credentials through the constrained delegation feature supported by Windows Server 2003. For more information about constrained delegation, see Constrained Delegation for UNC File Content. When using Microsoft .NET Passport authentication, you can store account information and user credentials in Active Directory. If account information is not mapped in Active

Directory, IIS automatically creates an Anonymous authentication session with anonymous user account credentials. In most cases, anonymous user account credentials equal IUSR_*ComputerName*.

The only difference between .NET Passport authentication IUSR credentials and standard Anonymous authentication IUSR credentials is that .NET Passport authentication creates an IIS authentication token for the anonymous account that contains a security identifier, known as the .NET Passport User ID (PUID). Active Directory returns a user authentication token if the account information is mapped in Active Directory, and the corresponding user is logged on to the local computer.

Users can register at a .NET Passport–enabled site, and their user information is then stored in encrypted profiles on .NET Passport servers. When.NET Passport users register at a participating site, their personal information can be shared with the site. This sharing can make the registration process faster. When the .NET Passport users sign in to that site again, their .NET Passport profiles can enable access to personalized accounts or services on that site.

For more information about .NET Passport authorization, see the Microsoft .NET Passport homepage.

**Conforming to Passport Privacy Guidelines**

When you implement .NET Passport for Web sites running on Windows Server 2003, you must ensure that you conform to the Passport privacy guidelines. Use one of the following configurations for your Web site:

- Configure IIS 6.0 to use .NET Passport authentication and Anonymous authentication. Your Web site will exhibit typical Passport behavior, but this configuration requires that you store all Passport-enabled Web pages on the Web site itself.

- Create a virtual directory for an IIS 6.0 Web site, and configure it for Anonymous authentication. Store a default Passport-enabled Web page in this virtual directory. This page should display the Passport sign-in logo, which results from the call to Manager.LogoTag(), and should also contain a return URL value that points to a second virtual directory on the same Web site.

  Configure the second virtual directory to use .NET Passport authentication only. You can set the Passport Manager Administration Utility **ForceSignin** and **TimeWindow** values as you choose. Store the rest of your Passport-enabled Web pages in this second virtual directory.

# FTP Site Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Based on your security requirements, you can select one of two IIS authentication methods to validate users requesting access to your FTP pages. Available authentication settings must be set at the site level for FTP sites.

| **Note** |
| --- |
| Digest and Integrated Windows authentication cannot be used with FTP sites. |

- Anonymous FTP authentication. If you select Anonymous FTP authentication for a resource, all requests for that resource are accepted without prompting the user for a user name or password. This is possible because IIS automatically creates a Windows user account called IUSR_*ComputerName*, where *ComputerName* is the name of the server on which IIS is running. This is very similar to Web-based Anonymous authentication. If Anonymous FTP authentication is enabled, IIS always tries to use that method first, even if you enable Basic FTP authentication.

- Basic FTP authentication. To establish an FTP connection with your Web server by using the Basic FTP authentication method, users must log on with a user name and password corresponding to a valid Windows user account. If the FTP server cannot verify a user's identity, the server returns an error message. Basic FTP authentication provides only low security because the user transmits the user name and password across the network in an unencrypted form.

Table 5.6 compares Anonymous and Basic FTP authentication.

**Table 5.6 Comparison of Anonymous and Basic FTP Authentication Methods**

| Method | Security Level | How Passwords Are Sent | Crosses Proxy Servers and Firewalls | Client Requirements |
| --- | --- | --- | --- | --- |
| Anonymous FTP authentication | None | N/A | Yes | Any FTP client |
| Basic FTP authentication | Low | Plaintext | Yes | Any FTP client |

# Access Control in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

You can control which users and computers can access your Web server and its resources. There are two main types of access control: NTFS permissions, which are controlled by the operating system, and Web site permissions, which are controlled by IIS. You can also use IP address restrictions to limit access by specific computers. To help secure your Web server, you should use a defense-in-depth strategy that combines suitable authentication methods with tools such as firewalls and the appropriate NTFS permissions and Web site permissions. IIS built-in accounts and features, such as URL authorization, help you control access to resources on multiple levels, from entire Web and FTP sites to individual files or specific URLs.

- Securing your files with NTFS. When you use the NTFS file system, you can limit access to your Web server's files and directories. You can configure the file and directory permissions that set the access level assigned to a particular user account or user group. For example, you can configure your Web server to enable a specific user to view and execute a file, while excluding all other users from accessing that file.

- Securing your site with Web site permissions. Web permissions, unlike NTFS permissions, apply to all users accessing your Web sites. NTFS permissions apply only to a specific user or group of users with a valid Windows account. NTFS controls access to physical directories on your server, whereas Web permissions control access to virtual directories on your Web site.

- Securing your site with IP address restrictions. With IP address restrictions, you can configure your Web server to assign or deny specific computers, groups of computers, or domains access to Web sites, directories, or files. For example, if your intranet server is connected to the Internet, you can prevent Internet users from accessing your Web server by assigning access only to members of your intranet, and explicitly denying access to outside users.

How Access Control Works

Access control involves both user rights and permissions. *User rights* are rights that allow a user to perform specific actions on a computer or network. *Permissions* are rules that are associated with an object, such as a file or folder, to regulate which accounts can gain access to that object. After you configure your Windows file system and Web server security features, when a user attempts to access your Web server, the server carries out several access-control processes to identify the user and determine the allowed level of access.

Figure 5.4 shows how the access-control process works.

The following steps outline the access-control process:

1. The client requests a resource on the server.

2. The IP address of the client is checked against any IP address restrictions in IIS. If the IP address is denied access, the request fails, and a 403 Access Forbidden message is returned to the user.

3. The server, if configured to require it, requests authentication information from the client. The browser either prompts the user for a user name and password or offers this information automatically.

4. IIS checks whether the user has a valid Windows user account. If the user does not, the request fails, and a 401 Access is denied message is returned to the user.

5. IIS checks whether the user has Web permissions for the requested resource. If the user does not, then the request fails, and a 403 Access Forbidden message is returned to the user.

6. Any security modules, such as ASP.NET impersonation, are added.

7. IIS checks the NTFS permissions on static files, ASP, and Common CGI files for the resource. If the user does not have NTFS permissions for the resource, then the request fails, and a 401 Access is denied message is returned to the user.

8. If the user has NTFS permissions, the request is fulfilled.

# NTFS Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

With NTFS access permissions as the foundation of your Web servers security, you can define the level of file and directory access that is granted to Windows users and groups. For example, if a business decides to publish its catalog on your Web server, you need to create a Windows user account for that business and then assign permissions for the specific Web site, directory, or file. The permissions should permit only the server administrator and the owner of the business to update the contents of the Web site. Public users should be allowed to view the Web site, but not to alter its contents.

To control access to directories and files in this manner, you must be using drives formatted in NTFS, not FAT32. Using FAT32 is strongly discouraged because it allows users access to every file on your hard drive. NTFS is a more powerful and restrictive file system than FAT and FAT32. With NTFS, you can limit access to your Web server's files and directories. You can also configure the access level granted to a particular user or group for the files and directories on your server.

Table 5.7 compares the security options of NTFS and FAT file systems.

**Table 5.7 Comparison of NTFS and FAT File Systems**

| NTFS | FAT |
|---|---|
| Allows administrators to control access to directories and files using NTFS permissions. Permissions can be set on the file level, as well as the directory level. | Does not allow administrators to control access to directories and files. |
| Supports file encryption, which greatly enhances file security. | Does not support file encryption. |
| Allows administrators to enable Web Distributed Authoring and Versioning (WebDAV) properties. | Does not allow administrators to enable WebDAV properties. |
| Supports Active Directory and domain-based security. | Does not support Active Directory and domain-based security. |

The NTFS permission levels are as follows:

- Full Control. Users can do anything to the file, including taking ownership of it. It is recommended that you grant this level of access only to administrators.
- Modify. Users can view and modify files and file properties, including deleting and adding files to a directory or file properties to a file. Users cannot take ownership or change permissions on the file.
- Read & Execute. Users can run executable files, including scripts.
- List Folder Contents. Users can view a list of a folder's contents.
- Read. Users can view files and file properties.
- Write. Users can write to a file.

**Important**

If you do not assign Read & Execute permissions to the IUSR_*ComputerName* account for a resource, anonymous users will be denied access to that resource. The default permissions assigned when you add a user or group to the Access Control List (ACL) are Read & Execute, List Folder Contents, and Read.

For more details about setting NTFS permissions, see Setting NTFS Permissions for Directories or Files.

# Access Control Lists

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

NTFS permissions are set and managed by using access control lists (ACLs). An *ACL* is a list that indicates which users or groups are able to access or modify a particular file. An ACL is made up of access control entries (ACEs).

**ACL Tools**
Many tools, such as the **cacls** command and the Xcacls.exe command-line tool, are available to help you set and manage ACLs.

**Cacls**
**Cacls** is a Windows Server 2003 command that allows you to display or modify discretionary access control lists (DACLs). For more information about the **cacls** command, see Cacls in Help and Support Center for Windows Server 2003.

**Xcacls.exe**
Xcacls.exe is a Windows Server 2003 command-line tool that you can use to set all file-system security options that are accessible in Windows Explorer from the command line. Xcacls.exe does this by displaying and modifying the ACLs of files. For more information, see Xcacls.exe.

**Default ACLs and Privileges for the IIS_WPG Group**
When you install IIS 6.0, some ACLs and privileges are set automatically for the IIS_WPG group. Table 5.8, Table 5.9, and Table 5.10 list the default ACLs that are set during the installation process.

**Table 5.8 Default File System ACLs for the IIS_WPG Group**

| Location | Setting | Description |
|---|---|---|
| %windir%\Help\iishelp\common | Read, Execute | Access to default error page |
| %windir%\IIS Temporary Compressed Files | Full | Access to the compression directory |
| %windir%\system32\MicrosoftPassport | Read, Execute, Write, Delete | Passport configuration |
| %windir%\inetsrv\ASP Compiled Templates | Full | Access to ASP compiled templates that are saved to disk |
| %windir%\inetpub\wwwroot | Read, Execute | Access to the content root directory |

**Table 5.9 Default Metabase ACLs for the IIS_WPG Group**

| Location | Setting | Description |
|---|---|---|
| / (IIS_ROOT key) | Read, Unsecure Read, Enumerate Keys | Give worker process access to read metabase data |
| /LM/W3SVC/AppPools | Unsecure Read | Give worker process access to read unsecured metabase properties |
| /LM/W3SVC/Filters | Read, Unsecure Read, Enumerate Keys, Write | Allow IIS to update filter state |
| /LM/W3SVC/*X*/Filters | Read, Unsecure Read, Enumerate Keys, Write | Allow IIS to update filter state (for new sites, where *X* is the Web site number) |

**Table 5.10 Default Registry Key ACLs for the IIS_WPG Group**

| Location | Setting | Description |
|---|---|---|
| HKLM\System\CurrentControlSet\Services\W3SVC | Read | Read W3SVC configured registry keys |
| HKLM\System\CurrentControlSet\Services\InetInfo | Read | Read InetInfo configured registry keys |
| HKLM\System\CurrentControlSet\Services\HTTP | Read | Read HTTP configured registry keys |
| HKLM\System\CurrentControlSet\Services\ASP | Read | Read ASP configured registry keys |

All worker process identities must be members of the IIS_WPG group. If the worker process identity account is not in the IIS_WPG group and does not have the appropriate privileges and permissions, the worker process will not start. In addition, if the worker process identity accounts are not members of the IIS_WPG group, they might not be able to launch a worker process after a modification to the operating system, such as upgrading to the next version or installing a service pack.

In addition, IIS sets restrictive ACLs on log files. For more information about log file permissions, see Analyzing Log Files.

**Metabase ACLs**

IIS installs the metabase files with strict ACLs set to prevent anyone but administrators from viewing your configuration data. You can use the MetaACL.vbs command-line tool to change the ACLs and grant granular permissions on a site-by-site or application-by-application basis. For more information about MetaACL.vbs, see Knowledge Base article 267904, Metaacl.exe modifying metabase permissions for IIS Admin Objects. For more information about metabase security, see Working with the Metabase.

| **Important** |
| --- |
| Before you edit the metabase, verify that you have a backup copy that you can restore if a problem occurs. For information about how to back up the metabase, see Working with the Metabase. |

# Web Site Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When configuring access control for your servers, it is important to understand the distinction between Web site permissions and NTFS permissions. Unlike NTFS permissions, Web site permissions apply to all of the users that access your Web sites. NTFS permissions apply only to a specific user or group of users with a valid Windows account. NTFS permissions control access to physical directories on your server, whereas Web site permissions control access to virtual directories on your Web site. For example, you can use Web site permissions to control whether users visiting your Web site are allowed to view a particular page, upload information, or run scripts on the site.

| **Note** |
| --- |
| If Web site permissions conflict with NTFS permissions for a directory or file, the more restrictive settings are applied. |

IIS 6.0 supports the following Web site permissions:

- Read. Users can view file content and properties. This permission is set by default.
- Write. Users can change content and properties of directories or files

  | **Important** |
  | --- |
  | Allowing users to have Read and Write access to source code can compromise the security of your server. |

- Script source access. Users can access the source code for files, such as the scripts in an ASP application. This option is available only if Read or Write permissions are assigned. If the Read permission is assigned, users can view the source code. If the Write permission is assigned, users can view and modify the source code.

  | **Note** |
  | --- |
  | When you use this option, users might be able to view sensitive information, such as a user name and a password, from scripts in an ASP program. They might also be able to change source code that runs on your server. This can seriously affect the security and the performance of your server. You might want to control access to this type of information and to these functions by using individual Windows accounts and a higher-level authentication method, such as Integrated Windows authentication. |

- Directory browsing. Users can view file lists and collections.
- Log visits. A log entry is created for each visit to the Web site.
- Index this resource. Allows Indexing Service to index this resource.

Whereas Web site permissions control whether users can access sites, code, or pages, another set of permissions, which are known as *Execute permissions*, control whether scripts and other executables can be run.

The following Execute permissions are supported by IIS 6.0:

- None. Prevents all scripts and executables from running.
- Scripts only. Enables applications that are mapped to a script engine to run in this directory, even if the applications are not assigned permissions for executables.
- Scripts and Executables. Enables any application to run in this directory, including applications that are mapped to script engines and Windows binaries (.dll and .exe files).

The Scripts only permission is more secure than the Scripts and Executables permission because the Scripts only permission allows you to limit the applications that can be run in the directory. For information about how to configure Web site permissions, see Securing Sites with Web Site Permissions.

# IIS and Built-in Accounts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS uses a number of built-in Windows accounts, as well as accounts that are specific to IIS. For security reasons, you should be aware of the different accounts and their default user privileges. It can be a security risk to change the identity of a worker process so that it runs as an account with a high level of access, such as the LocalSystem user account.

**LocalSystem**
The built-in LocalSystem user account has a high level of access privileges; it is part of the Administrators group. If a worker process identity runs as the LocalSystem user account, that worker process has full access to the entire system. When IIS 6.0 is running in IIS 5.0 isolation mode, this is the default user account for worker process identities. LocalSystem has one default user right, Full access.

**Network Service**
The built-in Network Service user account has fewer access privileges on the system than the LocalSystem user account, but the Network Service user account is still able to interact throughout the network with the credentials of the computer account. For IIS 6.0, it is recommended that the worker process identity that is defined for application pools run as the Network Service user account, which is the default setting. The following table shows the default user privileges for the Network Service account, along with how each privilege is derived.

| Privilege | Source |
|---|---|
| Replace a process-level token (SeAssignPrimaryTokenPrivilege) | Explicit assignment |
| Adjust memory quotas for a process (SeIncreaseQuotaPrivilege) | Explicit assignment |
| Generate security audits (SeAuditPrivilege) | Explicit assignment |
| Bypass traverse checking (SeChangeNotifyPrivilege) | Through membership in the Everyone group |
| • Access this computer from the network (SeNetworkLogonRight) | Through membership in the Everyone group |
| • Log on as a batch job (SeBatchLogonRight) | Through membership in the IIS_WPG group |
| • Log on as a service (SeInteractiveLogonRight) | Explicit assignment |
| • Impersonate a client after authentication | Through membership in the IIS_WPG group |

**Local Service**
The built-in Local Service user account has fewer access privileges on the computer than the Network Service user account, and those user privileges are limited to the local computer. Use the Local Service user account if the worker process does not require access outside the server on which it is running. The following table shows the default user privileges for the Local Service account, along with how each privilege is derived.

| Privilege | Source |
|---|---|
| Replace a process-level token (SeAssignPrimaryTokenPrivilege) | Explicit assignment |
| Adjust memory quotas for a process (SeIncreaseQuotaPrivilege) | Explicit assignment |
| Generate security audits (SeAuditPrivilege) | Explicit assignment |
| Bypass traverse checking (SeChangeNotifyPrivilege) | Through membership in the Everyone group |

| | |
|---|---|
| • Access this computer from the network (SeNetworkLogonRight) | Through membership in the Everyone group |
| • Log on as a batch job (SeBatchLogonRight) | Explicit assignment |

**IIS_WPG**

The IIS IIS_WPG group account has the minimum permissions and user privileges that are necessary to start and run a worker process on a Web server. Application pool identities must be members of this group so the application pool can register with Http.sys. The following table shows the default user privileges for the IIS_WPG account, along with how each privilege is derived.

| Privilege | Source |
|---|---|
| Access this computer from the network (SeNetworkLogonRight) | Through membership in the Everyone group |
| Bypass traverse checking (SeChangeNotifyPrivilege) | Through membership in the Everyone group |
| Impersonate a client after authentication (SeImpersonatePrivilege) | Explicit assignment |
| • Log on as a batch job (SeBatchLogonRight) | Explicit assignment |

**IUSR_ComputerName**

The IIS IUSR_*ComputerName* user account is for anonymous access to IIS. By default, when a user accesses a Web site that uses Anonymous authentication, that user is mapped to the IUSR_*ComputerName* account. The following table shows the default user privileges for the IUSR_*ComputerName* account, along with how each privilege is derived.

| Privilege | Source |
|---|---|
| Access this computer from the network (SeNetworkLogonRight) | Explicit assignment |
| • Allow log on locally (SeInteractiveLogonRight) | Explicit assignment |
| Bypass traverse checking (SeChangeNotifyPrivilege) | Through membership in the Everyone group |
| • Log on as a batch job (SeBatchLogonRight) | Explicit assignment |

**IWAM_ComputerName**

The IIS IWAM_*ComputerName* user account is for starting out-of-process applications in IIS 5.0 isolation mode. The following table shows the default user privileges for the IWAM_*ComputerName* account, along with how each privilege is derived.

| Privilege | Source |
|---|---|
| Access this computer from the network (SeNetworkLogonRight) | Explicit assignment |
| • Adjust memory quotas for a process (SeIncreaseQuotaPrivilege) | Explicit assignment |
| Bypass traverse checking (SeChangeNotifyPrivilege) | Through membership in the Everyone group |
| • Log on as a batch job (SeBatchLogonRight) | Explicit assignment |
| • Replace a process-level token (SeAssignPrimaryTokenPrivilege) | Explicit assignment |

**ASPNET**

The built-in ASPNET user account is for running the ASP.NET worker process in IIS 5.0 isolation mode. The following table

shows the default user privileges for the ASPNET account, along with how each privilege is derived.

| **Privilege** | **Source** |
|---|---|
| Access this computer from the network (SeNetworkLogonRight) | Explicit assignment |
| • Allow logon locally (SeInteractiveLogonRight) | Through membership in the Users group |
| Bypass traverse checking (SeChangeNotifyPrivilege) | Through membership in the Users group |
| • Deny logon locally (SeDenyInteractiveLogonRight) | Explicit assignment |
| • Log on as a batch job (SeBatchLogonRight) | Explicit assignment |
| • Log on as a service (SeInteractiveLogonRight) | Explicit assignment |

# Anonymous Access

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Anonymous access, the most common Web site access control method, allows anyone to visit the public areas of your Web sites. In IIS 6.0, anonymous users are assigned to the IUSR_*ComputerName* account, which is created when IIS is installed. This account is a valid Windows account and is a member of the **Guests** group. For example, if your computer name is SalesDept1, the anonymous account name is IUSR_SalesDept1. Each Web site on your server can use either the same or different anonymous user logon accounts. The IUSR_*ComputerName* account can be defined on a computer or on a domain.

In IIS 6.0, the IUSR_*ComputerName* account is denied Write access to Web content by default. In addition, this account is explicitly denied access to all executables (such as cmd.exe) in the %windir%\System32 folder. For security reasons, to run most executables in this folder, you must be a member of the Administrators group or of the LocalSystem, Interactive, or Service account. Therefore, an anonymous user cannot run these executables (for example, Common Gateway Interface (CGI) code that calls external programs such as PHP).

When the Web sites and applications running on your Web server require anonymous access, you must configure a user account specifically for anonymous access. This user account can be stored in the local account database on the Web server or in a domain.

| **Important** |
| --- |
| If you are upgrading to IIS6.0, be aware that the upgrade process automatically configures IIS to use the default anonymous user account IUSR_*ComputerName*, where *ComputerName* is the local computer. If you have a domain-based anonymous user account, you must configure the anonymous user identity to use this same domain-based account after the upgrade. |

# Configuring Application Pool Identity in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

When you run IIS in worker process isolation mode, applications can be configured to run in separate application pools. An application pool is a configuration that links one or more applications to a set of one or more worker processes. The *application pool identity* is the name of the account under which the worker process of the application pool runs.

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

In earlier versions of IIS, worker processes ran as the LocalSystem account. Because the LocalSystem account has access to almost all resources of the operating system, this had serious security implications. IIS 6.0 strengthens security because the worker process runs under the new built-in Network Service account by default. IIS 6.0 also allows you to configure the account under which worker processes will run. You have the option of using one of the following three predefined accounts, or creating your own account:

- Network Service. By default, application pools run under the Network Service user account, which has low-level user access rights, so it provides better security against attackers or malicious users who might attempt to take over the computer on which the WWW service is running.

- Local Service. The Local Service user account also has low-level access rights, and is useful when you want to configure application pools to run as the Local Service user account in situations that do not require access to resources on remote computers.

- LocalSystem. You can configure application pools to run as the LocalSystem user account, which has more user rights than the Network Service or Local Service user account. However, running an application pool under an account with increased user rights presents a high security risk.

For example, suppose an ISP wants to allow customers to upload CGI applications and then add them to an application pool. The ISP can run CGI-enabled applications in a separate application pool under the Network Service user account, which has lower user rights, to reduce the risk that these applications will be used to attack the server.

IIS_WPG Group

The IIS_WPG user group is new in IIS 6.0. It provides the minimum set of privileges and permissions required to start and run a worker process on a Web server. On a clean installation of IIS 6.0, the IIS_WPG group contains the Network Service, Local Service, LocalSystem, and IWAM_*ComputerName* accounts.

To designate a specific user account as a worker process identity for a Web site, make the user account a member of the IIS_WPG group. This is a convenient way to configure a custom identity for a worker process without manually assigning privileges and permissions.

All worker process identities must be members of the IIS_WPG group. If the worker process identity is not in the IIS_WPG group and does not have the appropriate privileges and permissions, the associated worker process will not start. In addition, the worker process identity might not be able to launch a worker process after a modification to the operating system, such as an upgrade or service pack.

| **Note** |
| --- |
| By default, the IIS_WPG group does not have the right to start CGI processes. If you create a configurable account and add it to the IIS_WPG group as a worker process identity, you must also assign this new account the following two user rights to start CGI processes: Adjust memory quotas for a process and Replace a process level token. |

When you install IIS 6.0, the setup process adds an ACL to the wwwroot directory of the default Web site. This ACL gives the IIS_WPG group permission to access that directory, which means that all worker process identities in the IIS_WPG group can access the contents of this directory on the default Web site. However, you should not give this group access by ACLs to content for a specific Web site. Instead, to isolate applications, do one of the following:

- Remove the IIS_WPG group from ACLs on site content.
- Allow access to a Web site's content directories and files by providing ACLs for the worker process identity associated with the Web site, rather than for the IIS_WPG group.
- If you create a configurable account to use as the worker process identity, add that account to any ACLs on the site's content directories and files.

For information about changing the account under which an application pool runs by using IIS Manager, see Configuring Application Pool Identity with IIS 6.0.

You can change the worker process identity programmatically by using the Microsoft® Visual Basic® Scripting Edition (VBScript) development system sample script provided in Listing 5.2. Listing 5.2 provides a customizable VBScript-based file that creates an application that runs in an application pool under the supplied identity. Then the script starts Task Manager to show the worker process, and it attempts to access the newly created application using Internet Explorer. When the script is complete, you should see, in Task Manager, a new worker process that serves the request and that runs under the supplied identity.

**Listing 5.2 Sample Script for Configuring Worker Process Identity**

```
' VBScript source code
option explicit

if WScript.Arguments.Count < 4 OR WScript.Arguments.Count > 5 then

# URL Authorization

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

A new authorization framework is available with Windows Server 2003. Implemented through the Windows Server 2003 Authorization Manager, role-based access control is designed to make it easier to manage access control for Web-based or line-of-business applications in enterprise environments.

For example, for an expense-reporting or Web-based shopping application, the authorization decisions often do not involve determining access to persistent objects. Instead, the applications might need to verify a workflow, or they might involve multiple distinct operations, such as querying a database and sending mail. Access decisions often are made based not only on token group membership but also on business logic, such as the amount that is submitted in an expense application or verification of workflow completion. For applications such as these, which do not have well-defined persistent objects, object-oriented ACLs are not effective.

IIS extends the use of role-based authentication by providing gatekeeper authorization to specific URLs. IIS URL authorization allows you to authorize user access to the URLs that make up a Web application. When a user requests access to a URL, URL authorization validates the users access based on the roles of that user, which can be defined in Lightweight Directory Access Protocol (LDAP) queries, custom user roles, and the Authorization Manager rules (scripts that are written in VBScript or JScript, which you can include in role definitions and task definitions). This allows you to control all user access to URLs instead of controlling access per ACL, on each resource.

Additionally, Web applications can use URL authorization together with Authorization Manager to control — from within the same policy store — access to the URLs that make up a Web application and the application-specific tasks and operations. Maintaining the policy in the same policy store allows you to manage access to the URLs and application features from a single point of administration while leveraging the store-level application groups and user-programmable business rules.

URL authorization is task-based, allowing you to create flexible authorization schemes that selectively allow or deny access to parts of the URL namespace for certain sets, users, or roles. The **URLAuthorizationModule** class maps users and roles to pieces of the URL namespace. This module implements both positive and negative authorization assertions and is available for use anytime. You need only to list users or roles in the <allow> or <deny> elements of the <authorization> section of a configuration file.

URL authorization is implemented as an ISAPI interceptor. When an application, virtual directory, or URL is configured to use URL authorization, each request to a URL is routed to the URL authorization ISAPI interceptor. The URL authorization wildcard script map uses Authorization Manager to authorize access to the requested URL. The URL must be associated with an Authorization Manager policy store that contains the authorization policy for the URL. After the client has been authorized to access the URL, the Execute URL feature of the URL authorization ISAPI passes the request to the appropriate handler for the URL, such as ASP.dll, another ISAPI, or the static file handler. Figure 5.5 shows this process. In this figure, the wildcard script map is named URL Authz ISAPI, Authorization Manager is named .NET Authz Framework, and the Execute URL feature is named ExecURL.

By using URL authorization, you can control access based on information that is available only at run time. For example, if you have a Web page that should be available only to employees in a given cost center or to employees of a certain age, you can assign roles to the correct users based on LDAP queries that check the cost center or age attributes on a user object. If employees can access only certain pages on certain days of the week or during a certain time of day, you can create a BizRule that grants access to the URL based on these values or any value that can be asserted at run time, including IIS server variables.

For more information about Authorization Manager, see "Authorization Manager" in Help and Support Center for Windows Server 2003.

# Using URL Authorization

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

IIS 6.0 does not provide graphical user interface (GUI) support for URL authorization. To use URL authorization in IIS 6.0, you must enable the wildcard script map, Urlauth.dll. In addition, you must set the following metabase properties on the application, virtual directory, or URL (Web site):

- AzEnable. This property enables URL authorization for the virtual directory, application, or URL that corresponds to the entry in the metabase.
- AzStoreName. This property associates an Authorization Manager store with the virtual directory, application, or URL.
- AzScopeName. This property associates the virtual directory, application, or URL with a scope. This scope will be the name of a scope in the IIS 6.0 URL authorization application in the Authorization Manager policy store referred to in the AzStoreName property. If no scope or an empty string is specified, the default scope of the URL authorization is used.
- AzImpersonationLevel. This property determines the impersonation behavior for the application, allowing you to configure the Web application to impersonate the client user, the IIS worker process, or the IUSR_*ComputerName* account for the worker process. Each setting significantly changes the environment and implied design of the Web application.

For more information about these metabase properties, see URL Authorization in IIS 6.0.

Although URL authorization controls access to other forms of authorization, such as settings for IIS directory security or ACL permissions, the application context still requires the correct IIS directory security and ACL permissions. URL authorization allows the IIS directory security and ACL permissions to be more easily maintained.

When URL authorization is configured, the AzStoreName property in the IIS metabase entry for the application, virtual directory, or URL identifies an Authorization Manager policy store. To manage the authorization policy, you must run Authorization Manager in Developer mode and use the **Open Policy Store** command from the **Action** menu. URL authorization is an application in this store. The AzScopeName property in the metabase entry is an Authorization Manager scope in URL authorization. Use this scope to manage access to the corresponding URL. When you configure an application, virtual directory, or URL for URL authorization, you must create a scope in the *authorization policy store*, a database that stores the authorization manager policies and that has the same name as the name that is specified in the AzScopeName property of the corresponding metabase entry.

Listing 5.3 provides a customizable text file, written in VBScript, that you can use to mark the root of the first site as a URL in MyAZScope, which is defined in the MyAZStore.xml file. Users with URLAccess rights in this scope will be able to access the site.

**Listing 5.3 Sample Script for URL Authorization**

```
var objVDir = GetObject("IIS://localhost/w3svc/1/root")
objVDir.AzEnable = true
objVDir.AZStoreName = "MSXML://d:\MyAZStore.xml"
objVDir.AzScopeName = "MyAZScope"
objVDir.AZImpersonationLevel = 0
objVDir.SetInfo()
```

# Securing FTP Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 with SP1

Although you can configure the FTP service to require a valid user name and password combination, neither the credentials that are specified at logon nor the data itself is encrypted or encoded in any way. The credentials are sent across the network in plaintext and can be intercepted and analyzed by any station on any network between the FTP client and the FTP server. If your plaintext credentials are intercepted and analyzed by a malicious user, someone other than the intended user can log on to your FTP site and download the files that you placed there or gain access to other network resources, even network resources that require Windows account authentication. For more information about setting the authentication method for your FTP site, see Configuring FTP Site Properties.
