# Index an attribute in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To index an attribute in Active Directory**

1. Open the Active Directory Schema snap-in.
2. In the console tree, click **Attributes**.

   **Where?**

   - Active Directory Schema/Attributes

3. In the details pane, right-click the attribute that you want to index, and then click **Properties**.
4. Click **Index this attribute in the Active Directory**.

## Notes

- To perform this procedure, you must be a member of the Schema Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- The Active Directory Schema snap-in must be connected to the schema master to perform this procedure. The Active Directory Schema snap-in connects to the schema master by default when it is started.
- If the Active Directory Schema snap-in is not installed, see Other Resources.
- Indexing an attribute improves the performance of queries run against the attribute.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Index an attribute for a containerized search

# Index an attribute for a containerized search

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To index attributes for a containerized search**

1. Open the Active Directory Schema snap-in.
2. In the console tree, click **Attributes**.

   **Where?**

   - Active Directory Schema/Attributes

3. In the details pane, right-click the attribute that you want to index, and then click **Properties**.
4. Select the **Index this attribute for containerized searches in the Active Directory** check box.

## Notes

- To perform this procedure, you must be a member of the Schema Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- The Active Directory Schema snap-in must be connected to the schema master to perform this procedure. The Active Directory Schema snap-in connects to the schema master by default when it is started.
- If the Active Directory Schema snap-in is not installed, see Other Resources.
- To complete this procedure, you must first index the attribute. For more information, see Other Resources.

# View a schema class or attribute definition

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view a schema class or attribute definition**

1. Open the Active Directory Schema snap-in.
2. In the console tree, click **Active Directory Schema**.
3. Do one of the following:
   - To view a class definition, in the console tree, click **Classes**. In the details pane, right-click the class for which you want to view the definition, and then click **Properties**.
   - To view an attribute definition, in the console tree, click **Attributes**. In the details pane, right-click the attribute for which you want to view the definition, and then click **Properties**.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- If the Active Directory Schema snap-in is not installed, see Other Resources.

# Modify an existing schema class or attribute definition

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify an existing schema class or attribute definition**

1. Open the Active Directory Schema snap-in.
2. In the console tree, click **Active Directory Schema**.
3. Do one of the following:
   - To modify a class definition, in the console tree, click **Classes**. In the details pane, right-click the class you want to modify, and then click **Properties**.
   - To modify an attribute definition, in the control tree, click **Attributes**. In the details pane, right-click the attribute you want to modify, and then click **Properties**.

## Notes

- To perform this procedure, you must be a member of the Schema Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- The Active Directory Schema snap-in must be connected to the schema master to perform this procedure. The Active Directory Schema snap-in connects to the schema master by default when it is started.

# Add a new schema class or attribute definition

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a new schema class or attribute definition**

1. Open the Active Directory Schema snap-in.
2. In the console tree, click **Active Directory Schema**.
3. Do one of the following:
   - To add a class definition, in the console tree, right-click **Classes**, click **Create Class**, and then follow the instructions.
   - To add an attribute definition, in the console tree, right-click **Attributes**, click **Create Attribute**, and then follow the instructions.

## Notes

- To perform this procedure, you must be a member of the Schema Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- The Active Directory Schema snap-in must be connected to the schema master to perform this procedure. The Active Directory Schema snap-in connects to the schema master by default when it is started.
- If the Active Directory Schema snap-in is not installed, see Other Resources.

# Deactivate a class or attribute

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To deactivate a class or attribute**

1. Open the Active Directory Schema snap-in.
2. In the console tree, click **Active Directory Schema**.
3. Do one of the following:
   - To deactivate a class, in the console tree, click **Classes**. In the details pane, right-click the class you want to deactivate, and then click **Properties**.
   - To deactivate an attribute, in the console tree, click **Attributes**. In the details pane, right-click the attribute you want to deactivate, and then click **Properties**.
4. On the **General** tab, clear the **Class is active** or **Attribute is active** check box, as appropriate.

## Notes

- To perform this procedure, you must be a member of the Schema Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- The Active Directory Schema snap-in must be connected to the schema master to perform this procedure. The Active Directory Schema snap-in connects to the schema master by default when it is started.
- If the Active Directory Schema snap-in is not installed, see Other Resources.
- The status of an attribute or class is displayed in the **Status** column of the details pane. Once a class or attribute has been deactivated, it is considered *defunct*.
- Default schema attributes or classes in the base schema cannot be deactivated. Only attributes or classes added as extensions to the base schema can be deactivated.
- Classes and attributes added to the base schema can be deactivated without raising the forest functional level. However, they can be redefined only in forests with the forest functional level set to Windows Server 2003.
- To view defunct classes or attributes, click **Classes** or **Attributes**, and then on the **View** menu, click **Defunct Objects**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable schema changes on a schema master running Windows 2000

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable schema changes on a schema master running Windows 2000**

1. Open Registry Editor.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

2. In Registry Editor, navigate to the **Parameters** registry key:

   **Where?**

   - HKEY_LOCAL_MACHINE/SYSTEM/CurrentControlSet/Services/NTDS/Parameters

3. On the **Edit** menu, click **New**, and then click **DWORD Value**.

4. Type **Schema Update Allowed**, and then press ENTER.

5. Double-click the **Schema Update Allowed** registry key that you just created, and then, in **Value data**, type **1** to enable schema changes.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Registry Editor, click **Start**, click **Run**, type **regedit**, and then click **OK**.

- To disable schema changes, in the **Schema Update Allowed** registry key, under **Value data**, type **0**.

- This procedure should only be performed on a domain controller that is running Windows 2000 and that also holds the schema master role.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Sites

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage sites**

- Configure Site Settings
- Configure Active Directory Server Settings
- Configure Replication Between Sites

# Configure Site Settings

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure site settings**

- Create a site
- Rename a site
- Delete a site
- Create a subnet
- Associate a subnet with a site
- Delete a subnet
- Select another licensing computer
- Cache universal group memberships
- Delegate control of a site
- Connect to a forest
- Connect to a domain controller
- Reveal the services node

# Create a site

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a site**

1. Open Active Directory Sites and Services.
2. Right-click the **Sites** folder, and then click **New Site**.
3. In **Name**, type the name of the new site.
4. Click a site link object, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- It is recommended that you use legal Domain Name System (DNS) names when you create new site names; otherwise, your site will only be accessible where a Microsoft DNS server is used. For more information about DNS names, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Rename a site

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To rename a site**

1. Open Active Directory Sites and Services.
2. In the console tree, right-click the site that you want to rename, and then click **Rename**.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that you want to rename*

3. Type the new site name.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- It is recommended that you use legal Domain Name System (DNS) names when you create new site names; otherwise, your site will only be accessible where a Microsoft DNS server is used. For more information about DNS names, see Related Topics.

# Delete a site

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a site**

1. Open Active Directory Sites and Services.
2. In the console tree, right-click the site that you want to delete, and then click **Delete**.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that you want to delete*

### Important

- Before a site can be deleted, any domain controller objects within the site must be deleted or moved to another site.

### Notes

- To perform this procedure, you must be a member of the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

**Information about functional differences**

# Create a subnet

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a subnet**

1. Open Active Directory Sites and Services.
2. In the console tree, right-click **Subnets**, and then click **New Subnet**.

   **Where?**

   - Active Directory Sites and Services/Sites/Subnets

3. In **Address**, type the subnet address.
4. In **Mask**, type the subnet mask that describes the range of addresses included in this subnet.
5. Under **Select a site object for this subnet**, click the site to associate with this subnet, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

# Select another licensing computer

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To select another licensing computer**

1. Open Active Directory Sites and Services.
2. In the console tree, click the site you want to configure.

   **Where?**

   - Active Directory Sites and Services/Sites/*site*

3. In the details pane, right-click **Licensing Site Settings**, and then click **Properties**.
4. On the **Licensing Settings** tab, click **Change**.
5. In **Enter the object name to select**, type the computer name of the alternative licensing computer, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- The licensing server collects licensing information from within the site for use by the licensing administrative tool. For more information, see Related Topics.
- Active Directory will automatically configure a licensing computer for each site. For optimal performance, the licensing computer for a site should reside within that same site. A licensing computer does not have to be a domain controller.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Cache universal group memberships

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To cache universal group memberships**

1. Open Active Directory Sites and Services.
2. In the console tree, click the site in which you want to enable universal group membership caching.

   **Where?**

   - Active Directory Sites and Services/Sites/*the site in which you want to enable universal group membership caching*

3. In the details pane, right-click **NTDS Site Settings**, and then click **Properties**.
4. Select the **Enable Universal Group Membership Caching** check box.
5. In **Refresh cache from**, click a site from which this site will refresh its cache, or accept **<Default>** to refresh the cache from the nearest site that has a global catalog.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delegate control of a site

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delegate control of a site**

1. Open Active Directory Sites and Services.
2. Right-click the container whose control you want to delegate, and then click **Delegate Control** to start the Delegation of Control Wizard.
3. Follow the instructions in the Delegation of Control Wizard.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- In Active Directory Sites and Services, you can delegate control for the subnets, intersite transports, sites, and server containers. Delegating control of an object allows you to specify who has permissions to access or modify that object or its child objects.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to a forest

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a forest**

1. Open Active Directory Sites and Services.
2. Right-click **Active Directory Sites and Services**, and then click **Connect to Forest**.
3. In **Root domain**, type the root domain of the forest, and then click **OK**.

   This is the root domain of the first domain tree created in the forest.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- Active Directory Sites and Services views a single forest. Change forests to view and configure Active Directory Sites and Services settings for a forest of your choosing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to a domain controller

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a domain controller**

1. Open Active Directory Sites and Services.
2. Right-click **Active Directory Sites and Services**, and then click **Connect to Domain Controller**.
3. In **Domain**, type a domain name, or click **Browse** to select from the list of available domains.
4. In **Enter the name of another domain controller**, click a domain controller from the list of available domain controllers, or accept the default value **Any Writable Domain Controller** to have a domain controller automatically selected.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- Active Directory Sites and Services views and configures a single copy of the directory data. Change the domain controller to select an alternate domain controller whose directory data will read and modify.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Reveal the services node

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To reveal the services node**

1. Open Active Directory Sites and Services.
2. In the console tree, right-click **Active Directory Sites and Services**, point to **View**, and then click **Show Services Node**.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- Show Services Node is a persistent setting.
- Managing objects located in the Services container from within Active Directory Sites and Services provides limited functionality. It is recommended that you use other appropriate administrative tools, including ADSI Edit, for managing objects located in the Services container. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Active Directory Server Settings

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure server settings**

- Select a query policy
- Enable or disable a global catalog
- Designate a preferred bridgehead server
- Move a domain controller between sites
- Check the replication topology
- Delete extinct server metadata

# Select a query policy

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To select a query policy**

1. Open Active Directory Sites and Services.

2. In the console tree, click the domain controller whose query policy you want to change.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that contains the domain controller whose query policy you want to change*/Servers/*domain controller whose query policy you want to change*

3. In the details pane, right-click **NTDS Settings**, and then click **Properties**.

4. On the **General** tab, in **Query Policy**, click a query policy.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the domain of the selected domain controller) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- A query policy prevents specific Lightweight Directory Access Protocol (LDAP) operations from adversely impacting the performance of the domain controller and also makes the domain controller more resilient to denial-of-service attacks.

- To create or modify query policies, use the Ntdsutil command-line tool.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable or disable a global catalog

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable a global catalog**

1. Open Active Directory Sites and Services.
2. In the console tree, click the domain controller where you want to enable or disable the global catalog.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that contains the domain controller that you want to disable or enable*/Servers/*domain controller*

3. In the details pane, right-click **NTDS Settings**, and then click **Properties**.
4. Select the **Global Catalog** check box to enable the global catalog, or clear the check box to disable the global catalog.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the domain of the selected domain controller) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- The Builtin Administrator account in the domain can always log on to the domain, even when a global catalog is not available.
- Enabling a global catalog can cause additional replication traffic.
- A domain controller on which you enable the global catalog does not advertise itself in Domain Name System (DNS) as a global catalog until all partial domain directory partitions have been received.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Designate a preferred bridgehead server

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To designate a preferred bridgehead server**

1. Open Active Directory Sites and Services.

2. In the console tree, right-click the domain controller that you want to make a preferred bridgehead server, and then click **Properties**.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that contains the domain controller that you want to make a preferred bridgehead server*/Servers/*the domain controller that you want to make a preferred bridgehead server*

3. On the **General** tab, click the intersite transport or transports for which this computer will be a preferred bridgehead server, and then click **Add**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the domain of the selected domain controller) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- Assigning a bridgehead server manually can cause replication problems because it prevents the Knowledge Consistency Checker (KCC) from making an automatic failover assignment if a manually selected bridgehead server fails. For more information, see Related Topics.

- You can establish preferred bridgehead servers for one or more protocols (such as IP or SMTP).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Move a domain controller between sites

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To move a domain controller between sites**

1. Open Active Directory Sites and Services.

2. In the console tree, right-click the domain controller that you want to move to a different site, and then click **Move**.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that contains the domain controller you want to move*/Servers/*domain controller to be moved*

3. In the **Move Server** dialog box, click the site to which you want to move the domain controller.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the domain of the selected domain controller) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- This procedure can be used to move member servers, as well as domain controllers, between sites.

- Before you move a domain controller to a different site, verify that the IP address of the domain controller is included in the range of IP addresses defined in a subnet of that site.

- You can also drag server objects to move them.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Locating a domain controller

# Check the replication topology

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To check the replication topology**

1. Open Active Directory Sites and Services.

2. In the console tree, click the domain controller you want to use to check replication topology.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that contains the domain controller whose replication topology you want to check*/Servers/*server you want to use to check replication topology*

3. In the details pane, right-click **NTDS Settings**, point to **All Tasks**, and then click **Check Replication Topology**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- Active Directory runs the intersite topology generator on one domain controller in a site to consider the cost of intersite connections and to check if any previously available domain controllers are no longer available or if new domain controllers have been added. Then, the Knowledge Consistency Checker (KCC) uses this information to add or remove connection objects as needed for efficient replication. This process does not affect manually created connection objects. Only one domain controller per site assumes the role of the intersite topology generator.

- To identify the intersite topology generator in each site, you can use the Dcdiag Windows Support tool available on your operating system installation CD.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete extinct server metadata

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete extinct server metadata**

1. Open Command Prompt.

2. Type:

   **ntdsutil**

3. At the **ntdsutil** command, type:

   **metadata cleanup**

4. Perform metadata cleanup as follows:

   - If you are performing metadata cleanup by using the version of Ntdsutil.exe that is included with Windows Server 2003 Service Pack 1 (SP1), at the **metadata cleanup** command, type:

     **remove selected server***ServerName*

     Or

     **remove selected server***ServerName1***on** *ServerName2*

     | Value | Description |
     |---|---|
     | *ServerName*, *ServerName1* | The distinguished name of the domain controller whose metadata you want to remove, in the form cn=*ServerName*,cn=Servers,cn=*SiteName*, cn=Sites,cn=Configuration,dc=*ForestRootDomain*. |
     | *ServerName2* | The DNS name of the domain controller to which you want to connect and from which you want to remove server metadata. |

   - If you are performing metadata cleanup by using the version of Ntdsutil.exe that is included with Windows Server 2003 with no service pack, perform metadata cleanup as follows:

   a. At the metadata cleanup command, type:

      **connection**

   b. At the **server connections** command, type:

      **connect to server** *Server*

   c. At the connection command, type:

      **quit**

   d. At the metadata cleanup command, type:

      **select operation target**

   e. At the select operation target command, type:

**list sites**

f. A numbered list of sites will be displayed, type:

**select site** *SiteNumber*

g. At the select operation target command, type:

**list domains in site**

h. A numbered list of domains in the selected site will be displayed, type:

**select domain** *DomainNumber*

i. At the select operation target command, type:

**list servers in site**

j. A numbered list of servers in a domain and site will be displayed, type:

**select server** *ServerNumber*

k. At the select operation target command, type:

**quit**

l. At the metadata cleanup command, type:

**remove selected server**

| Value | Description |
|---|---|
| *Server* | The DNS name of a domain controller that you want to connect to. |
| *SiteNumber* | The number associated to the site of the server that you want to clean up, which displays in the list. |
| *DomainNumber* | The number associated to the domain of the server that you want to clean up, which displays in the list. |
| *ServerNumber* | The number associated to the server that you want to clean up, which displays in the list. |

**Notes**

- To perform this procedure, you must be a member of the Domain Admins group (in the domain of the selected domain controller) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- You can use this procedure to delete from the directory the metadata of a domain controller that could not be cleanly decommissioned.

- Do not delete the metadata of existing domain controllers.

- To clean up metadata if you are using the version of Ntdsutil.exe that is included with Windows Server 2003 with no service pack installed, you must first select the operation target. When selecting the operation target for a server to clean up, you must first select the site, and then the domain, of that server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Replication Between Sites

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure replication between sites**

- Create a site link
- Delete a site link
- Create a site link bridge
- Delete a site link bridge
- Configure site link replication availability
- Configure site link cost
- Configure site link replication frequency
- Ignore replication schedules
- Enable or disable site link bridges
- Add a site to a site link
- Manually add connections
- Force replication over a connection

# Create a site link

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a site link**

1. Open Active Directory Sites and Services.
2. In the console tree, right-click the intersite transport protocol you want the site link to use, and then click **New Site Link**.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*inter-site transport protocol you want the site link to use*

3. In **Name**, type the name to be given to the link.
4. Click two or more sites to connect, and then click **Add**.
5. Configure the site link's cost, schedule, and replication frequency. See Related Topics for information.

### Important

- If you create a site link that uses SMTP, you must have an enterprise certification authority (Enterprise CA) available and SMTP must be installed on all domain controllers that will use the site link.

### Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- Creating a site link between two or more sites is a way to influence replication topology. By creating a site link, you provide Active Directory with information about what connections are available, which ones are preferred, and how much bandwidth is available. Active Directory uses this information to choose times and connections for replication that will afford the best performance.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete a site link

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a site link**

1. Open Active Directory Sites and Services.

2. In the console tree, click the inter-site transport folder that contains the site link you want to delete.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*inter-site transport folder that contains the site link you want to delete*

3. In the details pane, right-click the site link you want to delete, and then click **Delete**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- Before deleting a site link, you should ensure that its member sites will still belong to at least one existing site link.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a site link bridge

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a site link bridge**

1. Open Active Directory Sites and Services.

2. In the console tree, right-click the inter-site transport folder for which you want to create a new site link bridge, and then click **New Site Link Bridge**.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*intersite transport for which you want to create a new site link bridge*

3. In **Name**, type a name for the site link bridge.

4. Click two or more site links to be bridged, and then click **Add**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- If **Bridge all site links** is enabled (default setting), this procedure is redundant and will have no effect.

- A site link bridge creates a chain of site links across which domain controllers from different sites in the site links can directly communicate.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure site link replication availability

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure site link replication availability**

1. Open Active Directory Sites and Services.
2. In the console tree, click the inter-site transport folder that contains the site link whose schedule you want to adjust.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*inter-site transport folder that contains the site link whose schedule you want to adjust*

3. In the details pane, right-click the site link whose schedule you want to adjust, and then click **Properties**.
4. Click **Change Schedule**.
5. Select the block of time you want to schedule, and then click **Replication Not Available** or **Replication Available**.

**Notes**

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- Replication availability schedules can be temporarily ignored by selecting **Ignore schedules** on the appropriate inter-site transport folder. For more information, see Related Topics.
- By default, Simple Mail Transfer Protocol (SMTP) replication does not utilize site link availability information.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure site link cost

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure site link cost**

1. Open Active Directory Sites and Services.
2. In the console tree, click the inter-site transport folder that contains the type of link you are going to configure.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*inter-site transport folder that contains the type of link you are going to configure*

3. In the details pane, right-click the site link whose cost you want to set, and then click **Properties**.
4. In **Cost**, enter a value for the cost of replication.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- The Active Directory Knowledge Consistency Checker (KCC) considers a site link with a higher cost to be less desirable than a site link with a lower cost. When multiple paths for replication are available, the KCC prefers the site link with the lower cost.
- You cannot apply costs directly to site link bridges.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure site link replication frequency

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure site link replication frequency**

1. Open Active Directory Sites and Services.
2. In the console tree, click the inter-site transport folder that contains the site link you want to configure.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*inter-site transport folder that contains the site link you want to configure*

3. In the details pane, right-click the site link whose replication frequency you want to set, and then click **Properties**.
4. In **Replicate every**, type the number of minutes between replications.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- The default site link replication frequency is 180 minutes.
- The **Replicate every** value will be processed as the nearest multiple of 15 ranging from a minimum of 15 to a maximum of 10,080 minutes, which corresponds to one week.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Ignore replication schedules

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To ignore replication schedules**

1. Open Active Directory Sites and Services.

2. In the console tree, right-click the intersite transport protocol that contains the site link schedules you want ignored, and then click **Properties**.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*the intersite transport protocol for which you want replication schedules ignored*

3. Select the **Ignore schedules** check box.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- When **Ignore schedules** is selected, any site link availability schedules that have been configured are ignored, and all site links become always available for replication. When **Ignore schedules** is cleared, any previously configured site link availability schedules go back into effect. If no site link availability schedules have been configured, selecting **Ignore schedules** has no effect.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable or disable site link bridges

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable site link bridges**

1. Open Active Directory Sites and Services.

2. In the console tree, right-click the intersite transport folder (such as **IP** or **SMTP**) for which you want to enable or disable site link bridges, and then click **Properties**.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*intersite transport for which you want to enable or disable link bridges*

3. Do one of the following:

   - To enable site link bridges, select the **Bridge all site links** check box.

   - To disable site link bridges, clear the **Bridge all site links** check box.

### Important

- By default, all site links are bridged. For more information about disabling this option and its affects on intersite replication, see Related Topics.

### Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a site to a site link

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a site to a site link**

1. Open Active Directory Sites and Services.

2. In the console tree, click the inter-site transport folder that contains the site link to which you are adding the site.

   **Where?**

   - Active Directory Sites and Services/Sites/Inter-Site Transports/*inter-site transport folder that contains the site link to which you are adding the site*

3. In the details pane, right-click the site link to which you want to add the site, and then click **Properties**.

4. Click the site you want to add to this site link, and then click **Add**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manually add connections

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manually add connections**

1. Open Active Directory Sites and Services.

2. In the console tree, right-click **NTDS Settings** for the domain controller for which you want to manually add a connection, and then click **New Active Directory Connection**.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that contains the domain controller for which you want to manually add a connection*/Servers/*domain controller for which you want to manually add a connection*/NTDS Settings

3. In the **Find Domain Controllers** dialog box, click the domain controller that you want to include in the connection object.

4. In the **New Object-Connection** dialog box, type a name for the new connection object.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- Active Directory automatically creates and deletes connection objects under normal conditions.

- If you are certain that a connection is required and that you want it to persist until it is manually removed, create a connection manually.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Troubleshooting replication

# Force replication over a connection

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To force replication over a connection**

1. Open Active Directory Sites and Services.

2. In the console tree, click **NTDS Settings** for the server that you want to force replication.

   **Where?**

   - Active Directory Sites and Services/Sites/*site that contains the connection over which you want to replicate directory information*/Servers/*server that you want to force replication*/NTDS Settings

3. In the details pane, right-click the connection over which you want to replicate directory information, and then click **Replicate Now**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group (in the domain of the selected domain controller) or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority.

- If you want to synchronize the configuration and schema directory partitions on a domain controller in a child domain, you must be a member of the Domain Admins groups in the forest root domain or the Enterprise Admins group in the forest.

- As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

- You can also use the **repadmin** and **replmon** command-line tools, available on your operating system installation CD, to force replication. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage COM+ Partitions and Partition Sets

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage COM+ partitions and partition sets**

- Create a COM+ partition in Active Directory
- Create a COM+ partition set in Active Directory
- Map a user or organizational unit to a COM+ partition set
- View COM+ partitions and partition sets

# Create a COM+ partition in Active Directory

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a COM+ partition in Active Directory**

1. Open Active Directory Users and Computers.
2. On the **View** menu, select **Advanced Features**.
3. In the console tree, right-click **ComPartitions**, and then click **New Partition**.

   **Where?**

   - Active Directory Users and Computers\domain node\System\ComPartitions

4. Under **Partition Name**, type a name for the new partition.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- Once you have created a COM+ partition using Active Directory Users and Computers, you must then create an empty partition on a application server and associate it with the appropriate COM+ partition in Active Directory. For more information, see Related Topics.
- When creating a new COM+ partition, a partition ID is automatically generated and displayed under **Partition ID** in the **Properties** dialog box. If you want to specify a different GUID for the new COM+ partition, delete the existing partition ID and type a new one.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a COM+ partition set in Active Directory

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a COM+ partition set in Active Directory**

1. Open Active Directory Users and Computers.
2. On the **View** menu, select **Advanced Features**.
3. In the console tree, right-click **ComPartitionSets**, and then click **New Partition Set**.

   **Where?**

   - Active Directory Users and Computers/*domain node*/System/ComPartitionSets

4. Under **Name** and **Description**, type the name and description of the new partition set, and then click **Next**.
5. On the **Configure Partitions for New Set** page, click the partitions that you want to include in the partition set, click **Add**, and then click **Next**.
6. On the **Configure Users for New Set** page, click **Add User** and **Add Org Unit** to add the users and organizational units that are to be mapped to the partition set, and then click **Finish**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- By using COM+ partition sets, you can associate multiple users or organizational units with a COM+ partition set at one time instead of having to map multiple user identities or organizational units. A COM+ partition set is available to users or organizational units that are mapped to it.
- When creating a new COM+ partition set, a partition ID is automatically generated and displayed under **Partition Set ID** in the **Properties** dialog box. If you want to specify a different GUID for the new COM+ partition set, delete the existing partition ID and type a new one.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Map a user or organizational unit to a COM+ partition set

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To map a user or organizational unit to a COM+ partition set**

1. Open Active Directory Users and Computers.

2. On the **View** menu, select **Advanced Features**.

3. Do one of the following:

   **At the user or organizational unit**

   a. In the console tree, right-click the user name or organizational unit that you want to map to a partition set, and then click **Properties**.

   b. On the **COM+** tab, under **Partition Set**, click the partition set to which you want to map the user or organizational unit.

   **At the COM+ partition set**

   a. In the console tree, click **ComPartitionSets**.

   **Where?**

   - Active Directory Users and Computers/*domain node*/System/ComPartitionSets

   a. Right-click the COM+ partition set to which you want to map a user or organizational unit, and then click **Configure Set Members**.

   b. In the **Add/Remove Users** dialog box, click **Add User** and **Add Org Unit** to add the users and organizational units that you want to map to the partition set, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Domain Admins group or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.

- By using COM+ partition sets, you can associate multiple users or organizational units with a COM+ partition set at one time instead of having to map multiple user identities or organizational units. A COM+ partition set is available to users or organizational units that are mapped to it.

# Search Active Directory

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Search Active Directory**

- Find a user account
- Find a contact
- Find a printer
- Find a shared folder
- Find a group
- Find a computer account
- Find an organizational unit
- Find a domain controller
- Perform a custom search
- Create a saved query
- Export or import a saved query

# Find a user account

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To find a user account**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Active Directory Users and Computers.
2. If you want to search the entire domain, in the console tree, right-click the domain node, and then click **Find**.

   Or, if you know which organizational unit the user is in, in the console tree, right-click the organizational unit, and then click **Find**.
3. In **Name**, type the name of the user you want to find.
4. Click **Find Now**.

### Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- You can search using partial search criteria. For example, *B* will return all objects whose name begins with the letter *B*, such as Backup Operators.
- Use the **Advanced** tab for more powerful search options.
- To find a user, you can also click

  on the toolbar.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dsquery user***parameter*

| Value | Description |
|---|---|
| *parameter* | For the list of parameters, see Dsquery. |

### Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **dsquery user /?**

**Information about functional differences**

# Find a domain controller

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To find a domain controller**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Active Directory Users and Computers.
2. In the console tree, right-click any node or folder, and then click **Find**.

   Or, if you know which folder contains the domain controller, right-click that folder to narrow the search to that folder.
3. In **Find**, click **Computers** and in **Role**, click **Domain Controller**.

   If you do not know which folder contains the domain controller, in **In**, click the domain you want to search or click **Entire Directory**.
4. Click **Find Now**.

### Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- Use the **Advanced** tab for more powerful search options.
- To find a computer, you can also click

  on the toolbar.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dsquery server***Parameter*

| Value | Description |
|---|---|
| *Parameter* | There are several attributes of a server that you can search by using this command. For the list of parameters, see Dsquery. |

### Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice,

consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Perform a custom search

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To perform a custom search**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Active Directory Users and Computers.
2. In the console tree, right-click the domain node, and then click **Find**.
3. In **Find**, click **Custom Search**.
4. Click **Field**, point to the kind of object for which to search, and then click the attribute of that object for which you want to specify a search value.
5. In **Condition**, click the condition for your search.
6. In **Value**, type the attribute value for which the search will apply the condition.
7. Click **Add** to add this search condition to the custom search.
8. Repeat steps 4 through 7 until you have added all of the desired search conditions.
9. Click **Find Now**.

### Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- Use the **Advanced** tab to enter a query using LDAP syntax. For more information about LDAP, see Related Topics.
- To start a search, you can also click

  on the toolbar.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dsquery** *****_Parameter_

| Value | Description |
| --- | --- |
| *Parameter* | There are several attributes that you can search by using this command. For the list of parameters, see Dsquery. For more information about LDAP searches, see Related Topics. |

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a saved query

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a saved query**

1. Open Active Directory Users and Computers.
2. In the console tree, right-click **Saved Queries** or any of its subfolders in which you want to save a query.

   **Where?**

   - Active Directory Users and Computers/Saved Queries

3. Point to **New**, and then click **Query**.
4. In **Name**, type a query name.
5. In **Description**, type a query description.
6. Click **Browse** to define the container from which to begin your search.

   To search all subcontainers of the selected container, select the **Include subcontainers** check box.

7. Click **Define Query** to define your query.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- To organize your saved queries, you can create subfolders by right-clicking **Saved Query**, pointing to **New**, and then clicking **Folder**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Export or import a saved query

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To export or import a saved query**

1. Open Active Directory Users and Computers.
2. Do one of the following:
   - To export a saved query, in the Saved Queries folder, or a subfolder of Saved Queries, right-click the query you want to export, and then click **Export Query Definition**. Name the file, and then click **Open**.
   - To import a saved query, right-click **Saved Queries**, or a subfolder of Saved Queries, and then click **Import Query Definition**. Browse to the saved query, click it, and then click **Open**.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Active Directory Concepts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Concepts**

This section provides general background information about Active Directory®:

- Active Directory Overview
- Understanding Active Directory
- Deploying Active Directory
- Administering Active Directory
- Active Directory Resources

# Active Directory Overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory overview**
A directory is a hierarchical structure that stores information about objects on the network. A directory service, such as Active Directory Domain Services (AD DS), provides the methods for storing directory data and making this data available to network users and administrators. For example, AD DS stores information about user accounts, such as names, passwords, phone numbers, and so on, and enables other authorized users on the same network to access this information.

This section covers:

- Introduction to Active Directory
- New features for Active Directory
- Security information for Active Directory

# Introduction to Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Introduction to Active Directory**

Active Directory can be installed on servers running Microsoft® Windows Server® 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. Active Directory stores information about objects on the network and makes this information easy for administrators and users to find and use. Active Directory uses a structured data store as the basis for a logical, hierarchical organization of directory information.

This data store, also known as the directory, contains information about Active Directory objects. These objects typically include shared resources such as servers, volumes, printers, and the network user and computer accounts. For more information about the Active Directory data store, see Directory data store.

Security is integrated with Active Directory through logon authentication and access control to objects in the directory. With a single network logon, administrators can manage directory data and organization throughout their network, and authorized network users can access resources anywhere on the network. Policy-based administration eases the management of even the most complex network. For more information about Active Directory security, see Security overview.

Active Directory also includes:

- A set of rules, the schema, that defines the classes of objects and attributes contained in the directory, the constraints and limits on instances of these objects, and the format of their names. For more information about the schema, see Schema.
- A global catalog that contains information about every object in the directory. This allows users and administrators to find directory information regardless of which domain in the directory actually contains the data. For more information about the global catalog, see The role of the global catalog.
- A query and index mechanism, so that objects and their properties can be published and found by network users or applications. For more information about querying the directory, see Finding directory information.
- A replication service that distributes directory data across a network. All domain controllers in a domain participate in replication and contain a complete copy of all directory information for their domain. Any change to directory data is replicated to all domain controllers in the domain. For more information about Active Directory replication, see Replication overview.
- Support for Active Directory client software, which makes many features on Microsoft® Windows® 2000 Professional or Windows XP Professional available to computers running Windows 95, Windows 98, and Windows NT® Server 4.0. To client computers not running Active Directory client software, the directory will appear like a Windows NT directory. For more information about client software, see Active Directory clients.

**Note**

- You cannot install Active Directory on a server running Windows Server 2003, Web Edition, but you can join the server to an Active Directory domain as a member server. For more information about Windows Server 2003, Web Edition, see Overview of Windows Server 2003, Web Edition.

# New features for Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New Active Directory features in Windows Server 2003 with Service Pack 1 (SP1)**

The following list summarizes the Active Directory features that are new since the original release of Windows Server 2003.

- **Directory service backup reminders.** A new event message, event ID 2089, provides the backup status of each directory partition that a domain controller stores, including application directory partitions and Active Directory Application Mode (ADAM) partitions. If halfway through the tombstone lifetime a partition has not been backed up, this event is logged in the Directory Service event log and continues daily until the partition is backed up.

- **Added replication security and fewer replication errors.** Replication metadata for domain controllers from which Active Directory has been removed is no longer retained by default, although a waiting period can be configured. This change improves replication security and eliminates replication error messages that are caused by failed attempts to replicate with decommissioned domain controllers. For more information about preserving replication metadata, see How the Active Directory Replication Model Works.

- **Install from Media improvement for installing DNS servers.** Install from Media improvements make it easier to create a new domain controller that is a Domain Name System (DNS) server by providing a new option to include application directory partitions in the backup media that is used to install the new domain controller. This option eliminates the requirement for replication of the DomainDNSZones and ForestDNSZones application directory partitions before the DNS server is operational.

- **Enhancements for replication and DNS testing.** The Dcdiag.exe command-line tool, which is available in Windows Support Tools, provides new reporting on the overall health of replication with respect to Active Directory security. This test provides a summary of results, along with detailed information for each domain controller that is tested and a diagnosis of any security errors. Dcdiag.exe also has new DNS tests for connectivity, service availability, forwarders and root hints, delegation, dynamic update, locator record registrations, external name resolution, and enterprise infrastructure. These tests can be performed on one domain controller or on all domain controllers in a forest. For more information about using Dcdiag.exe, see Windows Support Tools Help.

- **Support for running domain controllers in virtual machines.** On a single physical server that is running Windows Server 2003 and Microsoft Virtual Server 2005, you can install multiple Windows Server 2003 or Windows 2000 Server domain controllers in separate virtual machines. This platform is well suited for test environments. By using virtual machines, you can effectively host multiple domains, multiple domain controllers for the same domain, or even multiple forests on one physical server that is running a single operating system. Windows Server 2003 SP1 also provides protection against directory corruption that can result from improper backup and restore of domain controller images. For more information about running domain controllers in virtual machines, see Running Domain Controllers in Virtual Server 2005.

- **Operations master health and status reporting.** If an operation that requires a domain controller that holds an operations master role (also known as flexible single-master operations (FSMO)) cannot be performed, events are now logged in the Directory Service event log. Events identify role holders that do not exist, exist but are not available, or are available but have not replicated recently with the contacting domain controller. For more information about operations masters, see How Operations Masters Work.

- **Extended storage of deleted objects.** The default period that a copy of a deleted object is retained in Active Directory, called the tombstone lifetime, is extended from 60 days to 180 days. Longer tombstone lifetime decreases the chance that a deleted object remains in the local directory of a disconnected domain controller beyond the time when the object is permanently deleted from online domain controllers. The tombstone lifetime is not changed automatically when you upgrade to Windows Server 2003 with SP1, but you can change the tombstone lifetime manually after the upgrade. New forests that are installed with Windows Server 2003 with SP1 have a default tombstone lifetime of 180 days. For more information about tombstone lifetime, see How the Data Store Works.

- **Improved domain controller name resolution.** In response to DNS name resolution failures that may be encountered

during location of replication partners and global catalog servers, domain controllers running Windows Server 2003 with SP1 request other variations of the server name that might be registered, which results in fewer failures due to DNS delays and misconfiguration. For more information about DNS name resolution, see How DNS Support for Active Directory Works.

- **Improved server metadata removal.** The Ntdsutil.exe command-line tool for managing the Active Directory database has new functionality that makes it easier to remove domain controller metadata. Preliminary steps, such as connecting to a server, domain, and site, are no longer required. You simply specify the server to remove. You can also specify the server on which to perform the deletion. Metadata removal is now more comprehensive: in addition to Active Directory replication metadata, the tool now removes File replication service (FRS) metadata and operations master metadata. If an operations master role is assigned to the server that is being removed, the tool attempts to transfer the role to an appropriate domain controller. For more information, see Delete extinct server metadata.

- **Improved security to protect confidential attributes.** To prevent Read access to confidential attributes, such as a Social Security number, while allowing Read access to other object attributes, you can designate specific attributes as confidential by setting a search flag on the respective attributeSchema object. By default, only domain administrators have Read access to confidential attributes, but this access can be delegated. For more information about access to attributes, see How Security Descriptors and Access Control Lists Work.

- **Retention of SID history on tombstones.** The **sIDHistory** attribute has been added to the set of attributes that are retained on an object tombstone when the object is deleted. If a tombstoned object is reactivated (undeleted), the **sIDHistory** attribute is now restored with the object. For more information about tombstones, see How the Data Store Works.

- **Adprep.exe improvements for Windows 2000 Server upgrades.** The Adprep tool has been improved to reduce the impact of FRS synchronization that results from updating SYSVOL files during upgrade. Adprep is used to upgrade the Windows 2000 Server schema to the Windows Server 2003 schema and to update some forest- and domain-specific configuration, including SYSVOL, that is required for a Windows Server 2003 domain controller to be operational. The tool now allows performing SYSVOL operations in a separate step when the domain is prepared for upgrade. A new switch, **/gpprep**, has been added to accommodate the SYSVOL updates, which can be performed at a convenient time following the upgrade. The **adprep /domainprep** command, which formerly performed both directory and SYSVOL updates, now updates only the directory. Adprep also now detects third-party schema extensions that block an upgrade, identifies the blocking extensions, and recommends fixes. Microsoft Exchange schema objects are also detected so that the Exchange schema can be prepared appropriately to accommodate inetOrgPerson naming. For more information about Adprep.exe, see Adprep.

- **Improved authoritative restore.** The **authoritative restore** option in Ntdsutil now locates backlinks for all objects that are authoritatively restored, including links that were created before implementation of the Windows Server 2003 or Windows Server 2003 interim forest functional level, in which linked-value replication (LVR) functionality was introduced. For example, suppose that a user object is restored and the user belongs to group G1, which was created before the forest functional level was raised, and the user also belongs to group G2, which was created after the forest functional level was raised. During authoritative restore of the user object, the member attribute of G2 is updated, but not the member attribute of G1. Ntdsutil now creates a text file that identifies the authoritatively restored objects and uses this file to create an LDAP Data Interchange Format (LDIF) file that can be used to restore all backlinks for pre-LVR groups in this domain. In the example, when this LDIF file is run after authoritative restore, the restored user is added to group G1. A new option in **authoritative restore** also allows you to generate an LDIF file that you can use to restore links in other domains in which a restored object has backlinks.

**New Active Directory features in Windows Server 2003**

With the new Active Directory features available in Microsoft® Windows Server® 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, more efficient administration of Active Directory is available to you.

The following list summarizes the Active Directory features that are available by default on any domain controller running Windows Server 2003.

- **Multiple selection of user objects.** Modify common attributes of multiple user objects at one time.

- **Drag-and-drop functionality.** Move Active Directory objects from container to container by dragging one or more objects to a desired location in the domain hierarchy. You can also add objects to group membership lists by dragging one or more objects (including other group objects) to the target group.

- **Efficient search capabilities.** Search functionality is object-oriented and provides an efficient search that minimizes network traffic associated with browsing objects. For more information, see Finding directory information.

- **Saved queries.** Save commonly used search parameters for reuse in Active Directory Users and Computers. For more information, see Using saved queries.

- **Active Directory command-line tools.** Run new directory service commands for administration scenarios. For more information, see Managing Active Directory from the command line.

- **InetOrgPerson class.** The **inetOrgPerson** class has been added to the base schema as a security principal and can be used in the same manner as the user class. The **userPassword** attribute can also be used to set the account password. For more information, see User and computer accounts.

- **Application directory partitions.** Configure the replication scope for application-specific data among domain controllers. For example, you can control the replication scope of Domain Name System (DNS) zone data stored in Active Directory so that only specific domain controllers in the forest participate in DNS zone replication. For more information, see Application directory partitions.

- **Ability to add additional domain controllers using backup media.** Reduce the time it takes to add an additional domain controller in an existing domain by using backup media. For more information, see Using the Active Directory Installation Wizard.

- **Universal group membership caching.** Prevent the need to locate a global catalog across a wide area network (WAN) when logging on by storing universal group membership information on an authenticating domain controller. For more information, see Global catalogs and sites.

- **Secure LDAP traffic.** Active Directory administrative tools sign and encrypt all Lightweight Directory Access Protocol (LDAP) traffic by default. Signing LDAP traffic guarantees that the packaged data comes from a known source and that it has not been tampered with. For more information, see Connecting to domain controllers running Windows 2000.

- **Active Directory quotas.** Quotas can be specified in Active Directory to control the number of objects a user, group, or computer can own in a given directory partition. Domain Administrators and Enterprise Administrators are exempt from quotas.

#### New domain- and forest-wide Active Directory features

New domain- or forest-wide Active Directory features can be enabled only when all domain controllers in a domain or forest are running Windows Server 2003 and the domain functionality or forest functionality has been set to Windows Server 2003. For more information about domain and forest functionality settings, see Domain and forest functionality.

The following list summarizes the domain- and forest-wide Active Directory features that can be enabled when either a domain or forest functional level has been raised to Windows Server 2003.

- **Domain controller rename tool.** Rename domain controllers without first demoting them. For more information, see Renaming domain controllers.

- **Domain rename.** Rename any Windows Server 2003 domain. You can change the NetBIOS name or DNS name of any child, parent, tree, or forest root domain. For more information, see Renaming domains.

- **Different location option for user and computer accounts.** You can now redirect the default location for user accounts and computer accounts that are created by the following application programming interfaces (APIs): NetUserAdd, NetGroupAdd, and NetJoinDomain. You can redirect the location of the accounts from the Users and Computers containers to organizational units (OUs) where Group Policy settings can be applied. For more information, see Redirect the Users and Computers Containers.

- **Forest trusts.** Create a forest trust to extend two-way transitivity beyond the scope of a single forest to a second forest. For more information, see Forest trusts.

- **Forest restructuring.** Move existing domains to other locations in the domain hierarchy. For more information, see Renaming domains.

- **Defunct schema objects.** Deactivate unnecessary classes or attributes from the schema. For more information, see Deactivating a class or attribute.

- **Dynamic auxiliary classes.** Provides support for dynamically linking auxiliary classes to individual objects, and not just to entire classes of objects. In addition, auxiliary classes that have been attached to an object instance can subsequently be removed from the instance.

- **Global catalog replication improvements.** Preserves the synchronization state of the global catalog when an administrative action results in an extension of the partial attribute set. This minimizes the replication traffic as a result of a partial attribute set extension by only transmitting attributes that were added. For more information, see Global catalog replication.

- **Replication enhancements.** Linked-value replication allows individual group members to be replicated across the network instead of treating the entire group membership as a single unit of replication. For more information about linked-value replication, see How replication works. In addition, new spanning tree algorithms make replication more efficient, as well as more scalable across a larger number of domains and sites in both Windows 2000 and Windows Server 2003 forests. For more information, see Replication overview.

- **User access control to resources between domains or forests.** Block users in a domain or forest from accessing resources in another domain or forest, and then allow selective access by setting the Allow to authenticate access control entry (ACE) on a local resource for the user or group object. For more information, see Accessing resources across domains or Accessing resources across forests.

# Security information for Active Directory

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for Active Directory**

Active Directory® provides a secure directory environment for your organization using built-in logon authentication and user authorization, which are core features of the Local Security Authority (LSA). Logon authentication and user authorization are available by default and provide immediate protection for network access and network resources.

For information about additional security tools and features that you can use to further secure Active Directory, see Securing Active Directory and Active Directory Best practices.

**Protecting access to the network**

Active Directory requires confirmation of the identity of a user before allowing access to the network, a process known as authentication. Users only need to provide a single sign-on to the domain (or to trusted domains) to gain access to the network. Once Active Directory confirms the identity of the user, the LSA on the authenticating domain controller generates an access token that determines what level of access that user has on network resources. For more information about the authentication process, see Access control in Active Directory and Certificates and Authentication.

Active Directory supports a number of secure Internet-standard protocols and authentication mechanisms used to prove identity upon logon, including Kerberos V5, X.509 v3 certificates, smart cards, public key infrastructure (PKI) and Lightweight Directory Access Protocol (LDAP) using Secure Sockets Layer (SSL).

Authentication between domains occurs through trusts. A trust is a relationship established between two or more domains to allow users in one domain to be authenticated by a domain controller in another domain.

Trust relationships can be transitive or nontransitive but must always be present in order for users in one domain to access shared resources in another domain. For more information, see Trusts.

In addition to securing network access through authentication, Active Directory helps to protect shared resources by facilitating user authorization. Once a user logon has been authenticated by Active Directory, the user rights assigned to the user through security groups and the permissions assigned on the shared resource will determine if the user will be authorized to access that resource. This authorization process protects shared resources from unauthorized access and permits access to only authorized users or groups.

For more information about user rights and security groups, see Group types. For more information about the user rights assigned to default groups, see Default groups. For more information about authorization, see "Designing an Authorization Strategy" at the Microsoft Windows Resource Kits Web site.

For more information about authentication, see "Logon and Authentication" at the Microsoft Windows Resource Kits Web site. For more information about authorization and access control, see "Authorization and Access Control" at the Microsoft Windows Resource Kits Web site.

# Understanding Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Active Directory**
Active Directory is an implementation of Internet standard directory and naming protocols. It uses a database engine for transactional support and supports a variety of application programming interface standards.

This section covers:

- Securing Active Directory
- Access control in Active Directory
- Active Directory naming
- Directory data store
- Directory access protocol
- User and computer accounts
- Object names
- Organizational units
- Active Directory server roles
- Active Directory clients
- Understanding Domains and Forests
- Understanding Groups
- Understanding Trusts
- Understanding Sites and Replication
- Understanding the Global Catalog
- Interoperating with DNS and Group Policy
- Understanding Schema

# Securing Active Directory

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing Active Directory**
Active Directory provides a secure directory environment for your organization using built-in logon authentication and user authorization. To further secure Active Directory once it has been deployed, consider the following precautions and recommendations.

For general security information about Active Directory, see Security information for Active Directory.

For more information about authentication, see "Logon and Authentication" at the Microsoft Windows Resource Kits Web Site. For more information about authorization, see "Authorization and Access Control" at the Microsoft Windows Resource Kits Web Site.

**Important**

- Physical access to a domain controller can provide a malicious user unauthorized access to encrypted passwords. Therefore, it is recommended that all domain controllers be locked in a secured room with limited public access. In addition, you should limit membership in the Enterprise Admins, Domain Admins, Account Operators, Server Operators, Print Operators, and Backup Operators groups to trusted personnel in your organization. For more information about domain controllers and groups, see Domain controllers and Default groups.

| Use strong encryption techniques to secure account password information on local computers, member servers, or domain controllers. | Syskey<br><br>See The system key utility. |

# Access control in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Access control in Active Directory**
Administrators can use access control to manage user access to shared resources for security purposes. In Active Directory, access control is administered at the object level by setting different levels of access, or permissions, to objects, such as Full Control, Write, Read, or No Access. Access control in Active Directory defines how different users can use Active Directory objects. By default, permissions on objects in Active Directory are set to the most secure setting.

The elements that define access control permissions on Active Directory objects include security descriptors, object inheritance, and user authentication.

**Security descriptors**
Access control permissions are assigned to shared objects and Active Directory objects to control how different users can use each object. A shared object, or shared resource, is an object that is intended to be used over a network by one or more users and includes files, printers, folders, and services. Both shared objects and Active Directory objects store access control permissions in security descriptors.

A security descriptor contains two access control lists (ACLs) used to assign and track security information for each object: the discretionary access control list (DACL) and the system access control list (SACL).

- **Discretionary access control lists (DACLs).** DACLs identify the users and groups that are assigned or denied access permissions on an object. If a DACL does not explicitly identify a user, or any groups that a user is a member of, the user will be denied access to that object. By default, a DACL is controlled by the owner of an object or the person who created the object, and it contains access control entries (ACEs) that determine user access to the object.

- **System access control lists (SACLs).** SACLs identify the users and groups that you want to audit when they successfully access or fail to access an object. Auditing is used to monitor events related to system or network security, to identify security breaches, and to determine the extent and location of any damage. By default, a SACL is controlled by the owner of an object or the person who created the object. A SACL contains access control entries (ACEs) that determine whether to record a successful or failed attempt by a user to access a object using a given permission, for example, Full Control and Read.

  For more information about auditing, see Auditing settings on objects.

To view DACLs and SACLs on Active Directory objects using Active Directory Users and Computers, on the **View** menu, click **Advanced Features** to access the **Security** tab for each object. For more information, see Assign, change, or remove permissions on Active Directory objects or attributes. You can also use the DSACLS support tool to manage access control lists in Active Directory. For more information, see Active Directory support tools.

By default, DACLs and SACLs are associated with every Active Directory object, which reduces attacks to your network by malicious users or any accidental mistakes made by domain users. However, if a malicious user obtains a user name and password of any account with administrative credentials to Active Directory, your forest will be vulnerable to attack. For this reason, consider renaming or disabling the default administrator account and following the best practices as described in Active Directory Best practices.

**Object inheritance**
By default, Active Directory objects inherit ACEs from the security descriptor located in their parent container object. Inheritance enables the access control information defined at a container object in Active Directory to apply to the security descriptors of any subordinate objects, including other containers and their objects. This eliminates the need to apply permissions each time a child object is created. If necessary, you can change the inherited permissions. However, as a best practice, avoid changing the default permissions or inheritance settings on Active Directory objects. For more information, see Best practices for assigning permissions on Active Directory objects and Changing inherited permissions.

**User authentication**
Active Directory also authenticates and authorizes users, groups, and computers to access objects on the network. The Local Security Authority (LSA) is the security subsystem responsible for all interactive user authentication and authorization services on a local computer. The LSA is also used to process authentication requests made through the Kerberos V5 protocol or NTLM

protocol in Active Directory. For more information about Kerberos authentication, see Kerberos V5 authentication. For more information about NTLM authentication, see NTLM authentication.

Once the identity of a user has been confirmed in Active Directory, the LSA on the authenticating domain controller generates a user access token and associates a security ID (SID) with the user.

- **Access token.** When a user is authenticated, LSA creates a security access token for that user. An access token contains the user's name, the groups to which that user belongs, a SID for the user, and all of the SIDs for the groups to which the user belongs. If you add a user to a group after the user access token has been issued, the user must log off and log on again before the access token will be updated.

- **Security ID (SID).** Active Directory automatically assigns SIDs to security principal objects at the time they are created. Security principals are accounts in Active Directory that can be assigned permissions such as computer, group, or user accounts. Once a SID is issued to the authenticated user, it is attached to the access token of the user.

The information in the access token is used to determine a user's level of access to objects whenever the user attempts to access them. The SIDs in the access token are compared with the list of SIDs that make up the DACL for the object to ensure that the user has sufficient permission to access the object. This is because the access control process identifies user accounts by SID rather than by name.

**Important**

- When a domain controller provides an access token to a user, the access token only contains information about membership in domain local groups if the domain local groups are local to the domain controller's domain. For domain directory objects replicated in the global catalog, this fact requires certain security considerations. For more information, see Global catalog replication.

For more information about authentication, see "Logon and Authentication" at the Microsoft Windows Resource Kits Web site.

For more information about access control and permissions, see Access control overview. For more information about authorization and access control, see "Authorization and Access Control" at the Microsoft Windows Resource Kits Web site.

For information about additional security measures that can be implemented to protect Active Directory, see Securing Active Directory and Security information for Active Directory.

# Active Directory naming

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory naming**
Active Directory domain names are usually the full Domain Name System (DNS) name of the domain. However, for backward compatibility, each domain also has a pre-Windows 2000 name for use by computers running pre-Windows 2000 operating systems. The pre-Windows 2000 domain name can be used to log on to a Windows Server 2003 domain from computers running pre-Windows 2000 operating systems using the *DomainName\UserName* format. This same format can also be used to log on to a Windows Server 2003 domain from computers running Windows 2000, Windows XP, or servers running Windows Server 2003. Users can also log on to computers running Windows 2000, Windows XP, or servers running Windows Server 2003 using the user principal name (UPN) associated with their user account.

**User accounts**
In Active Directory, each user account has a user logon name, a pre-Windows 2000 user logon name (security account manager account name), and a UPN suffix. The administrator enters the user logon name and selects the UPN suffix when creating the user account. Active Directory suggests a pre-Windows 2000 user logon name using the first 20 bytes of the user logon name. Administrators can change the pre-Windows 2000 logon name at any time.

In Active Directory, each user account has a UPN based on IETF RFC 822, *Standard for the Format of ARPA Internet Text Messages*. The UPN is composed of the user logon name and the UPN suffix joined by the @ sign.

**Note**

- Do not add the @ sign to the user logon name or to the UPN suffix. Active Directory automatically adds it when it creates the UPN. A UPN that contains more than one @ sign is invalid.

**Important**

- Windows NT 4.0 and earlier domains allowed the use of a period (.) at the end of a user logon name as long as the user logon name did not consist solely of period characters. Windows Server 2003 domains do not allow the use of a period or multiple periods at the end of a user logon name.

The second part of the UPN, the UPN suffix, identifies the domain in which the user account is located. This UPN suffix can be the DNS domain name, the DNS name of any domain in the forest, or it can be an alternative name created by an administrator and used just for log on purposes. This alternative UPN suffix does not need to be a valid DNS name.

In Active Directory, the default UPN suffix is the DNS name of the domain in which user account created. In most cases, this is the domain name registered as the enterprise domain on the Internet. Using alternative domain names as the UPN suffix can provide additional logon security and simplify the names used to log on to another domain in the forest.

For example, if your organization uses a deep domain tree, organized by department and region, domain names can get quite long. The default user UPN for a user in that domain might be *sales.westcoast.microsoft.com*. The logon name for a user in that domain would be *user@sales.westcoast.microsoft.com*. Creating a UPN suffix of "microsoft" would allow that same user to log on using the much simpler logon name of *user@microsoft*. For more information about user accounts, see User and computer accounts and Object names.

You can add or remove UPN suffixes using Active Directory Domains and Trusts. For more information, see Add user principal name suffixes.

**Computer accounts**
Each computer account created in Active Directory has a relative distinguished name, a pre-Windows 2000 computer name (security account manager account name), a primary DNS suffix, a DNS host name, and a service principal name (SPN). The administrator enters the computer name when creating the computer account. This computer name is used as the Lightweight Directory Access Protocol (LDAP) relative distinguished name.

Active Directory suggests the pre-Windows 2000 name using the first 15 bytes of the relative distinguished name. The administrator can change the pre-Windows 2000 name at any time.

The DNS name for a host is called a full computer name and is a DNS fully qualified domain name (FQDN). The full computer

name is a concatenation of the computer name (the first 15 bytes of the SAM account name of the computer account without the "$" character) and the primary DNS suffix (the DNS domain name of the domain in which the computer account exists). It is listed on the **Computer Name** tab in System Properties in Control Panel.

By default, the primary DNS suffix portion of the FQDN for a computer must be the same as the name of the Active Directory domain where the computer is located. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by creating the msDS-AllowedDNSSuffixes attribute in the domain object container. This attribute is created and managed by the domain administrator using Active Directory Service Interfaces (ADSI) or the Lightweight Directory Access Protocol (LDAP).

For more information, see Object names and User and computer accounts.

The service principal name (SPN) is a multivalue attribute. It is usually built from the DNS name of the host. The SPN is used in the process of mutual authentication between the client and the server hosting a particular service. The client finds a computer account based on the SPN of the service to which it is trying to connect. The SPN can be modified by members of the Domain Admins group.

# Directory data store

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Directory data store**

The Active Directory directory service uses a data store for all directory information. This data store is often referred to as the directory. The directory contains information about objects such as users, groups, computers, domains, organizational units, and security policies. This information can be published for use by users and administrators.

The directory is stored on domain controllers and can be accessed by network applications or services. A domain can have one or more domain controllers. Each domain controller has a copy of the directory for the entire domain in which it is located. Changes made to the directory on one domain controller are replicated to other domain controllers in the domain, domain tree, or forest. Active Directory uses four distinct directory partition types to store and copy different types of data. Directory partitions contain domain, configuration, schema, and application data. This storage and replication design provides directory information to users and administrators throughout the domain.

Directory data is stored in the Ntds.dit file on the domain controller. It is recommended that you store this file on an NTFS partition. For more information about the tool used to manage the Active Directory database and log files, see **Files** in Ntdsutil. Private data is stored securely, and public directory data is stored on a shared system volume where it can be replicated to other domain controllers in the domain. For more information about replication, see Replication overview.

Directory data replicated between domain controllers includes the following:

- **Domain data**

  The domain data holds information about objects within a domain. This is information such as e-mail contacts, user and computer account attributes, and published resources that are of interest to administrators and users.

  For example, when a user account is added to your network, a user account object and attribute data are stored in the domain data. When changes to your organization's directory objects occur, such as object creation, deletion, or attribute modification, this data is stored in the domain data.

- **Configuration data**

  The configuration data describes the topology of the directory. This configuration data includes a list of all domains, trees, and forests and the locations of the domain controllers and global catalogs.

- **Schema data**

  The schema is the formal definition of all object and attribute data that can be stored in the directory. Domain controllers running Windows Server 2003 include a default schema that defines many object types, such as user and computer accounts, groups, domains, organizational units, and security policies. Administrators and programmers can extend the schema by defining new object types and attributes or by adding new attributes for existing objects. Schema objects are protected by access control lists, ensuring that only authorized users can alter the schema.

  For more information, see Schema.

- **Application data**

  Data stored in the application directory partition is intended to satisfy cases where information needs to be replicated but not necessarily on a global scale. Application directory partitions are not part of the directory data store by default; they must be created, configured, and managed by the administrator.

  For more information, see Application directory partitions.

**Note**

- If a domain controller is also a global catalog, it stores a subset of the directory data for all other domains in the forest.

For more information about domain controllers, see Domain controllers. For more information about the global catalog, see The role of the global catalog.

**Quotas and directory partitions**

Quotas, a new feature with domain controllers running Windows Server 2003 , determine the number of objects that can be owned in a given directory partition by a security principal. (The owner of an object is usually, but not always, the creator of the object.) Quotas can help prevent the denial of service that can occur if a security principal accidentally, or intentionally, creates objects until the affected domain controller runs out of storage space.

Quotas are specified and administered for each directory partition separately. The schema partition, however, has no quotas. On a given directory partition, you can assign quotas for any security principal, including users, inetOrgPersons, computers, and groups. Members of the Domain Admins and Enterprise Admins groups are exempt from quotas. In some cases, a security principal might be covered by multiple quotas. For example, a user might be assigned an individual quota, and also belong to one or more security groups that also have quotas assigned to them. In such cases, the effective quota is the maximum of the quotas assigned to the security principal.

If a security principal is not assigned a quota either directly or through a group membership, a default quota on the partition governs the security principal. If you do not explicitly set the default quota on a given partition, the default quota of that partition is unlimited (ie, there is no limit).

Tombstone objects owned by a security principal are also counted as part of the quota consumption of that security principal. For each partition, you can specify a tombstone quota factor to determine the percentage weight given to a tombstone object in quota accounting. For example, if the tombstone quota factor for a given partition is set to 25 (or 25%), then a tombstone object on the partition is counted as 0.25 (or ¼) of a normal object. If a quota of 100 is specified for a user on this partition, then the user could own a maximum of 100 normal objects, or a maximum 400 tombstone objects. The default tombstone quota factor for each partition is initially set to 100 (or 100%), meaning that normal and tombstones objects are weighted equally.

The following example illustrates how quotas can be used. Consider the domain "sales.northwindtraders.com." Because this domain supports a lot of printing activity, the domain contains several print servers that each support 1,000 or more print queues. Initially, the default quota of the sales.northwindtraders.com domain partition is set to unlimited. To help control the number of objects created and owned, the administrator specifies a default quota of 500. Now, each user can own a maximum of 500 objects on the partition. Because print queues are directory objects that are created and owned by the respective print servers, the new default quota of 500 limits each print server to 500 print queues. To remove this constraint, the administrator creates a group called "Print Servers" and adds the computer account of each print server to the group. The administrator then specifies a quota of 2,000 for the Print Servers group. Now, each print server can support its original number of print queues, while the default quota continues to prevent excess object creation by all other security principals.

Only domain controllers running Windows Server 2003 can enforce quotas. Quotas are enforced only on originating directory operations; quotas are not enforced on replicated operations. In order for quotas to be fully effective for any given directory partition, all domain controllers that contain a writable copy of that partition must be running Windows Server 2003 . Therefore, for quotas to be effective on a domain directory partition, all domain controllers in that domain must be running Windows Server 2003 . For quotas to be effective on the configuration partition, all domain controllers in the forest must by running Windows Server 2003 .

For information about creating, modifying, and querying quotas, default quotas, and tombstone quota factors, see Dsadd, Dsmod, and Dsquery.

# Directory access protocol

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Directory access protocol**
Active Directory clients must communicate with domain controllers when logging on to the network and when searching for shared resources. Access to domain controllers and global catalogs is performed using the Lightweight Directory Access Protocol (LDAP).

**Lightweight Directory Access Protocol**
LDAP is a communication protocol designed for use on TCP/IP networks. LDAP defines how a directory client can access a directory server and how the client can perform directory operations and share directory data. LDAP standards are established by working groups of the Internet Engineering Task Force (IETF). Active Directory implements the LDAP attribute draft specifications and the IETF standards for LDAP versions 2 and 3.

As its name implies, LDAP is designed as an efficient method for accessing directory services without the complexity of other directory service protocols. Because LDAP defines what operations can be performed to query and modify information in a directory and how information in a directory can be securely accessed, you can use LDAP to find or enumerate directory objects and to query or administer Active Directory.

**LDAP and interoperability**
LDAP is an open Internet standard. By using LDAP, Active Directory enables interoperability with other vendor directory services. Active Directory support for LDAP includes an LDAP provider object as part of Active Directory Service Interfaces (ADSI). ADSI supports the C-binding application programming interfaces for LDAP. Other directory service applications can be easily modified to access information in Active Directory by using ADSI and LDAP.

For more information about LDAP, see the Internet Engineering Task Force at the Internet Engineering Task Force Web site.

### Note

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# User and computer accounts

Updated: July 26, 2013

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**User and computer accounts**

Active Directory user accounts and computer accounts represent a physical entity such as a computer or person. User accounts can also be used as dedicated service accounts for some applications.

User accounts and computer accounts (as well as groups) are also referred to as security principals. Security principals are directory objects that are automatically assigned security IDs (SIDs), which can be used to access domain resources. A user or computer account is used to:

- Authenticate the identity of a user or computer.

  A user account enables a user to log on to computers and domains with an identity that can be authenticated by the domain. For information about authentication, see Access control in Active Directory. Each user who logs on to the network should have his or her own unique user account and password. To maximize security, you should avoid multiple users sharing one account.

- Authorize or deny access to domain resources.

  Once the user has been authenticated, the user is authorized or denied access to domain resources based on the explicit permissions assigned to that user on the resource. For more information, see Security information for Active Directory.

- Administer other security principals.

  Active Directory creates a foreign security principal object in the local domain to represent each security principal from a trusted external domain. For more information about foreign security principals, see When to create an external trust.

- Audit actions performed using the user or computer account.

  Auditing can help you monitor account security. For more information about auditing, see Auditing overview.

**User accounts**

The Users container located in Active Directory Users and Computers displays the three built-in user accounts: Administrator, Guest, and HelpAssistant. These built-in user accounts are created automatically when you create the domain.

Each built-in account has a different combination of rights and permissions. The Administrator account has the most extensive rights and permissions over the domain, while the Guest account has limited rights and permissions. The table below describes each default user account on domain controllers running Windows Server 2003.

| Default user account | Description |
|---|---|

| | |
|---|---|
| Administrator account | The Administrator account has full control of the domain and can assign user rights and access control permissions to domain users as necessary. This account must be used only for tasks that require administrative credentials. It is recommended that you set up this account with a strong password. For more information, see Strong passwords. For additional security considerations for accounts with administrative credentials, see Active Directory Best practices.<br><br>The Administrator account is a default member of the Administrators, Domain Admins, Enterprise Admins, Group Policy Creator Owners, and Schema Admins groups in Active Directory. The Administrator account can never be deleted or removed from the Administrators group, but it can be renamed or disabled. Because the Administrator account is known to exist on many versions of Windows, renaming or disabling this account will make it more difficult for malicious users to try and gain access to it. For more information about how to rename or disable a user account, see Rename a local user account or Disable or enable a user account.<br><br>The Administrator account is the first account created when you set up a new domain using the Active Directory Installation Wizard.<br><br>• **Important** When the Administrator account is disabled, it can still be used to gain access to a domain controller using Safe Mode. |
| Guest account | The Guest account is used by people who do not have an actual account in the domain. A user whose account is disabled (but not deleted) can also use the Guest account. The Guest account does not require a password.<br><br>You can set rights and permissions for the Guest account just like any user account. By default, the Guest account is a member of the built-in Guests group and the Domain Guests global group, which allows a user to log on to a domain. The Guest account is disabled by default, and it is recommended that it stay disabled. |
| HelpAssistant account (installed with a Remote Assistance session) | The primary account used to establish a Remote Assistance session. This account is created automatically when you request a Remote Assistance session and has limited access to the computer. The HelpAssistant account is managed by the Remote Desktop Help Session Manager service and will be automatically deleted if no Remote Assistance requests are pending. For more information about Remote Assistance, see Administering Remote Assistance. |

**Securing user accounts**

If built-in account rights and permissions are not modified or disabled by a network administrator, they could be used by a malicious user (or service) to illegally log on to a domain using the Administrator or Guest identity. A good security practice for protecting these accounts is to rename or disable them. Because it retains its security ID (SID), a renamed user account retains all its other properties, such as its description, password, group memberships, user profile, account information, and any assigned permissions and user rights.

To obtain the security of user authentication and authorization, create an individual user account for each user who will participate on your network by using Active Directory Users and Computers. Each user account (including the Administrator and Guest account) can then be added to a group to control the rights and permissions assigned to the account. Using accounts and groups that are appropriate for your network ensures that users logging on to a network can be identified and can access only the permitted resources.

You can help defend your domain from attackers by requiring strong passwords and implementing an account lockout policy. Strong passwords reduce the risk of intelligent guessing and dictionary attacks on passwords. For more information, see Strong passwords and Password Best practices for passwords.

An account lockout policy decreases the possibility of an attacker compromising your domain through repeated logon attempts. This is because an account lockout policy determines how many failed logon attempts a user account can have before it is disabled. For more information, see Apply or modify account lockout policy.

For more information about securing user accounts, see Securing Active Directory.

**Account options**

Each Active Directory user account has a number of account options that determine how someone logging on with that particular user account is authenticated on the network. You can use the following options to configure password settings and security-specific information for user accounts:

| Account option | Description |
| --- | --- |
| User must change password at next logon | Forces a user to change their password the next time the user logs on to the network. Use this option when you want to ensure that the user will be the only person to know their password. |
| User cannot change password | Prevents a user from changing their password. Use this option when you want to maintain control over a user account, such as for a guest or temporary account. |
| Password never expires | Prevents a user password from expiring. It is recommended that Service accounts should have this option enabled and should use strong passwords. For more information about strong passwords, see Strong passwords. |
| Store passwords using reversible encryption | Allows a user to log on to a Windows network from Apple computers. If a user is not logging on from an Apple computer, this option should not be used. For more information, see Store passwords using reversible encryption. |
| Account is disabled | Prevents a user from logging on with the selected account. Many administrators use disabled accounts as templates for common user accounts. For more information, see Disable or enable a user account. |
| Smart card is required for interactive logon | Requires that a user possess a smart card to log on to the network interactively. The user must also have a smart card reader attached to their computer and a valid personal identification number (PIN) for the smart card. When this option is selected, the password for the user account is automatically set to a random and complex value. For more information about smart cards, see Logging on to a computer with a smart card and Authentication process. |
| Account is trusted for delegation | Allows a service running under this account to perform operations on behalf of other user accounts on the network. A service running under a user account (otherwise known as a service account) that is trusted for delegation can impersonate a client to gain access to resources on the computer where the service is running or on other computers. In a forest set to the Windows Server 2003 functional level, this setting is found on the **Delegation** tab, and is only available for accounts that have been assigned service principal names (SPNs), as set using the **setspn** command from the Windows Support Tools. This is a security-sensitive capability and should be cautiously assigned. For more information, see Allow a user to be trusted for delegation and Delegating authentication.<br><br>This option is only available on domain controllers running Windows Server 2003 where the domain functionality is set to Windows 2000 mixed or Windows 2000 native. On domain controllers running Windows Server 2003 where the domain functional level is set to Windows Server 2003, the **Delegation** tab is used to configure delegation settings. The **Delegation** tab only appears for accounts which have an assigned SPN. For more information about domain functionality, see Domain and forest functionality. For more information about configuring delegation in a Windows Server 2003 domain, see Allow a user to be trusted for delegation. |
| Account is sensitive and cannot be delegated | Allows control over a user account, such as for a guest or temporary account. This option can be used if this account cannot be assigned for delegation by another account. |
| Use DES encryption types for this account | Provides support for the Data Encryption Standard (DES). DES supports multiple levels of encryption, including MPPE Standard (40-bit), MPPE Standard (56-bit), MPPE Strong (128-bit), IPSec DES (40-bit), IPSec 56-bit DES, and IPSec Triple DES (3DES). For more information about DES encryption, see Data encryption. |
| Do not require Kerberos preauthentication | Provides support for alternate implementations of the Kerberos protocol. Domain controllers running Windows 2000 or Windows Server 2003 can use other mechanisms to synchronize time. Because preauthentication provides additional security, use caution when enabling this option. For more information about Kerberos, see Kerberos V5 authentication. |

**InetOrgPerson accounts**

Active Directory provides support for the InetOrgPerson object class and its associated attributes defined in RFC 2798. The InetOrgPerson object class is used in several non-Microsoft LDAP and X.500 directory services to represent people within an organization.

Support for InetOrgPerson makes migrations from other LDAP directories to Active Directory more efficient. The InetOrgPerson object is derived from the user class and can be used as a security principal just like the user class. For

information about creating an inetOrgPerson user account, see Create a new user account.

When the domain functional level has been set to Windows Server 2003, you can set the userPassword attribute on InetOrgPerson and user objects as being the effective password just like you can with the *unicodePwd* attribute.

**Computer accounts**

Every computer running Windows NT, Windows 2000, Windows XP, or a server running Windows Server 2003 that joins a domain has a computer account. Similar to user accounts, computer accounts provide a means for authenticating and auditing computer access to the network and to domain resources. Each computer account must be unique.

**Note** Computers running Windows 95 and Windows 98 do not have advanced security features and are not assigned computer accounts.

User and computer accounts can be added, disabled, reset, and deleted using Active Directory Users and Computers. A computer account can also be created when you join a computer to a domain. For more information about user and computer accounts, see Active Directory naming and Object names.

When the domain functional level has been set to Windows Server 2003, a new lastLogonTimestamp attribute is used to track the last logon time of a user or computer account. This attribute is replicated within the domain and can provide you with important information regarding the history of a user or computer.

# Object names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Object names**

Every object in Active Directory is an instance of a class defined in the schema. Each class has attributes that ensure:

- Unique identification of each object (instance of a class) in a directory data store
- Backward compatibility with security IDs used in Windows NT 4.0 and earlier
- Compatibility with LDAP standards for directory object names

For more information about schema, classes, and attributes, see Schema.

Each object in Active Directory can be referenced by several different names. Active Directory creates a relative distinguished name and a canonical name for each object based upon information that was provided when the object was created or modified. Each object can also be referenced by its distinguished name, which is derived from the relative distinguished name of the object and all of its parent container objects.

- The LDAP relative distinguished name uniquely identifies the object within its parent container. For example, the LDAP relative distinguished name of a computer named my computer is CN=mycomputer. Relative distinguished names must be unique in that users cannot have the same name within an organizational unit.
- The LDAP distinguished name is globally unique. For example, the distinguished name of a computer named mycomputer in the MyOrganizationalUnit organizational unit in the microsoft.com domain is CN=mycomputer, OU=MyOrganizationalUnit, DC=microsoft, DC=com.
- The canonical name is constructed the same way as the distinguished name, but it is represented using a different notation. The canonical name of the computer in the previous example would be Microsoft.com/MyOrganizationalUnit/mycomputer.

Security principal objects are Active Directory objects that are assigned security IDs (SIDs) and can be used to log on to the network and can be assigned access to domain resources. An administrator needs to provide names for security principal objects (user accounts, computer accounts, and groups) that are unique within a domain.

Consider what occurs when a new user account is added to your directory. You provide a name the user must use to log on to the network, the name of the domain that contains the user account, and other descriptive data, such as first name, last name, telephone number and so on (called attributes). All this information is recorded in the directory.

The names of security principal objects can contain all Unicode characters except the special LDAP characters defined in RFC 2253. This list of special characters includes: a leading space; a trailing space; and any of the following characters: # , + " \ < > ;

Security principal names must conform to the following guidelines:

| Type of account name | Maximum size | Special limitations |
|---|---|---|
| User account | Computers running Windows Server 2003 and Windows 2000 can use a user principal name (UPN) for a user account. Computers running Windows NT 4.0 and earlier are limited to 20 characters or 20 bytes depending upon the character set; individual characters may require more than one byte. | A user account cannot consist solely of periods (.) or spaces, or end in a period. Any leading periods or spaces are cropped. Use of the @ symbol is not supported with the logon format for Windows NT 4.0 and earlier, which is *DomainName**UserName*. Windows 2000 logon names are unique to the domain and Windows Server 2003 logon names are unique within the forest. |

| | | |
|---|---|---|
| Computer account | NetBIOS = 15 characters, or 15 bytes depending upon the character set; individual characters may require more than one byte.<br><br>DNS = 63 characters or 63 bytes depending upon the character set and 255 characters for a fully qualified domain name (FQDN) individual characters may require more than one byte. | A computer account cannot consist solely of numbers, periods (.), or spaces. Any leading periods or spaces are cropped. |
| Group account | 63 characters, or 63 bytes depending upon the character set; individual characters may require more than one byte. | A group account cannot consist solely of numbers, periods (.), or spaces. Any leading periods or spaces are cropped. |

**Note**

- If the administrator changes the default security settings, then it is possible to use computer names containing more than 15 characters. For more information, see Active Directory naming.

From the information provided by the person who creates the security principal object, Active Directory generates a security ID (SID), and a globally unique ID used to identify the security principal. Active Directory also creates an LDAP relative distinguished name, based on the security principal name. An LDAP distinguished name and a canonical name are derived from the relative distinguished name and the names of the domain and container contexts in which the security principal object is created.

If your organization has several domains, it is possible to use the same user name or computer name in different domains. The SID, globally unique ID, LDAP distinguished name, and canonical name generated by Active Directory will uniquely identify each user, computer, or group in the forest. If the security principal object is renamed or moved to a different domain, the SID, LDAP relative distinguished name, LDAP distinguished name, and canonical name will change, but the globally unique ID generated by Active Directory will not change.

Security principal objects, such as user accounts, may be renamed, moved, or contained within a nested domain hierarchy. To reduce the effect of renaming, moving, or assigning user account names within a nested domain hierarchy, Active Directory provides a method for simplifying user logon names. For information about user logon names, see Active Directory naming and Add user principal name suffixes, and User and computer accounts.

# Organizational units

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Organizational units**

A particularly useful type of directory object contained within domains is the organizational unit. Organizational units are Active Directory containers into which you can place users, groups, computers, and other organizational units. An organizational unit cannot contain objects from other domains.

An organizational unit is the smallest scope or unit to which you can assign Group Policy settings or delegate administrative authority. Using organizational units, you can create containers within a domain that represent the hierarchical, logical structures within your organization. You can then manage the configuration and use of accounts and resources based on your organizational model. For more information about Group Policy settings, see Group Policy (pre-GPMC).

As shown in the figure, organizational units can contain other organizational units. A hierarchy of containers can be extended as necessary to model your organization's hierarchy within a domain. Using organizational units will help you minimize the number of domains required for your network.

You can use organizational units to create an administrative model that can be scaled to any size. A user can have administrative authority for all organizational units in a domain or for a single organizational unit. An administrator of an organizational unit does not need to have administrative authority for any other organizational units in the domain. For more information about delegating administrative authority, see Delegating administration.

# Active Directory server roles

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory server roles**
Computers that function as servers within a domain can have one of two roles: member server or domain controller. A server that is not in a domain is a stand-alone server.

**Member servers**
A member server is a computer that:

- Runs an operating system in the Windows 2000 Server family or the Windows Server 2003 family.
- Belongs to a domain.
- Is not a domain controller.

A member server does not process account logons, participate in Active Directory replication, or store domain security policy information.

Member servers typically function as the following types of servers: file servers, application servers, database servers, Web servers, certificate servers, firewalls, and remote access servers. For more information about server roles, see Server roles.

The following security-related features are common to all member servers:

- Member servers adhere to Group Policy settings that are defined for the site, domain, or organizational unit.
- Access control for resources that are available on a member server.
- Member server users have assigned user rights.
- Member servers contain a local security account database, the Security Accounts Manager (SAM).

**Domain controllers**
A domain controller is a computer that:

- Runs an operating system in the Windows 2000 Server family or the Windows Server 2003 family.
- Uses Active Directory to store a read-write copy of the domain database, participate in multimaster replication, and authenticate users.

Domain controllers store directory data and manage communication between users and domains, including user logon processes, authentication, and directory searches. Domain controllers synchronize directory data using multimaster replication, ensuring consistency of information over time. For more information about multimaster replication, see Replication overview.

Active Directory supports multimaster replication of directory data between all domain controllers in a domain; however, multimaster replication is not appropriate for some directory data replication. In this case, a domain controller, called the operations master, will process data. In an Active Directory forest, there are at least five different operations master roles that are assigned to one or more domain controllers. For more information about operations masters, see Operations master roles.

As the needs of your computing environment change, you might want to change the role of a server. Using the Active Directory Installation Wizard, you can install Active Directory on a member server to make it a domain controller, or you can remove Active Directory from a domain controller to make it a member server. For more information about domain controllers, see Domain controllers.

**Note**

- You cannot install Active Directory on a computer running Windows Server 2003, Web Edition, but you can join the

computer to an Active Directory domain as a member server. For more information about Windows Server 2003, Web Edition, see Overview of Windows Server 2003, Web Edition.

# Active Directory clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory clients**
With the Active Directory client, many of the Active Directory features available on Windows 2000 Professional or Windows XP Professional are available to computers running Windows 95, Windows 98, and Windows NT 4.0.

- **Site awareness**

  You can log on to the domain controller that is closest to the client in the network. For more information, see Locating a domain controller.

- **Active Directory Service Interfaces (ADSI)**

  You can use scripting to Active Directory. ADSI also provides a common programming API to Active Directory programmers.

- **Distributed File System (DFS)**

  You can access DFS shared resources on servers running Windows 2000 and Windows Server 2003.

- **NTLM version 2 authentication**

  You can use the improved authentication features in NTLM version 2.

  For more information about enabling NTML version 2, see article Q239869, "How to Enable NTLM 2 Authentication," in the Microsoft Knowledge Base.

- **Active Directory Windows Address Book (WAB) property pages**

  You can change properties, such as phone number and address, on user object pages.

- **Active Directory search capability**

  From the **Start** button, you can locate printers and people in a Windows 2000 Server or Windows Server 2003 domain.

  For information about publishing printers in Active Directory, see article Q234619, "Publishing a Printer in Windows 2000 Active Directory," in the Microsoft Knowledge Base.

Windows 2000 Professional and Windows XP Professional provide functionality that the Active Directory client on Windows 95, Windows 98, and Windows NT 4.0 does not, including Kerberos V5 support; Group Policy or IntelliMirror support; and service principal name (SPN), or mutual authentication. You can take advantage of these additional features by upgrading to Windows 2000 Professional or Windows XP Professional.

To install the Active Directory client, see the Active Directory client page at the Microsoft Web site.

# Understanding Domains and Forests

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Domains and Forests**

This section covers:

- Domain controllers
- Renaming domain controllers
- Connecting to domain controllers running Windows 2000
- Domains
- Renaming domains
- Domain and forest functionality
- Raising domain and forest functional levels
- Application directory partitions
- Application directory partitions and domain controller demotion
- Managing application directory partitions
- Operations master roles
- Transferring operations master roles
- Responding to operations master failures

# Domain controllers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Domain controllers**
When you create the first domain controller in your organization, you are also creating the first domain, the first forest, the first site, and installing Active Directory. Domain controllers running Windows Server 2003 store directory data and manage user and domain interactions, including user logon processes, authentication, and directory searches. Domain controllers are created by using the Active Directory Installation Wizard. For more information, see Using the Active Directory Installation Wizard.

**Note**

- You cannot install Active Directory on a computer running Windows Server 2003, Web Edition, but you can join the computer to an Active Directory domain as a member server. For more information about Windows Server 2003, Web Edition, see Overview of Windows Server 2003, Web Edition.

When using domain controllers in your organization, you will want to think about how many domain controllers you'll need, the physical security of those domain controllers, a plan for backing up the domain data, and upgrading domain controllers.

**Determining the number of domain controllers you need**
A small organization using a single local area network (LAN) might need only one domain with two domain controllers for high availability and fault tolerance. A larger organization with many network locations will need one or more domain controllers in each site to provide high availability and fault tolerance.

If your network is divided into sites, it is often good practice to put at least one domain controller in each site to enhance network performance. When users log on to the network, a domain controller must be contacted as part of the logon process. If clients must connect to a domain controller located in a different site, the logon process can take a long time. For more information, see Replication between sites.

By creating a domain controller in each site, user logons are processed more efficiently within the site. For information about how to create additional domain controllers, see Create an additional domain controller.

To optimize network traffic, you can also configure domain controllers to receive directory replication updates only during off-peak hours. For information about how to schedule site replication, see Configure site link replication availability.

The best network performance is available when the domain controller at a site is also a global catalog. This way, the server can fulfill queries about objects in the entire forest. However, enabling many domain controllers as global catalogs can increase the replication traffic on your network. For more information about the global catalog, see The role of the global catalog. For more information about adding global catalogs to sites, see Global catalogs and sites.

In domains with more than one domain controller, do not enable the domain controller holding the infrastructure master role as a global catalog. For more information, see Operations master roles.

**Physical security**
Physical access to a domain controller can provide a malicious user unauthorized access to encrypted passwords. For this reason, it is recommended that all domain controllers in your organization be locked in a secured room with limited public access. You can use additional security measures such as Syskey for extra protection on domain controllers. For more information about Syskey, see The system key utility.

**Backing up domain controllers**
You can back up domain directory partition data and data from other directory partitions by using Backup, which is included with the Windows Server 2003 family, from any domain controller in a domain. By using the backup tool on a domain controller, you can:

- Back up Active Directory while the domain controller is online.
- Back up Active Directory using batch file commands.
- Back up Active Directory to removable media, an available network drive, or a file.

- Back up other system and data files.

When you use the backup tool on a domain controller it will automatically back up all of the system components and all of the distributed services upon which Active Directory is dependent. This dependent data, which includes Active Directory, is known collectively as the System State data.

On a domain controller running Windows Server 2003, the System State data consists of the system startup files; the system registry; the class registration database of COM+ (an extension to the Component Object Model); the SYSVOL directory; Certificate Services database (if installed); Domain Name System (if installed); Cluster service (if installed); and Active Directory. It is recommended that you regularly back up System State data.

For general information about the System State, see System State data. For more information about how to back up the System State, see Back up System State data. For more information about how to restore a System State backup, see Restore System State data.

You can install Active Directory on a server running Windows Server 2003 by using a restored backup taken from a domain controller running Windows Server 2003. For more information, see Creating an additional domain controller.

**Upgrading domain controllers**

On domain controllers running Windows NT 4.0, you will first need to upgrade the primary domain controller (PDC) to successfully upgrade the domain. Once the PDC has been upgraded, you can upgrade the backup domain controllers (BDCs). For more information, see Upgrading from a Windows NT domain.

If you currently have a Windows 2000 forest that does not have any domain controllers running Windows Server 2003, you will need to prepare the forest and the target domain before you can upgrade domain controllers running Windows 2000. For more information, see Upgrading from a Windows 2000 domain.

# Renaming domain controllers

Updated: April 23, 2013

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Renaming domain controllers**

The ability to rename domain controllers running Windows Server 2003 provides you with the flexibility to make changes in a Windows Server 2003 domain whenever the need arises. Rename a domain controller to:

- Restructure your network for organizational and business needs.
- Make management and administrative control easier.

When you rename a domain controller, you must ensure that there will be no interruption in the ability of clients to locate or authenticate to the renamed domain controller, except when the domain controller is restarted. The recommended practice for renaming a domain controller without interruption to clients is to use the Netdom tool. To rename a domain controller using the Netdom tool, the domain functional level must be set to Windows Server 2003. For more information about renaming a domain controller, see Rename a domain controller.

The **System Properties** dialog box can also be used to rename a domain controller, and it does not require the functional level to be raised to Windows Server 2003. Using this dialog box may result in a service interruption to clients. For more information about functional levels, see Domain and forest functionality.

The new name of the domain controller is automatically updated to Domain Name System (DNS) and Active Directory. Once the new name propagates to DNS and Active Directory, clients are then capable of locating and authenticating to the renamed domain controller. DNS and Active Directory replication latency may delay client ability to locate or authenticate to the renamed domain controller. The length of time this takes depends on specifics of your network and the replication topology of your particular organization.

During replication latency, clients may not be able to access the newly renamed domain controller. This might be acceptable for clients that try to locate and authenticate to a particular domain controller since other domain controllers should be available to process the authentication request.

| **Note** |
| --- |
| The corresponding nTFRSMember or msDFSR-Member object is not renamed automatically, but the reference attributes are correctly set so SYSVOL replication is not impacted. The only potential problem with not renaming these objects is that if another domain controller is created at a later date with the same NetBIOS name of the old domain controller, then a conflict can occur as described in KB article 316826. After the rename is complete, you can optionally rename the nTFRSMember or msDFSR-Member object as part of cleanup. |

# Connecting to domain controllers running Windows 2000

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connecting to domain controllers running Windows 2000**
When you need to connect to a domain controller running Windows 2000 from a domain controller running Windows Server 2003, a number of Active Directory administrative tools are available, such as Active Directory Domains and Trusts.

The following Windows Server 2003 Active Directory administrative tools will sign and encrypt all LDAP traffic by default:

- Active Directory Users and Computers
- Active Directory Sites and Services
- Active Directory Domains and Trusts
- Active Directory Schema
- ADSI Edit
- Dsrm.exe
- Dsmove.exe
- Dsadd.exe
- Dsmod.exe
- Dsget.exe
- Dsquery.exe

Signing LDAP traffic guarantees that the packaged data comes from a known source and that it has not been tampered with. The Active Directory administrative tools in Windows 2000 do not sign and encrypt all LDAP traffic by default. In order to maintain a secure network, it is strongly recommended that you upgrade all domain controllers running Windows 2000 to Service Pack 3 or later.

You can use the corresponding Active Directory administrative tools in Windows 2000 to manage Windows 2000 domain controllers that do not have the Windows 2000 Server Service Pack 3 or later installed. However, traffic is not signed and encrypted by LDAP on domain controllers running Windows 2000.

Although it is not recommended, you can disable encrypted and signed LDAP traffic used with Active Directory administrative tools on a server running Windows Server 2003 or on a computer running Windows XP Professional that has the Windows Server 2003 Administration Tools Pack installed. For more information, see Disable signed or encrypted LDAP traffic.

# Domains

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Domains**

Domains are units of replication. All of the domain controllers in a particular domain can receive changes and replicate those changes to all other domain controllers in the domain. Each domain in Active Directory is identified by a Domain Name System (DNS) domain name and requires one or more domain controllers. If your network requires more than one domain, you can easily create multiple domains.

One or more domains that share a common schema and global catalog are referred to as a forest. The first domain in a forest is referred to as the forest root domain. For more information about forests, see Creating a new forest. If multiple domains in the forest have contiguous DNS domain names, then the structure is referred to as a domain tree. For more information, see Active Directory naming and Creating a new domain tree.

A single domain can span multiple physical locations or sites and can contain millions of objects. Site structure and domain structure are separate and flexible. A single domain can span multiple geographical sites, and a single site can include users and computers belonging to multiple domains. For more information, see Sites overview.

A domain provides several benefits:

- **Organizing objects.**

  You do not need to create separate domains merely to reflect your company's organization of divisions and departments. Within a domain, you can use organizational units for this purpose. Using organizational units helps you manage the accounts and resources in the domain. You can then assign Group Policy settings and place users, groups, and computers into the organizational units. Using a single domain greatly simplifies administrative overhead. For more information, see Organizational units.

- **Publishing resources and information about domain objects.**

  A domain stores only the information about objects located in that domain, so by creating multiple domains, you are partitioning or segmenting the directory to better serve a disparate user base. When using multiple domains, you can scale the Active Directory directory service to accommodate your administrative and directory publishing requirements. For more information, Publishing resources.

- **Applying a Group Policy object to the domain consolidates resource and security management.**

  A domain defines a scope or unit of policy. A Group Policy object (GPO) establishes how domain resources can be accessed, configured, and used. These policies are applied only within the domain and not across domains. For more information about applying GPOs, see Group Policy (pre-GPMC).

- **Delegating authority eliminates the need for a number of administrators with broad administrative authority.**

  Using delegated authority in conjunction with Group Policy objects and group memberships enables you to assign an administrator rights and permissions to manage objects in an entire domain or in one or more organizational units within the domain. For more information about delegating administrative control, see Delegating administration.

- **Security policies and settings (such as user rights and password policies) do not cross from one domain to another.**

  Each domain has its own security policies and trust relationships with other domains. However, the forest is the final security boundary. For more information, see Creating a new forest.

- **Each domain stores only the information about the objects located in that domain.**

  By partitioning the directory this way, Active Directory can scale to very large numbers of objects.

**Creating a domain**
You create a domain by creating the first domain controller for a domain. To do this, install Active Directory on a member server running Windows Server 2003 by using the Active Directory Installation Wizard. The wizard uses the information that you provide to create the domain controller and create the domain within the existing domain structure of your organization. Depending on the existing domain structure, the new domain could be the first domain in a new forest, the first domain in a new domain tree, or a child domain of an existing domain tree. For more information, see Creating a new forest, Creating a new domain tree, and Creating a new child domain.

A domain controller provides the Active Directory directory service to network users and computers, stores directory data, and manages user and domain interactions, including user logon processes, authentication, and directory searches. Every domain must contain at least one domain controller. For more information, see Domain controllers.

After you create the first domain controller for a domain, you can create additional domain controllers in an existing domain for fault tolerance and high availability of the directory. For more information, see Creating an additional domain controller.

**Planning for multiple domains**
Some reasons to create more than one domain are:

- Different password requirements between departments or divisions
- Massive numbers of objects
- Decentralized network administration
- More control of replication

Although using a single domain for an entire network has several advantages, to meet additional scalability, security, or replication requirements you may consider creating one or more domains for your organization. Understanding how directory data is replicated between domain controllers will help you plan the number of domains needed by your organization. For more information about replication, see How replication works.

**Removing a domain**
In order to remove a domain, you must first remove Active Directory from all of the domain controllers associated with that domain. Once Active Directory has been removed from the last domain controller the domain will be removed from the forest and all of the information in that domain will be deleted. A domain can only be removed from the forest if it has no child domains. If this is the last domain in the forest, removing this domain will also delete the forest.

For more information about how to remove a domain, see Remove a domain.

### Caution

- Removing a domain will result in the permanent loss of amy data contained in that domain. This includes all user, group, and computer accounts.

Before removing Active Directory from a domain controller, you should first remove any application directory partitions from that domain controller. For more information, see Application directory partitions and Create or delete an application directory partition.

**Trust relationships between domains**
Trust relationships are automatically created between adjacent domains (parent and child domains) when a domain is created in Active Directory. In a forest, a trust relationship is automatically created between the forest root domain and any tree root domains or child domains that are subordinate to the forest root domain. Because these trust relationships are transitive, users and computers can be authenticated between any domains in the forest. For more information about trust relationships, see Trust transitivity.

When upgrading a Windows NT domain to a Windows Server 2003 domain, the existing one-way trust relationship between that domain and any other domains remains intact. This includes all trusts with other Windows NT domains. If you are creating a new Windows Server 2003 domain and want trust relationships with any Windows NT domains, you must create external trusts with those domains. For more information about external trusts, see When to create an external trust.

# Renaming domains

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Renaming domains**

The ability to rename a domain provides you with the flexibility to make important changes to your forest structure and namespace as the needs of your organization change. Renaming domains can accommodate acquisitions, mergers, name changes, or reorganizations. Domain rename allows you to:

- Change the Domain Name System (DNS) and NetBIOS names of any domain in the forest (including the forest root domain).
- Restructure the position of any domain in the forest (except the forest root domain).

You can only rename domains in a forest where all of the domain controllers are running Windows Server 2003 and the forest functional level has been raised to Windows Server 2003. For more information, see Domain and forest functionality.

**Forest restructuring**

Using domain rename, you can also restructure the hierarchy of domains in your forest so that a domain residing in one domain tree can be moved to another domain tree. Restructuring a forest allows you to move a domain anywhere within the forest in which it resides (except the forest root domain). This includes the ability to move a domain so that it becomes the root of its own domain tree.

You can use the domain rename utility (Rendom.exe) to rename or restructure a domain. A domain rename will affect every domain controller in your forest and is a multistep process that requires a detailed understanding of the operation. For more information about this process and to download the Rendom.exe tool, see the Windows Server 2003 Active Directory Domain Rename Tools page at the Microsoft Web site.

# Domain and forest functionality

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Domain and forest functionality**

Domain and forest functionality, introduced in Windows Server 2003 Active Directory, provides a way to enable domain- or forest-wide Active Directory features within your network environment. Different levels of domain functionality and forest functionality are available depending on your environment.

If all domain controllers in your domain or forest are running Windows Server 2003 and the functional level is set to Windows Server 2003, all domain- and forest-wide features are available. When Windows NT 4.0 or Windows 2000 domain controllers are included in your domain or forest with domain controllers running Windows Server 2003, Active Directory features are limited. For more information about how to enable domain- or forest-wide features, see Raising domain and forest functional levels.

The concept of enabling additional functionality in Active Directory exists in Windows 2000 with mixed and native modes. Mixed-mode domains can contain Windows NT 4.0 backup domain controllers and cannot use Universal security groups, group nesting, and security ID (SID) history capabilities. When the domain is set to native mode, Universal security groups, group nesting, and SID history capabilities are available. Domain controllers running Windows 2000 Server are not aware of domain and forest functionality.

**Domain functionality**

Domain functionality enables features that will affect the entire domain and that domain only. Four *domain* functional levels are available: Windows 2000 mixed (default), Windows 2000 native, Windows Server 2003 interim, and Windows Server 2003. By default, domains operate at the Windows 2000 mixed functional level.

The following table lists the domain functional levels and their corresponding supported domain controllers.

| Domain functional level | Domain controllers supported |
|---|---|
| **Windows 2000 mixed** (default) | Windows NT 4.0<br>Windows 2000<br>Windows Server 2003 family |
| **Windows 2000 native** | Windows 2000<br>Windows Server 2003 family |
| **Windows Server 2003 interim** | Windows NT 4.0<br>Windows Server 2003 family |
| **Windows Server 2003** | Windows Server 2003 family |

Once the domain functional level has been raised, domain controllers running earlier operating systems cannot be introduced into the domain. For example, if you raise the domain functional level to Windows Server 2003, domain controllers running Windows 2000 Server cannot be added to that domain.

The following table describes the domain-wide features that are enabled for three of the domain functional levels. For information about the Windows Server 2003 interim functional level, see Upgrading from a Windows NT domain.

| Domain feature | Windows 2000 mixed | Windows 2000 native | Windows Server 2003 |
|---|---|---|---|
| **Domain controller rename tool**<br>For more information, see Renaming domain controllers. | Disabled | Disabled | Enabled |

| | | | |
|---|---|---|---|
| **Different location option for user and computer accounts**<br><br>For more information about how to redirect the default location for user and computer accounts, see Redirect the Users and Computers Containers. | Disabled | Disabled | Enabled |
| **Update logon timestamp**<br><br>For more information about the lastLogonTimestamp attribute, see User and computer accounts. | Disabled | Disabled | Enabled |
| **User password on InetOrgPerson object**<br><br>For more information about InetOrgPerson objects, see User and computer accounts. | Disabled | Disabled | Enabled |
| **Universal Groups**<br><br>For more information, see Group types and Group scope. | Enabled for distribution groups.<br><br>Disabled for security groups. | Enabled<br><br>Allows both security and distribution groups. | Enabled<br><br>Allows both security and distribution groups. |
| **Group Nesting**<br><br>For more information, see Nesting groups. | Enabled for distribution groups.<br><br>Disabled for security groups, except for domain local security groups that can have global groups as members. | Enabled<br><br>Allows full group nesting. | Enabled<br><br>Allows full group nesting. |
| **Converting Groups**<br><br>For more information, see Converting groups. | Disabled<br><br>No group conversions allowed. | Enabled<br><br>Allows conversion between security groups and distribution groups. | Enabled<br><br>Allows conversion between security groups and distribution groups. |
| **SID history** | Disabled | Enabled<br><br>Allows migration of security principals from one domain to another. | Enabled<br><br>Allows migration of security principals from one domain to another. |

**Forest functionality**

Forest functionality enables features across all the domains within your forest. Three forest functional levels are available: Windows 2000 (default), Windows Server 2003 interim, and Windows Server 2003 . By default, forests operate at the Windows 2000 functional level. You can raise the forest functional level to Windows Server 2003 .

The following table lists the forest functional levels and their corresponding supported domain controllers:

| Forest functional level | Domain controllers supported |
|---|---|
| **Windows 2000** (default) | Windows NT 4.0<br><br>Windows 2000<br><br>Windows Server 2003 family |
| **Windows Server 2003 interim** | Windows NT 4.0<br><br>Windows Server 2003 family |

| | |
|---|---|
| **Windows Server 2003** | Windows Server 2003 family |

Once the forest functional level has been raised, domain controllers running earlier operating systems cannot be introduced into the forest. For example, if you raise the forest functional level to Windows Server 2003, domain controllers running Windows 2000 Server cannot be added to the forest.

If you are upgrading your first Windows NT 4.0 domain so that it becomes the first domain in a new Windows Server 2003 forest, you can set the domain functional level to Windows Server 2003 interim. For more information, see Upgrading from a Windows NT domain.

The following table describes the forest-wide features that are enabled for the Windows 2000 and Windows Server 2003 forest functional levels.

| Forest feature | Windows 2000 | Windows Server 2003 |
|---|---|---|
| **Global catalog replication improvements**<br><br>For more information, see Global catalog replication. | Enabled if both replication partners are running Windows Server 2003.<br><br>Otherwise, disabled. | Enabled |
| **Defunct schema objects**<br><br>For more information, see Deactivating a class or attribute. | Disabled | Enabled |
| **Forest trusts**<br><br>For more information, see Forest trusts. | Disabled | Enabled |
| **Linked value replication**<br><br>For more information, see How replication works. | Disabled | Enabled |
| **Domain rename**<br><br>For more information, see Renaming domains. | Disabled | Enabled |
| **Improved Active Directory replication algorithms**<br><br>For more information, see Replication overview. | Disabled | Enabled |
| **Dynamic auxiliary classes**.<br><br>For more information, see New features for Active Directory. | Disabled | Enabled |
| **InetOrgPerson objectClass change**<br><br>For more information about InetOrgPerson objects, see User and computer accounts. | Disabled | Enabled |

# Raising domain and forest functional levels

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Raising domain and forest functional levels**

When Active Directory is installed on a server running Windows Server 2003, a set of basic Active Directory features is enabled by default. For more information about the new default features, see New features for Active Directory.

In addition to the basic Active Directory features on individual domain controllers, there are new domain- and forest-wide Active Directory features available when *all* domain controllers in a domain or forest are running Windows Server 2003.

To enable the new domain-wide features, all domain controllers in the domain must be running Windows Server 2003, and the domain functional level must be raised to Windows Server 2003 . For information about raising the domain functional level, see Raise the domain functional level.

To enable new forest-wide features, all domain controllers in the forest must be running Windows Server 2003, and the forest functional level must be raised to Windows Server 2003 . Before raising the *forest* functional level to Windows Server 2003 , verify that all *domains* in the forest are set to the *domain* functional level of Windows 2000 native or Windows Server 2003 . Note that domains that are set to the domain functional level of Windows 2000 native will automatically be raised to Windows Server 2003 at the same time the *forest* functional level is raised to Windows Server 2003 . For information about raising the forest functional level, see Raise the forest functional level.

# Application directory partitions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Application directory partitions**
An application directory partition is a directory partition that is replicated only to specific domain controllers. A domain controller that participates in the replication of a particular application directory partition hosts a replica of that partition. Only domain controllers running Windows Server 2003 can host a replica of an application directory partition.

Applications and services can use application directory partitions to store application-specific data. Application directory partitions can contain any type of object, except security principals. TAPI is an example of a service that stores its application-specific data in an application directory partition.

Application directory partitions are usually created by the applications that will use them to store and replicate data. For testing and troubleshooting purposes, members of the Enterprise Admins group can manually create or manage application directory partitions using the Ntdsutil command-line tool.

One of the benefits of an application directory partition is that, for redundancy, availability, or fault tolerance, the data in it can be replicated to different domain controllers in a forest. The data can be replicated to a specific domain controller or any set of domain controllers anywhere in the forest. This differs from a domain directory partition in which data is replicated to all domain controllers in that domain. Storing application data in an application directory partition instead of in a domain directory partition may reduce replication traffic because the application data is only replicated to specific domain controllers. Some applications may use application directory partitions to replicate data only to servers where the data will be locally useful.

Another benefit of application directory partitions is that applications or services that use Lightweight Directory Access Protocol (LDAP) can continue using it to access and store their application data in Active Directory. For more information, see Managing application directory partitions.

**Application directory partition naming**
An application directory partition is part of the overall forest namespace just like a domain directory partition. It follows the same Domain Name System (DNS) and distinguished names naming conventions as a domain directory partition. An application directory partition can appear anywhere in the forest namespace that a domain directory partition can appear.

There are three possible application directory partition placements within your forest namespace:

- A child of a domain directory partition.
- A child of an application directory partition.
- A new tree in the forest.

If you created an application directory partition called *example1* as a child of the microsoft.com domain, the DNS name of the application directory partition would be example1.microsoft.com. The distinguished name of the application directory partition would be dc=example1, dc=microsoft, dc=com.

If you then created an application directory partition called *example2* as a child of example1.microsoft.com, the DNS name of the application directory partition would be example2.example1.microsoft.com and the distinguished name would be dc=example2, dc=example1, dc=microsoft, dc=com.

If the domain microsoft.com was the root of the only domain tree in your forest, and you created an application directory partition with the DNS name of *example1* and the distinguished name of dc=example1, this application directory partition is not in the same tree as the microsoft.com domain. This application directory partition would be the root of a new tree in the forest.

Domain directory partitions cannot be children of an application directory partition. For example, if you created an application directory partition with the DNS name of example1.microsoft.com, you could not create a domain with the DNS name of domain.example1.microsoft.com.

**Application directory partition replication**
The Knowledge Consistency Checker (KCC) automatically generates and maintains the replication topology for all application

directory partitions in the enterprise. When an application directory partition has replicas in more than one site, those replicas follow the same intersite replication schedule as the domain directory partition.

### Notes

- Objects stored in an application directory partition are never replicated to the global catalog as read-only replicas. Any domain controller running Windows Server 2003 can hold a replica, including global catalogs.

- Additionally, if an application requests data through the global catalog port, that query will not return any objects from an application directory partition, even if the computer hosting the application directory partition is also hosting the global catalog. This is done so that LDAP queries to different global catalogs will not return inconsistent results because the application directory partition is replicated to only one of the global catalogs.

**Security descriptor reference domain**

Every container and object on the network has a set of access control information attached to it. Known as a security descriptor, this information controls the type of access allowed by users, groups, and computers. If the object or container is not assigned a security descriptor by the application or service that created it, then it is assigned the default security descriptor for that object class as defined in the schema. This default security descriptor is ambiguous in that it may assign members of the Domain Admins group read permissions to the object, but it does not specify to what domain the domain administrators belong. When this object is created in a domain naming partition, that domain naming partition is used to specify which Domain Admins group actually is assigned read permission. For example, if the object is created in mydomain.microsoft.com then members of the mydomain Domain Admins group would be assigned read permission.

When an object is created in an application directory partition, the definition of the default security descriptor is difficult because an application directory partition can have replicas on different domain controllers belonging to different domains. Because of this potential ambiguity, a default security descriptor reference domain is assigned when the application directory partition is created.

The default security descriptor reference domain defines what domain name to use when an object in the application directory partition needs to define a domain value for the default security descriptor. The default security descriptor reference domain is assigned at the time of creation.

If the application directory partition is a child of a domain directory partition, by default, the parent domain directory partition becomes the security descriptor reference domain. If the application directory partition is a child object of another application directory partition, the security descriptor reference domain of the parent application directory partition becomes the reference domain of the new, child, application directory partition. If the new application directory partition is created as the root of a new tree, then the forest root domain is used as the default security descriptor reference domain.

You can manually specify a security reference domain using Ntdsutil. However, if you plan to change the default security descriptor reference domain of a particular application directory partition, you should do so before creating the first instance of that partition. To do this, you must prepare the cross-reference object and change the default security reference domain before completing the application directory partition creation process. For information about precreating the cross-reference object, see Prepare a cross-reference object. For information about changing the default security reference domain, see Set an application directory partition reference domain.

# Application directory partitions and domain controller demotion

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Application directory partitions and domain controller demotion**
If a domain controller holds a replica of an application directory partition, then you must remove the domain controller from the replica set of the application directory partition or delete the application directory partition before you can demote the domain controller.

If a domain controller holds the *last* replica of a particular application directory partition, then you must delete the application directory partition before you can demote the domain controller.

The Active Directory Installation Wizard will not remove a replica or delete an application directory partition programmatically. You must decide when it is safe to delete the last replica of a particular partition.

Before deleting the last replica of an application directory partition, identify the applications that use the application directory partition, determine if it is safe to delete the last replica, identify the partition deletion tool provided by the application, and then remove the application directory partition by using the tool provided or by using the Ntdsutil command-line tool.

**Identify the applications that use the application directory partition**
To determine what application directory partitions are hosted on a computer, refer to the list on the first page of the Active Directory Installation Wizard. If the list does not provide enough information to identify the programs using a particular application directory partition, you may be able to identify them in one of the following ways:

- Speak to a member of the Enterprise Admins group.
- Consult the network change control records for your organization.
- Use LDP or ADSI Edit to view the data contained in the partition. For more information about these tools, see the Active Directory Programmer's Guide at the Microsoft Web site.

**Determine if it is safe to delete the last replica**
Removing the last replica of an application directory partition will result in the permanent loss of any data contained in the partition. If you have identified the applications using the application directory partition, consult the documentation provided with those applications to determine if there is any reason to keep the data. If the applications that use the application directory partition are out of service, it is probably safe to remove the partition.

If it is not safe to delete the last replica, or if you cannot determine whether or not it is safe, and you must demote the domain controller holding the last replica of a particular application directory partition, follow these steps: Add a replica of the partition on another domain controller, force the replication of the contents of the application directory partition to the domain controller holding the new replica, and then remove the replica of the partition on the domain controller to be demoted. For more information, see Add or remove an application directory partition replica.

**Identify the partition deletion tool provided by the application**
Most applications that create application directory partitions provide a utility to remove the partitions. When possible, always delete an application directory partition using the utility provided. For example, to delete a TAPI partition, use the Tapicfg.exe command-line tool. For more information about TAPI and removing TAPI application directory partitions, see Telephony.

**Remove the application directory partition using the tool provided or use Ntdsutil**
Refer to the application's documentation for information about removing application directory partitions that were created and used by that application.

### Caution

- If possible, use the application's tool for managing its application directory partitions. The application may keep other data in addition to Active Directory managed data for the application directory partitions. By using Ntdsutil, the two sets of data could cause a conflict.

If you cannot identify the application that created the application directory partition, or if your application does not provide a means to delete application directory partitions that it created, you can use the Ntdsutil command-line tool. To do this, see Create or delete an application directory partition.

For information about demoting a domain controller, see Demote a domain controller. For general information about application directory partitions, see Application directory partitions.

# Managing application directory partitions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing application directory partitions**
You can use the following tools to create, delete, or manage application directory partitions.

- application-specific tools from the application vendor
- Ntdsutil command-line tool
- LDP
- Active Directory Service Interfaces (ADSI)

For information about creating and managing application directory partitions with ADSI, see Active Directory Service Interfaces (ADSI) at the Microsoft Web site. For information about LDP, see Administration tools for the Active Directory schema.

For information about the Ntdsutil command-line tool, see Ntdsutil.

The following provides information about using Ntdsutil to create and manage application directory partitions.

**Creating an application directory partition**
When you create an application directory partition, you are creating the first instance of this partition. You can create an application directory partition by using the *create nc* option in the **domain management** menu of Ntdsutil. When creating an application directory partition using LDP or ADSI, provide a description in the description attribute of the domain DNS object that indicates the specific application that will use the partition. For example, if the application directory partition will be used to store data for a Microsoft accounting program, the description could be Microsoft accounting application. Ntdsutil does not facilitate the creation of a description. For more information, see Create or delete an application directory partition.

**Deleting an application directory partition**
When you delete an application directory partition, you are removing all replicas of that partition from your forest. You can delete an application directory partition by using the *delete nc* command in the **domain management** menu of Ntdsutil. The deletion process will need to replicate to all domain controllers that contain a replica of the application directory partition before the deletion process is complete. Any data that is contained in the application directory partition will be lost.

The Active Directory Promotion Wizard (Dcpromo) cannot demote a domain controller if that domain controller holds a copy of an application directory partition. For more information, see Create or delete an application directory partition.

**Adding and removing a replica of an application directory partition**
An application directory partition replica is an instance of an partition on another domain controller. The information in the application directory partition is replicated between the domain controllers. Application directory partition replicas are created for either redundancy or data access purposes. You can add a replica of an application directory partition by using the *add nc replica* command in the **domain management** menu of Ntdsutil. You can remove an application directory partition replica by using the *delete nc replica* command in the **domain management** menu of Ntdsutil. For more information, see Add or remove an application directory partition replica.

**Setting application directory partition reference domain**
The security descriptor reference domain defines a domain name for the default security descriptor for objects in the application directory partition. By default, the security descriptor reference domain is the parent domain of the application directory partition. If the application directory partition is a child of another application directory partition, the default security descriptor reference domain is the security descriptor reference domain of the parent application directory partition. If the application directory partition has no parent, the forest root domain becomes the default security descriptor reference domain. You can use Ntdsutil to change the default security descriptor reference domain. For more information, see Set an application directory partition reference domain.

**Setting replication notification delays**
Changes made to a particular directory partition on a particular domain controller are replicated to the other domain controllers that contain that directory partition. The domain controller on which the change was made notifies its replication partners that it has a change. You can configure how long the domain controller will wait to send the change notification to its

first replication partner. You can also configure how long it waits to send the subsequent change notification to its remaining replication partners. These delays can be set for any directory partition (including domain directory partitions) on a particular domain controller. For more information, see Set a notification delay.

**Displaying application directory partition information**

Any domain controller that holds a replica of a particular directory partition (including application directory partitions) is said to be a member of the replica set for that directory partition. You can use Ntdsutil to list the domain controllers that are members of a particular replica set for an application directory partition. An addition of a domain controller to the replica set attribute on the cross-reference object does not create the replica, but it will display when the **list nc replica** command is used in Ntdsutil. The creation of the instance must replicate before the creation of the replica is complete. For more information, see Display application directory partition information.

**Delegating the creation of application directory partitions**

There are two things that happen when creating an application directory partition:

- Creation of the cross-reference object.
- Creation of the application directory partition root node.

Normally only members of the Enterprise Admins group can create an application directory partition. However, it is possible for a member of the Enterprise Admins group to prepare a cross-reference object for the application directory partition and to delegate the rest of the process to someone with more limited permissions.

The cross-reference object for an application directory partition holds several valuable pieces of information, including the domain controllers that are to have a replica of this partition and the security descriptor reference domain. The partition root node is the Active Directory object at the root of the partition

The Enterprise Admin can create the cross-reference object then delegate to a person or group with less permissions the right to create the application directory partition root node. Both creation of the cross-reference object and the application directory partition root node can be accomplished using Ntdsutil.

After using Ntdsutil to create the cross-reference object, the enterprise administrator must modify the cross-reference object's access control list to allow the delegated administrator to modify this cross-reference. This will allow the delegated administrator to create the application directory partition and modify the list of domain controllers that holds replicas of this application directory partition. The delegated administrator must use the names of the application directory partition and the domain controller name that were specified during the precreation process. For more information, see Prepare a cross-reference object.

For more information about application directory partitions, see Application directory partitions.

# Operations master roles

Updated: October 24, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2

**Operations master roles**
Active Directory supports multimaster replication of the directory data store between all domain controllers (DC) in the domain, so all domain controllers in a domain are essentially peers. However, some changes are impractical to perform in using multimaster replication, so, for each of these types of changes, one domain controller, called the *operations master*, accepts requests for such changes.

In every forest, there are at least five operations master roles that are assigned to one or more domain controllers. Forest-wide operations master roles must appear only once in every forest. Domain-wide operations master roles must appear once in every domain in the forest.

### Note

- The operations master roles are sometimes called flexible single master operations (FSMO) roles.

**Forest-wide operations master roles**
Every forest must have the following roles:

- Schema master
- Domain naming master

These roles must be unique in the forest. This means that throughout the entire forest there can be only one schema master and one domain naming master.

**Schema master**
The schema master domain controller controls all updates and modifications to the schema. To update the schema of a forest, you must have access to the schema master. There can be only one schema master in the entire forest.

**Domain naming master**
The domain controller holding the domain naming master role controls the addition or removal of domains in the forest. There can be only one domain naming master in the entire forest.

### Note

- Any domain controller running Windows Server 2003 can hold the role of the domain naming master. A domain controller running Windows 2000 Server that holds the role of domain naming master must also be enabled as a global catalog server.

**Domain-wide operations master roles**
Every domain in the forest must have the following roles:

- Relative ID (RID) master
- Primary domain controller (PDC) emulator master
- Infrastructure master

These roles must be unique in each domain. This means that each domain in the forest can have only one RID master, PDC emulator master, and infrastructure master.

**RID master**
The RID master allocates sequences of relative IDs (RIDs) to each of the various domain controllers in its domain. At any time,

there can be only one domain controller acting as the RID master in each domain in the forest.

Whenever a domain controller creates a user, group, or computer object, it assigns the object a unique security ID (SID). The SID consists of a *domain* SID, which is the same for all SIDs created in the domain, and a RID, which is unique for each SID created in the domain.

To move an object between domains (using Movetree.exe), you must initiate the move on the domain controller acting as the RID master of the domain that currently contains the object.

**PDC emulator master**
The PDC emulator master processes password changes from client computers and replicates these updates to all domain controllers throughout the domain. At any time, there can be only one domain controller acting as the PDC emulator master in each domain in the forest.

The PDC emulator role is used in the following ways:

- To provide consistent password experience for users across sites (can be turned off with AvoidPdcOnWan registry parameter) - The PDC emulator is used as a reference DC to double-check incorrect passwords and it also receives new password changes. When the PDC is reachable, users can use a new password immediately and consistently across the environment. For more information about AvoidPdcOnWan see, New Password Change and Conflict Resolution Functionality in Windows (http://go.microsoft.com/fwlink/?LinkId=202451)

- As a preferred point of administration for services (examples are Group Policy and Distributed File System, DFS) - For more information about DFS see, DFS Management (http://go.microsoft.com/fwlink/?LinkId=202456). For more information about DCs and Group Policy see, Specifying a Domain Controller for Editing Group Policy (http://go.microsoft.com/fwlink/?LinkId=202457).

- As a point of contact for applications hard-coded to the PDC (often written for Windows NT 4.0 and older domains) - The legacy API often used for this is NetGetDcName. It is strongly suggested to change applications to use the new API to locate DCs. DsGetDcName by default does not target the PDC, and has more options that allows you to pick the type of DC needed to perform the operation. For more information about locating DCs from applications see, DSGetDcName Function (http://go.microsoft.com/fwlink/?LinkId=202455).

- As a default time server for all other DCs in the domain - The time server configuration of a PDC requires manual consideration and should be reviewed when you change the owner of the PDC role.

The domain controller configured with the PDC emulator role supports two authentication protocols:

- The Kerberos V5 protocol

- The NTLM protocol

| **Note** |
| --- |
| For instructions on how to configure the PDC emulator to synchronize with an external time source, see Synchronize the Time Server for the Domain Controller with an External Source (http://go.microsoft.com/fwlink/?LinkId=122513). |

**Infrastructure master**
At any time, there can be only one domain controller acting as the infrastructure master in each domain. The infrastructure master is responsible for updating references from objects in its domain to objects in other domains. The infrastructure master compares its data with that of a global catalog. Global catalogs receive regular updates for objects in all domains through replication, so the global catalog data will always be up to date. If the infrastructure master finds data that is out of date, it requests the updated data from a global catalog. The infrastructure master then replicates that updated data to the other domain controllers in the domain.

**Important**

- Unless there is only one domain controller in the domain, the infrastructure master role should not be assigned to the domain controller that is hosting the global catalog. If the infrastructure master and global catalog are on the same domain controller, the infrastructure master will not function. The infrastructure master will never find data that is out of

date, so it will never replicate any changes to the other domain controllers in the domain.

In the case where all of the domain controllers in a domain are also hosting the global catalog, all of the domain controllers will have the current data and it does not matter which domain controller holds the infrastructure master role.

The infrastructure master is also responsible for updating the group-to-user references whenever the members of groups are renamed or changed. When you rename or move a member of a group (and that member resides in a different domain from the group), the group may temporarily appear not to contain that member. The infrastructure master of the group's domain is responsible for updating the group so it knows the new name or location of the member. This prevents the loss of group memberships associated with a user account when the user account is renamed or moved. The infrastructure master distributes the update via multimaster replication.

There is no compromise to security during the time between the member rename and the group update. Only an administrator looking at that particular group membership would notice the temporary inconsistency.

For information about transferring operations master roles, see Transferring operations master roles. For information about what to do when an operations master fails, see Responding to operations master failures.

# Transferring operations master roles

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Transferring operations master roles**

Transferring an operations master role means moving it from one domain controller to another with the cooperation of the original role holder. Depending upon the operations master role to be transferred, you perform the role transfer using one of the three Active Directory consoles in Microsoft Management Console (MMC).

| Role | Console in MMC |
|---|---|
| Schema master | Active Directory Schema |
| Domain naming master | Active Directory Domains and Trusts |
| RID master | Active Directory Users and Computers |
| PDC emulator master | Active Directory Users and Computers |
| Infrastructure master | Active Directory Users and Computers |

For general information about operations master roles, see Operations master roles.

**Note**

- The operations master roles are sometimes called flexible single master operations (FSMO) roles.

For procedures describing the transfer of operations master roles, see:

- Transfer the schema master role
- Transfer the domain naming master role
- Transfer the RID master role
- Transfer the PDC emulator role
- Transfer the infrastructure master role

# Responding to operations master failures

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2

**Responding to operations master failures**

Some of the operations master roles are crucial to the operation of your network. Others can be unavailable for quite some time before their absence becomes a problem. Generally, you will notice that a single master operations role holder is unavailable when you try to perform some function controlled by the particular operations master.

If an operations master is not available due to computer failure or network problems, you can seize the operations master role. This is also referred to as forcing the transfer of the operations master role. Do not seize the operations master role if you can transfer it instead. For more information, see Transferring operations master roles.

### Note

- The operations master roles are sometimes called flexible single master operations (FSMO) roles.

Before forcing the transfer, first determine the cause and expected duration of the computer or network failure. If the cause is a networking problem or a server failure that will be resolved soon, wait for the role holder to become available again. If the domain controller that currently holds the role has failed, you must determine if it can be recovered and brought back online.

In general, seizing an operations master role is a drastic step that should be considered only if the current operations master will never be available again. The decision depends upon the role and how long the particular role holder will be unavailable. The impact of various role holder failures is discussed in the following topics.

**Schema master failure**

Temporary loss of the schema master is not visible to network users. It will not be visible to network administrators either, unless they are trying to modify the schema or install an application that modifies the schema during installation.

If the schema master will be unavailable for an unacceptable length of time, you can seize the role to the standby operations master. However, seizing this role is a drastic step that you should take only when the failure of the schema master is permanent.

### Important

- A domain controller whose schema master role has been seized must *never* be brought back online.

For procedures on how to seize the schema master role, see Seize the schema master role.

**Domain naming master failure**

Temporary loss of the domain naming master is not visible to network users. It will not be visible to network administrators either, unless they are trying to add a domain to the forest or remove a domain from the forest.

If the domain naming master will be unavailable for an unacceptable length of time, you can seize the role to the standby operations master. However, seizing this role is a drastic step that you should take only when the failure of the domain naming master is permanent.

### Important

- A domain controller whose domain naming master role has been seized must *never* be brought back online.

For procedures on how to seize the domain naming master role, see Seize the domain naming master role.

**RID master failure**

Temporary loss of the RID master is not visible to network users. It will not be visible to network administrators either, unless they are creating objects and the domain in which they are creating the objects runs out of relative IDs (RIDs).

If the RID master will be unavailable for an unacceptable length of time, you can seize the role to the operations master. However, seizing this role is a drastic step that you should take only when the failure of the RID master is permanent.

**Important**

- A domain controller whose RID master role has been seized must *never* be brought back online.

For procedures on how to seize the RID master role, see Seize the RID master role.

**PDC emulator master failure**

The severity of a PDC outage depends on your Service Level Agreement (SLA) and the actual behavior and configuration of the environment. For example, inconsistent password change behavior may affect users beyond what your SLAs allow, or the lack of time synchronization may cause resource access failures.

Also, in smaller environments, it may happen that the PDC as the first server in the domain is the only DNS or Global Catalog Server, or is the only domain controller (DC) with a valid SYSVOL in case other DCs did not successfully initiate or maintain SYSVOL replication. The PDC role holder may also be the target for regular file server access. When this is done for folder redirection or logon script activities, it may also affect users when logging on and while they work.

Other than the conditions described above, there is no direct dependency of the domain members on the PDC role holder. However, you might be using applications that are coded to contact the PDC only. You should try to avoid having this single point of failure.

Often, these applications were written for Windows NT 3.x and 4.0 deployments where the PDC was the only writable DC. However, since Active Directory, all DCs except Read-Only DCs are writable. The DsGetDcName API allows you to pick the right type; similar options are available in AD API interfaces like ADSI (ADS_READONLY_SERVER) or the .NET runtime.

The loss of the primary domain controller (PDC) emulator master may affect network users. Therefore, when the PDC emulator master is not available, you may need to immediately seize the role.

For procedures on how to seize the PDC emulator role, see Seize the PDC emulator role.

**Infrastructure master failure**

Temporary loss of the infrastructure master is not visible to network users. It will not be visible to network administrators either, unless they have recently moved or renamed a large number of accounts.

If the infrastructure master will be unavailable for an unacceptable length of time, you can seize the role to a domain controller that is not a global catalog but is well connected to a global catalog (from any domain), ideally in the same site as the current global catalog. When the original infrastructure master is returned to service, you can transfer the role back to the original domain controller.

For procedures on how to seize the infrastructure master role, see Seize the infrastructure master role.

For general information about operations masters, see Operations master roles.

# Understanding Groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

- Group types
- Default groups
- Nesting groups
- Special identities
- Where groups can be created

# Groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Groups**

A group is a collection of user and computer accounts, contacts and other groups that can be managed as a single unit. Users and computers that belong to a particular group are referred to as group members.

Using groups can simplify administration by assigning a common set of permissions and rights to many accounts at once, rather than assigning permissions and rights to each account individually. For an overview of permissions and rights, see Access control overview.

Groups can be either directory-based or local to a particular computer. Groups in Active Directory are directory objects that reside within a domain and organizational unit container objects. Active Directory provides a set of default groups upon installation, and also allows the option to create groups. For more information, see Default groups.

Local groups, which exist on local computers and not in Active Directory, are discussed in Default local groups.

Groups in Active Directory allow you to:

- Simplify administration by assigning permissions on a shared resource to a group, rather than to individual users. This assigns the same access on the resource to all members of that group.
- Delegate administration by assigning user rights once to a group through Group Policy, and then adding necessary members to the group that you want to have the same rights as the group.
- Create e-mail distribution lists. For more information, see Group types.

Groups are characterized by their scope and their type. The scope of a group determines the extent to which the group is applied within a domain or forest. For information about group scope, see Group scope. The group type determines whether a group can be used to assign permissions from a shared resource (for security groups) or if a group can be used for e-mail distribution lists only (for distribution groups). For information about security groups and distribution groups, see Group types.

There are also groups for which you cannot modify or view the memberships. These groups are referred to as special identities and are used to represent different users at different times, depending on the circumstances. For example, the Everyone group represents all current network users, including guests and users from other domains. For more information, see Special identities.

# Group scope

Updated: October 1, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Group scope**

Any group, whether it is a security group or a distribution group, is characterized by a scope that identifies the extent to which the group is applied in the domain tree or forest. The boundary, or reach, of a group scope is also determined by the domain functional level setting of the domain in which it resides. There are three group scopes: universal, global, and domain local.

The following table describes the differences between the scopes of each group.

| Group scope | Group can include as members... | Group can be assigned permissions in... | Group scope can be converted to... |
|---|---|---|---|
| Universal | • Accounts from any domain within the forest in which this Universal Group resides<br>• Global groups from any domain within the forest in which this Universal Group resides<br>• Universal groups from any domain within the forest in which this Universal Group resides | Any domain or forest | • Domain local<br>• Global (as long as no other universal groups exist as members) |
| Global | • Accounts from the same domain as the parent global group<br>• Global groups from the same domain as the parent global group | Member permissions can be assigned in any domain | Universal (as long as it is not a member of any other global groups) |
| Domain local | • Accounts from any domain<br>• Global groups from any domain<br>• Universal groups from any domain<br>• Domain local groups but only from the same domain as the parent domain local group | Member permissions can be assigned only within the same domain as the parent domain local group | Universal (as long as no other domain local groups exist as members) |

**Note**

The information in this table implies that the domain functional level is set to either Windows 2000 native or Windows Server 2003. When the domain functional level is set to Windows 2000 mixed or Windows Server 2003 interim, security groups with universal scope cannot be created, although distribution groups with universal scope are still permitted.

**When to use groups with domain local scope**

Groups with domain local scope help you define and manage access to resources within a single domain. For example, to give five users access to a particular printer, you can add all five user accounts in the printer permissions list. If, however, you later want to give the five users access to a new printer, you must again specify all five accounts in the permissions list for the new

printer.

With a little planning, you can simplify this routine administrative task by creating a group with domain local scope and assigning it permission to access the printer. Put the five user accounts in a group with global scope, and then add this group to the group having domain local scope. When you want to give the five users access to a new printer, assign the group with domain local scope permission to access the new printer. All members of the group with global scope automatically receive access to the new printer.

**When to use groups with global scope**

Use groups with global scope to manage directory objects that require daily maintenance, such as user and computer accounts. Because groups with global scope are not replicated outside their own domain, you can change accounts in a group having global scope frequently without generating replication traffic to the global catalog. For more information about groups and replication, see How replication works.

Although rights and permissions assignments are valid only within the domain in which they are assigned, by applying groups with global scope uniformly across the appropriate domains, you can consolidate references to accounts with similar purposes. This simplifies and rationalizes group management across domains. For example, in a network with two domains, Europe and UnitedStates, if you have a group with global scope called GLAccounting in the UnitedStates domain, create a group called GLAccounting in the Europe domain (unless the accounting function does not exist in the Europe domain).

It is strongly recommended that you use global groups or universal groups instead of domain local groups when you specify permissions on domain directory objects that are replicated to the global catalog. For more information, see Global catalog replication.

| **Note** |
| --- |
| When the domain functional level is set to Windows 2000 mixed, members of global groups can include only accounts from the same domain. |

**When to use groups with universal scope**

Use groups with universal scope to consolidate groups that span domains. To do this, add the accounts to groups with global scope, and then nest these groups within groups that have universal scope. When you use this strategy, any membership changes in the groups that have global scope do not affect the groups with universal scope.

For example, in a network with two domains, Europe and UnitedStates, and a group that has global scope called GLAccounting in each domain, create a group with universal scope called UAccounting that has as its members the two GLAccounting groups, UnitedStates\GLAccounting and Europe\GLAccounting. The UAccounting group can then be used anywhere in the enterprise. Any changes in the membership of the individual GLAccounting groups will not cause replication of the UAccounting group.

If the forest functional level is Windows Server 2003 or higher, changes to the membership of universal groups are replicated to each global catalog server using linked-value replication. This means that only the changed membership is replicated, rather than the entire group. If the forest functional level is lower than Windows Server 2003, you should not change the membership of a group with universal scope frequently because any changes to these group memberships cause the entire membership of the group to be replicated to every global catalog in the forest. For more information about universal groups and replication, see Global catalogs and sites. For more information about linked value replication, see How the Active Directory Replication Model Works.

| **Note** |
| --- |
| When the domain functional level is set to Windows 2000 mixed, you cannot create security groups with universal scope. |

**Changing group scope**

When you create a new group, by default the new group is configured as a security group with global scope, regardless of the current domain functional level. Although changing a group scope is not allowed in domains with a domain functional level of Windows 2000 mixed, the following conversions are allowed in domains with the domain functional level of Windows 2000 native or Windows Server 2003:

- **Global to universal.** This conversion is allowed only if the group that you want to change is not a member of another global scope group.

- **Domain local to universal.** This conversion is allowed only if the group that you want to change does not have another domain local group as a member.

- **Universal to global.** This conversion is allowed only if the group that you want to change does not have another universal group as a member.

- **Universal to domain local.** There are no restrictions for this operation.

For more information, see Change group scope.

**Groups on client computers and stand-alone servers**

Some group features, such as universal groups, group nesting, and the distinction between security groups and distribution groups, are available only on Active Directory domain controllers and member servers. Group accounts on Windows 2000 Professional, Windows XP Professional, Windows 2000 Server, and stand-alone servers running Windows Server 2003 work the same way as in Windows NT 4.0:

- Only local groups can be created locally on the computer.

- A local group that is created on one of these computers can be assigned permissions only on that one computer.

For more information, see Default local groups.

# Group types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group types**
Groups are used to collect user accounts, computer accounts, and other group accounts into manageable units. Working with groups instead of with individual users helps simplify network maintenance and administration.

There are two types of groups in Active Directory: distribution groups and security groups. You can use distribution groups to create e-mail distribution lists and security groups to assign permissions to shared resources.

**Distributions groups**
Distribution groups can be used only with e-mail applications (such as Exchange) to send e-mail to collections of users. Distribution groups are not security-enabled, which means that they cannot be listed in discretionary access control lists (DACLs). If you need a group for controlling access to shared resources, create a security group.

**Security groups**
Used with care, security groups provide an efficient way to assign access to resources on your network. Using security groups, you can:

- **Assign user rights to security groups in Active Directory**

  User rights are assigned to security groups to determine what members of that group can do within the scope of a domain (or forest). User rights are automatically assigned to some security groups at the time Active Directory is installed to help administrators define a person's administrative role in the domain. For example, a user who is added to the Backup Operators group in Active Directory has the ability to backup and restore files and directories located on each domain controller in the domain.

  This is possible because by default, the user rights Back up files and directories and Restore files and directories are automatically assigned to the Backup Operators group. Therefore, members of this group inherit the user rights assigned to that group. For more information about user rights, see User rights. For more information about the user rights assigned to security groups, see Default groups.

  You can assign user rights to security groups, using Group Policy, to help delegate specific tasks. You should always use discretion when assigning delegated tasks because an untrained user assigned too many rights on a security group can potentially cause significant harm to your network. For more information, see Delegating administration. For more information about assigning user rights to groups, see Assign user rights to a group in Active Directory.

- **Assign permissions to security groups on resources**

  Permissions should not be confused with user rights. Permissions are assigned to the security group on the shared resource. Permissions determine who can access the resource and the level of access, such as Full Control. Some permissions set on domain objects are automatically assigned to allow various levels of access to default security groups such as the Account Operators group or the Domain Admins group. For more information about permissions, see Access control in Active Directory.

  Security groups are listed in DACLs that define permissions on resources and objects. When assigning permissions for resources (file shares, printers, and so on), administrators should assign those permissions to a security group rather than to individual users. The permissions are assigned once to the group, instead of several times to each individual user. Each account added to a group receives the rights assigned to that group in Active Directory and the permissions defined for that group at the resource.

Like distribution groups, security groups can also be used as an e-mail entity. Sending an e-mail message to the group sends the message to all the members of the group.

**Converting between security and distribution groups**
A group can be converted from a security group to a distribution group, and vice versa, at any time, but only if the domain functional level is set to Windows 2000 native or higher. No groups can be converted while the domain functional level is set

to Windows 2000 mixed.

For specific procedural information, see Convert a group to another group type. For information about domain functionality, see Domain and forest functionality.

**Note**

- Although a contact can be added to a security group as well as to a distribution group, contacts cannot be assigned rights and permissions. Contacts in a group can be sent e-mail.

# Default groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Default groups**

Default groups, such as the Domain Admins group, are security groups that are created automatically when you create an Active Directory domain. You can use these predefined groups to help control access to shared resources and delegate specific domain-wide administrative roles. For information about default groups stored on *local* computers, see Default local groups.

Many default groups are automatically assigned a set of user rights that authorize members of the group to perform specific actions in a domain, such as logging on to a local system or backing up files and folders. For example, a member of the Backup Operators group has the right to perform backup operations for all domain controllers in the domain.

When you add a user to a group, the user receives all the user rights assigned to the group and all the permissions assigned to the group on any shared resources. For more information about user rights and permissions, see Group types.

You can manage groups by using the Active Directory Users and Computers snap-in in Microsoft Management Console (MMC). Default groups are located in the **Builtin** container and the **Users** container.

The **Builtin** container default groups contain groups that are defined with domain local scope. You can move groups in and out of this container, but you cannot move the default groups in this container to another location or to another domain.

The **Users** container default groups contain groups that are defined with global scope and groups that are defined with domain local scope. You can add the groups in this container to other groups and you can move the default groups in this container to other organizational units (OUs) or containers, but you cannot move the group to another domain.

As a security best practice, it is recommended that members of default groups with broad administrative access use the **Run as** command to perform administrative tasks. For more information, see Using Run as. For information about security best practices, see Active Directory Best practices. For information about additional security measures that can be used to protect Active Directory, see Securing Active Directory.

**Note**

- To learn what group you need to be a member of to perform a particular procedure, many procedural topics under **How To** in Help and Support Center provide a note that identifies this information.

**Groups in the Builtin container**

The following table provides descriptions of the default groups located in the Builtin container and lists the assigned user rights for each group. For complete descriptions of the user rights listed in the table, see User Rights Assignment. For information about editing these rights, see Edit security settings on a Group Policy object.

| Group | Description | Default user rights |
|---|---|---|
| Account Operators | Members of this group can create, modify, and delete accounts for users, groups, and computers located in the Users or Computers containers and organizational units in the domain, except the Domain Controllers organizational unit. Members of this group do not have permission to modify the Administrators or the Domain Admins groups, nor do they have permission to modify the accounts for members of those groups. Members of this group can log on locally to domain controllers in the domain and shut them down. Because this group has significant power in the domain, add users with caution. | Allow log on locally; Shut down the system. |

| | | |
|---|---|---|
| Administrators | Members of this group have full control of all domain controllers in the domain. By default, the Domain Admins and Enterprise Admins groups are members of the Administrators group. The Administrator account is also a default member. Because this group has full control in the domain, add users with caution. | Access this computer from the network; Adjust memory quotas for a process; Back up files and directories; Bypass traverse checking; Change the system time; Create a pagefile; Debug programs; Enable computer and user accounts to be trusted for delegation; Force a shutdown from a remote system; Increase scheduling priority; Load and unload device drivers; Allow log on locally; Manage auditing and security log; Modify firmware environment values; Profile single process; Profile system performance; Remove computer from docking station; Restore files and directories; Shut down the system; Take ownership of files or other objects. |
| Backup Operators | Members of this group can back up and restore all files on domain controllers in the domain, regardless of their own individual permissions on those files. Backup Operators can also log on to domain controllers and shut them down. This group has no default members. Because this group has significant power on domain controllers, add users with caution. | Back up files and directories; Allow log on locally; Restore files and directories; Shut down the system. |
| Guests | By default, the Domain Guests group is a member of this group. The Guest account (which is disabled by default) is also a default member of this group. | No default user rights. |
| Incoming Forest Trust Builders (only appears in the forest root domain) | Members of this group can create one-way, incoming forest trusts to the forest root domain. For example, members of this group residing in Forest A can create a one-way, incoming forest trust from Forest B. This one-way, incoming forest trust allows users in Forest A to access resources located in Forest B. Members of this group are granted the permission Create Inbound Forest Trust on the forest root domain. This group has no default members. For more information about creating forest trusts, see Create a forest trust. | No default user rights. |
| Network Configuration Operators | Members of this group can make changes to TCP/IP settings and renew and release TCP/IP addresses on domain controllers in the domain. This group has no default members. | No default user rights. |
| Performance Monitor Users | Members of this group can monitor performance counters on domain controllers in the domain, locally and from remote clients without being a member of the Administrators or Performance Log Users groups. | No default user rights. |
| Performance Log Users | Members of this group can manage performance counters, logs and alerts on domain controllers in the domain, locally and from remote clients without being a member of the Administrators group. | No default user rights. |
| Pre-Windows 2000 Compatible Access | Members of this group have read access on all users and groups in the domain. This group is provided for backward compatibility for computers running Windows NT 4.0 and earlier. By default, the special identity Everyone is a member of this group. For more information about special identities, see Special identities. Add users to this group only if they are running Windows NT 4.0 or earlier. | Access this computer from the network; Bypass traverse checking. |

| | | |
|---|---|---|
| Print Operators | Members of this group can manage, create, share, and delete printers connected to domain controllers in the domain. They can also manage Active Directory printer objects in the domain. Members of this group can log on locally to domain controllers in the domain and shut them down. This group has no default members. Because members of this group can load and unload device drivers on all domain controllers in the domain, add users with caution. | Allow log on locally; Shut down the system. |
| Remote Desktop Users | Members of this group can remotely log on to domain controllers in the domain. This group has no default members. | No default user rights. |
| Replicator | This group supports directory replication functions and is used by the File Replication service on domain controllers in the domain. This group has no default members. Do not add users to this group. | No default user rights. |
| Server Operators | On domain controllers, members of this group can log on interactively, create and delete shared resources, start and stop some services, back up and restore files, format the hard disk, and shut down the computer. This group has no default members. Because this group has significant power on domain controllers, add users with caution. | Back up files and directories; Change the system time; Force shutdown from a remote system; Allow log on locally; Restore files and directories; Shut down the system. |
| Users | Members of this group can perform most common tasks, such as running applications, using local and network printers, and locking the server. By default, the Domain Users group, Authenticated Users, and Interactive are members of this group. Therefore, any user account created in the domain becomes a member of this group. | No default user rights. |

**Groups in the Users container**

The following table provides a description of the default groups located in the Users container and lists the assigned user rights for each group. For complete descriptions of the user rights listed in the table, see User Rights Assignment. For information about editing these rights, see Edit security settings on a Group Policy object.

| Group | Description | Default user rights |
|---|---|---|
| Cert Publishers | Members of this group are permitted to publish certificates for users and computers. This group has no default members. | No default user rights. |
| DnsAdmins (installed with DNS) | Members of this group have administrative access to the DNS Server service. This group has no default members. | No default user rights. |
| DnsUpdateProxy (installed with DNS) | Members of this group are DNS clients that can perform dynamic updates on behalf of other clients, such as DHCP servers. This group has no default members. | No default user rights. |

| | | |
|---|---|---|
| Domain Admins | Members of this group have full control of the domain. By default, this group is a member of the Administrators group on all domain controllers, all domain workstations, and all domain member servers at the time they are joined to the domain. By default, the Administrator account is a member of this group. Because the group has full control in the domain, add users with caution. | Access this computer from the network; Adjust memory quotas for a process; Back up files and directories; Bypass traverse checking; Change the system time; Create a pagefile; Debug programs; Enable computer and user accounts to be trusted for delegation; Force a shutdown from a remote system; Increase scheduling priority; Load and unload device drivers; Allow log on locally; Manage auditing and security log; Modify firmware environment values; Profile single process; Profile system performance; Remove computer from docking station; Restore files and directories; Shut down the system; Take ownership of files or other objects. |
| Domain Computers | This group contains all workstations and servers joined to the domain. By default, any computer account created becomes a member of this group automatically. | No default user rights. |
| Domain Controllers | This group contains all domain controllers in the domain. | No default user rights. |
| Domain Guests | This group contains all domain guests. | No default user rights. |
| Domain Users | This group contains all domain users. By default, any user account created in the domain becomes a member of this group automatically. This group can be used to represent all users in the domain. For example, if you want all domain users to have access to a printer, you can assign permissions for the printer to this group (or add the Domain Users group to a local group, on the print server, that has permissions for the printer). | No default user rights. |
| Enterprise Admins (only appears in the forest root domain) | Members of this group have full control of all domains in the forest. By default, this group is a member of the Administrators group on all domain controllers in the forest. By default, the Administrator account is a member of this group. Because this group has full control of the forest, add users with caution. | Access this computer from the network; Adjust memory quotas for a process; Back up files and directories; Bypass traverse checking; Change the system time; Create a pagefile; Debug programs; Enable computer and user accounts to be trusted for delegation; Force shutdown from a remote system; Increase scheduling priority; Load and unload device drivers; Allow log on locally; Manage auditing and security log; Modify firmware environment values; Profile single process; Profile system performance; Remove computer from docking station; Restore files and directories; Shut down the system; Take ownership of files or other objects. |
| Group Policy Creator Owners | Members of this group can modify Group Policy in the domain. By default, the Administrator account is a member of this group. Because this group has significant power in the domain, add users with caution. | No default user rights. |

| | | |
|---|---|---|
| IIS_WPG (installed with IIS) | The IIS_WPG group is the Internet Information Services (IIS) 6.0 worker process group. Within the functioning of IIS 6.0 are worker processes that serve specific namespaces. For example, www.microsoft.com is a namespace served by one worker process, which can run under an identity added to the IIS_WPG group, such as MicrosoftAccount. This group has no default members. | No default user rights. |
| RAS and IAS Servers | Servers in this group are permitted access to the remote access properties of users. | No default user rights. |
| Schema Admins (only appears in the forest root domain) | Members of this group can modify the Active Directory schema. By default, the Administrator account is a member of this group. Because this group has significant power in the forest, add users with caution. | No default user rights. |

# Nesting groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Nesting groups**

Using nesting, you can add a group as a member of another group. You nest groups to consolidate member accounts and reduce replication traffic.

Nesting options depend on whether the domain functionality of your Windows Server 2003 domain is set to Windows 2000 native or Windows 2000 mixed.

By default, when you nest a group within another group, user rights are inherited. For example, if you make Group_1 a member of Group_2, users in Group_1 have the same permissions as the users in Group_2.

Groups in domains set to the Windows 2000 native functional level or distribution groups in domains set to the Windows 2000 mixed functional level can have the following members:

- Groups with universal scope can have the following members: accounts, computer accounts, other groups with universal scope, and groups with global scope from any domain.
- Groups with global scope can have the following members: accounts from the same domain and other groups with global scope from the same domain.
- Groups with domain local scope can have the following members: accounts, groups with universal scope, and groups with global scope, all from any domain. This group can also have as members other groups with domain local scope from within the same domain.

Security groups in domains set to the Windows 2000 mixed functional level are restricted to the following types of membership:

- Groups with global scope can have as their members only accounts.
- Groups with domain local scope can have as their members other groups with global scope and accounts.

Security groups with universal scope cannot be created in domains with the domain functional level set to Windows 2000 mixed because universal scope is supported only in domains where the domain functional level is set to Windows 2000 native or Windows Server 2003.

| **Note** |
| --- |
| You cannot add the default groups that are located in the Builtin container as members to other groups. However, you can add other groups as members to the default groups that are located in the Builtin container. |

For more information about domain functionality, see Domain and forest functionality.

# Special identities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Special identities**
In addition to the groups in the Users and Builtin containers, servers running Windows Server 2003 include several special identities. For convenience, these identities are generally referred to as groups. These special groups do not have specific memberships that can be modified, but they can represent different users at different times, depending on the circumstances. The special groups are:

- Anonymous Logon

  Represents users and services that access a computer and its resources through the network without using an account name, password, or domain name. On computers running Windows NT and earlier, the Anonymous Logon group is a default member of the Everyone group. On computers running a member of the Windows Server 2003 family, the Anonymous Logon group is not a member of the Everyone group by default.

- Everyone

  Represents all current network users, including guests and users from other domains. Whenever a user logs on to the network, the user is automatically added to the Everyone group.

- Network

  Represents users currently accessing a given resource over the network (as opposed to users who access a resource by logging on locally at the computer where the resource is located). Whenever a user accesses a given resource over the network, the user is automatically added to the Network group.

- Interactive

  Represents all users currently logged on to a particular computer and accessing a given resource located on that computer (as opposed to users who access the resource over the network). Whenever a user accesses a given resource on the computer to which they are currently logged on, the user is automatically added to the Interactive group.

Although the special identities can be assigned rights and permissions to resources, the memberships cannot be modified or viewed. Group scopes do not apply to special identities. Users are automatically assigned to these special identities whenever they log on or access a particular resource.

For general information about groups, see Groups.

# Where groups can be created

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Where groups can be created**

In Active Directory, groups are created in domains. You use Active Directory Users and Computers to create groups. With the necessary permissions, groups can be created in the root domain of the forest, in any other domain in the forest, or in an organizational unit.

Besides the domain in which it is created, a group is also characterized by its scope. The scope of a group determines:

- The domain from which members can be added
- The domain in which the rights and permissions assigned to the group are valid

For more information about group scopes, see Group scope.

Choose the particular domain or organizational unit where you create a group based on the administration required for the group. For example, if your directory has multiple organizational units, each of which has a different administrator, you may want to create groups with global scope within those organizational units so those administrators can manage group membership for users in their respective organizational units. If groups are required for access control outside the organizational unit, the groups within the organizational unit can be nested into groups with universal scope (or other groups with global scope) that can be used elsewhere in the forest.

If the domain functional level is set to Windows 2000 native or higher, the domain contains a hierarchy of organizational units and administration is delegated to administrators at each organizational unit, it may be more efficient to nest groups with global scope. For example, if the organizational unit OU1 contained organizational units OU2 and OU3, a group with global scope in OU1 could have as its members groups with global scope in OU2 and OU3. In OU1, the administrator could add or remove group members from OU1, and the administrators of OU2 and OU3 could add or remove group members for accounts from their own organizational units without having administrative rights for the group with global scope in OU1.

**Note**

- Groups can be moved within a domain. However, only groups with universal scope can be moved from one domain to another. The rights and permissions assigned to a group with universal scope are lost when the group is moved to another domain and new assignments must be made.

For information about the tools used to move groups between domains, see Using the Windows Deployment and Resource Kits.

# Understanding Trusts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding trusts**
This section covers:

- Trusts
- Trust types
- Trust direction
- Trust transitivity
- When to create an external trust
- When to create a shortcut trust
- When to create a realm trust
- When to create a forest trust
- Forest trusts
- Accessing resources across domains
- Accessing resources across forests
- Routing name suffixes across forests

# Trusts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Trusts**
A trust is a relationship established between domains that enables users in one domain to be authenticated by a domain controller in the other domain. Trust relationships in Windows NT are different than in Windows 2000 and Windows Server 2003 operating systems.

**Trusts in Windows NT**
In Windows NT 4.0 and earlier, trusts are limited to two domains and the trust relationship is one-way and nontransitive. In the following figure, the nontransitive, one-way trust is shown by the straight arrow pointing to the trusted domain.

**Trusts in Windows Server 2003 and Windows 2000 Server operating systems**
All trusts in a Windows 2000 and Windows Server 2003 forest are transitive, two-way trusts. Therefore, both domains in a trust relationship are trusted. As shown in the following figure, this means that if Domain A trusts Domain B and Domain B trusts Domain C, then users from Domain C can access resources in Domain A (when assigned the proper permissions). Only members of the Domain Admins group can manage trust relationships.

**Trust protocols**
A domain controller running Windows Server 2003 authenticates users and applications using one of two protocols: Kerberos V5 or NTLM. The Kerberos V5 protocol is the default protocol for computers running Windows 2000, Windows XP Professional, or Windows Server 2003. If any computer involved in a transaction does not support Kerberos V5, the NTLM protocol will be used.

With the Kerberos V5 protocol, the client requests a ticket from a domain controller in its account domain to the server in the trusting domain. This ticket is issued by an intermediary trusted by the client and the server. The client presents this trusted ticket to the server in the trusting domain for authentication. For more information, see Kerberos V5 authentication.

When a client tries to access resources on a server in another domain using NTLM authentication, the server containing the resource must contact a domain controller in the client account domain to verify the account credentials.

**Trusted domain objects**
Trusted domain objects (TDOs) are objects that represent each trust relationship within a particular domain. Each time a trust is established a unique TDO is created and stored (in the System container) in its domain. Attributes such as a trust transitivity, type, and the reciprocal domain names are represented in a TDO.

Forest trust TDOs store additional attributes to identify all of the trusted namespaces from its partner forest. These attributes include domain tree names, user principal name (UPN) suffixes, service principal name (SPN) suffixes, and security ID (SID) namespaces.

For more information about domain trusts, see "Domain Trust" at the Microsoft Windows Resource Kits Web site. For more information about trust relationships, see "Designing an Authorization Strategy" at the Microsoft Windows Resource Kits Web

site.

# Trust types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Trust types**

Communication between domains occurs through trusts. Trusts are authentication pipelines that must be present in order for users in one domain to access resources in another domain. Two default trusts are created when using the Active Directory Installation Wizard. There are four other types of trusts that can be created using the New Trust Wizard or the Netdom command-line tool.

**Default trusts**

By default, two-way, transitive trusts are automatically created when a new domain is added to a domain tree or forest root domain using the Active Directory Installation Wizard. The two default trust types are defined in the following table.

| Trust type | Transitivity | Direction | Description |
|---|---|---|---|
| Parent and child | Transitive | Two-way | By default, when a new child domain is added to an existing domain tree, a new parent and child trust is established. Authentication requests made from subordinate domains flow upward through their parent to the trusting domain. For information about creating a new child domain, see Create a new child domain. |
| Tree-root | Transitive | Two-way | By default, when a new domain tree is created in an existing forest, a new tree-root trust is established. For information about creating a new domain tree, see Create a new domain tree. |

**Other trusts**

Four other types of trusts can be created using the New Trust Wizard or the Netdom command-line tool: external, realm, forest, and shortcut trusts. These trusts are defined in the following table.

| Trust type | Transitivity | Direction | Description |
|---|---|---|---|
| External | Nontransitive | One-way or two-way | Use external trusts to provide access to resources located on a Windows NT 4.0 domain or a domain located in a separate forest that is not joined by a forest trust. For more information, see When to create an external trust. |
| Realm | Transitive or nontransitive | One-way or two-way | Use realm trusts to form a trust relationship between a non-Windows Kerberos realm and a Windows Server 2003 domain. For more information, see When to create a realm trust. |
| Forest | Transitive | One-way or two-way | Use forest trusts to share resources between forests. If a forest trust is a two-way trust, authentication requests made in either forest can reach the other forest. For more information, see When to create a forest trust. |
| Shortcut | Transitive | One-way or two-way | Use shortcut trusts to improve user logon times between two domains within a Windows Server 2003 forest. This is useful when two domains are separated by two domain trees. For more information, see When to create a shortcut trust. |

When creating external, shortcut, realm, or forest trusts, you have the option to create each side of the trust separately or both sides of a trust simultaneously.

If you choose to create each side of the trust separately, then you will need to run the New Trust Wizard twice--once for each domain. When creating trusts using the method, you will need to supply the same trust password for each domain. As a security best practice, all trust passwords should be strong passwords. For more information, see Strong passwords.

If you choose to create both sides of the trust simultaneously, you will need to run the New Trust Wizard once. When you choose this option, a strong trust password is automatically generated for you.

You will need the appropriate administrative credentials for each domain between which you will be creating a trust.

Netdom.exe can also be used to create trusts. For more information about Netdom, see Active Directory support tools.

For more information about trusts, see Trust transitivity and Trust direction.

# Trust direction

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Trust direction**

The trust type and its assigned direction will impact the trust path used for authentication. A trust path is a series of trust relationships that authentication requests must follow between domains. Before a user can access a resource in another domain, the security system on domain controllers running Windows Server 2003 must determine whether the trusting domain (the domain containing the resource the user is trying to access) has a trust relationship with the trusted domain (the user's logon domain). To determine this, the security system computes the trust path between a domain controller in the trusting domain and a domain controller in the trusted domain. In the following figure, trust paths are indicated by arrows showing the direction of the trust (this is a one-way trust):

All domain trust relationships have only two domains in the relationship: the trusting domain and the trusted domain.

**One-way trust**

A one-way trust is a unidirectional authentication path created between two domains. This means that in a one-way trust between Domain A and Domain B, users in Domain A (trusted domain) can access resources in Domain B (trusting domain). However, users in Domain B cannot access resources in Domain A. Some one-way trusts can be a nontransitive trust or a transitive trust depending on the type of trust being created. For more information about trust types, see Trust types.

**Two-way trust**

All domain trusts in a Windows Server 2003 forest are two-way, transitive trusts. When a new child domain is created, a two-way, transitive trust is automatically created between the new child domain and the parent domain. In a two-way trust, both domains that are involved in a trust relationship trust each other. This means that authentication requests can be passed between the two domains in both directions. Some two-way relationships can be nontransitive or transitive depending on the type of trust being created. For more information, see Trust types.

A Windows Server 2003 domain can establish a one-way or two-way trust with:

- Windows Server 2003 domains in the same forest
- Windows Server 2003 domains in a different forest
- Windows NT 4.0 domains
- Kerberos V5 realms

For more information Kerberos V5, see Kerberos V5 authentication.

# Trust transitivity

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Trust transitivity**
Transitivity determines whether a trust can be extended outside of the two domains with which it was formed. A transitive trust can be used to extend trust relationships with other domains and a nontransitive trust can be used to deny trust relationships with other domains.

**Transitive trusts**
Each time you create a new domain in a forest, a two-way, transitive trust relationship is automatically created between the new domain and its parent domain. If child domains are added to the new domain, the trust path flows upward through the domain hierarchy extending the initial trust path created between the new domain and its parent domain.

Transitive trust relationships flow upward through a domain tree as it is formed, creating transitive trusts between all domains in the domain tree.

Authentication requests follow these trust paths, so accounts from any domain in the forest can be authenticated at any other domain in the forest. With a single logon process, accounts with the proper permissions can access resources in any domain in the forest. For more information, see Authentication protocols overview.

The diagram displays that all domains in the Domain A tree and all domains in the Domain 1 tree have transitive trust relationships by default. As a result, users in the Domain A tree can access resources in domains in the Domain 1 tree and users in the Domain 1 tree can access resources in the Domain A tree, when the proper permissions are assigned at the resource.

In addition to the default transitive trusts established in a Windows Server 2003 forest, using the New Trust Wizard, you can manually create the following transitive trusts.

- **Shortcut trust.** A transitive trust between a domain in the same domain tree or forest used to shorten the trust path in a large and complex domain tree or forest.
- **Forest trust.** A transitive trust between a forest root domain and a second forest root domain.
- **Realm trust.** A transitive trust between an Active Directory domain and an Kerberos V5 realm. For more information about Kerberos V5 realms, see Kerberos V5 authentication.

For more information about trust types, see Trust types.

**Nontransitive trust**
A nontransitive trust is restricted by the two domains in the trust relationship and does not flow to any other domains in the forest. A nontransitive trust can be a two-way trust or a one-way trust.

Nontransitive trusts are one-way by default, although you can also create a two-way relationship by creating two one-way trusts. In summary, nontransitive domain trusts are the only form of trust relationship possible between:

- A Windows Server 2003 domain and a Windows NT domain
- A Windows Server 2003 domain in one forest and a domain in another forest (when not joined by a forest trust)

Using the New Trust Wizard, you manually create the following nontransitive trusts:

- **External trust.** A nontransitive trust created between a Windows Server 2003 domain and a Windows NT domain or a Windows 2000 domain or Windows Server 2003 domain in another forest.

  When you upgrade a Windows NT domain to a Windows Server 2003 domain, all existing Windows NT trusts are preserved intact. All trust relationships between Windows Server 2003 domains and Windows NT domains are nontransitive.

- **Realm trust.** A nontransitive trust between an Active Directory domain and an Kerberos V5 realm. For more information about Kerberos V5 realms, see Kerberos V5 authentication.

For more information about trust types, see Trust types.

# When to create an external trust

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**When to create an external trust**

You can create an external trust to form a one-way or two-way, nontransitive trust with domains outside of your forest. External trusts are sometimes necessary when users need access to resources located in a Windows NT 4.0 domain or in a domain located within a separate forest that is not joined by a forest trust, as shown in the figure.

When a trust is established between a domain in a particular forest and a domain outside of that forest, security principals from the external domain can access resources in the internal domain. Active Directory creates a foreign security principal object in the internal domain to represent each security principal from the trusted external domain. These foreign security principals can become members of domain local groups in the internal domain. Domain local groups can have members from domains outside of the forest.

Directory objects for foreign security principals are created by Active Directory and should not be manually modified. You can view foreign security principal objects from Active Directory Users and Computers by enabling advanced features. For information about enabling advanced features, see To view advanced features.

In domains with the functional level set to Windows 2000 mixed, it is recommended that you delete external trusts from a domain controller running Windows Server 2003. External trusts to Windows NT 4.0 or 3.51 domains can be deleted by authorized administrators on the domain controllers running Windows NT 4.0 or 3.51. However, only the trusted side of the relationship can be deleted on the domain controllers running Windows NT 4.0 or 3.51. The trusting side of the relationship (created in the Windows Server 2003 domain) is not deleted, and although it will not be operational, the trust will continue to display in Active Directory Domains and Trusts. To remove the trust completely, you will need to delete the trust from a domain controller running Windows Server 2003 in the trusting domain. If an external trust is inadvertently deleted from a domain controller running Windows NT 4.0 or 3.51, you will need to recreate the trust from any domain controller running Windows Server 2003 in the trusting domain.

For more information about how to create an external trust, see Create an external trust.

**Securing external trusts**

To improve the security of Active Directory forests, domain controllers running Windows Server 2003 and Windows 2000 Service Pack 4 (or higher) enable security identifier (SID) filter quarantining on all new outgoing external trusts by default.

By applying SID filter quarantining to outgoing external trusts, you prevent malicious users who have domain administrator level access in the trusted domain from granting, to themselves or other user accounts in their domain, elevated user rights to the trusting domain.

When a malicious user can grant unauthorized user rights to another user it is known as an elevation of privilege attack. For more information about SID filtering and how to further mitigate an elevation of privilege attack, see MS02-001: Forged SID could result in elevated privileges in Windows 2000 (http://go.microsoft.com/fwlink/?LinkId=102075).

**How SID filter quarantining works**

When security principals are created in a domain, the domain SID is included in the security principal's SID to identify the domain in which it was created. The domain SID is an important characteristic of a security principal because the Windows security subsystem uses it to verify the security principal's authenticity.

In a similar fashion, outgoing external trusts created from the trusting domain use SID filter quarantining to verify that

incoming authentication requests made from security principals in the trusted domain contain SIDs of security principals from the trusted domain only. This is done by comparing the SIDs of the incoming security principal to the domain SID of the trusted domain. If any of the security principal SIDs include a domain SID other than the one from the trusted domain, the trust removes the offending SID.

SID filtering ensures that any misuse of the SID history attribute on security principals (including inetOrgPerson) in the trusted forest cannot pose a threat to the integrity of the trusting forest.

The SID history attribute can be useful to domain administrators when they migrate user and group accounts from one domain to another. Domain administrators can add SIDs from an old user or group account to the SID history attribute of the new, migrated account. By doing this, domain administrators give the new account the same level of access to resources as the old account.

If domain administrators could not use the SID history attribute in this way, they would have to track down and reapply permissions for the new account on each network resource that the old account had access to.

**Understanding the threat**
If not for SID filtering on outgoing external trusts, a malicious user with administrative credentials residing in the trusted domain could sniff network authentication requests from the trusting domain to obtain the SID information of a user who has full access to resources in the trusting domain, such as a domain administrator.

After obtaining the domain administrators SID from the trusting domain, a malicious user with administrative credentials can add that SID to a user account's SID history attribute in the trusted domain and attempt to gain full access to the trusting domain and the resources within that domain. In this scenario, a malicious user who has domain administrator credentials in the trusted domain is a threat to the entire trusting forest.

SID filtering neutralizes the threat of malicious users in the trusted domain from using the SID history attribute to gain elevated privileges.

**Impact of SID filter quarantining**
SID filter quarantining on external trusts can affect your existing Active Directory infrastructure in the following two areas:

- SID history data that contains SIDs from any domain other than the trusted domain will be removed from authentication requests made from the trusted domain. This will result in access being denied to resources that have the user's old SID.

- Universal group access control strategy between forests will require changes.

When SID filter quarantining is enabled, users who use SID history data for authorization to resources in the trusting domain no longer have access to those resources.

If you typically assign universal groups from a trusted forest to access control lists (ACLs) on shared resources in the trusting domain, SID filter quarantining will have a major impact on your access control strategy.

Because universal groups must adhere to the same SID filter quarantining guidelines as other security principal objects (that is, the universal group object SID must also contain the domain SID), you should verify that any universal groups that are assigned to shared resources in the trusting domain were created in the trusted domain.

If the universal group in the trusted forest was not created in the trusted domain, even though it may contain users from the trusted domain as members, authentication requests made from members of that universal group will be filtered and discarded.

Therefore, before assigning access to resources in the trusting domain for users in the trusted domain, you should confirm that the universal group containing the trusted domain users was created in the trusted domain.

**Disabling SID Filter quarantining**
Although it is not recommended, you can disable SID filter quarantining for an external trust by using the Netdom.exe tool. You should consider disabling SID filter quarantining only in the following situations:

- You have the same level of trust for all administrators who have physical access to domain controllers in the trusted domain as the administrators in the trusting domain.

- You have a strict requirement to assign universal groups to resources in the trusting domain that were not created in the trusted domain.

- Users have been migrated to the trusted domain with their SID histories preserved, and you want to grant them access to resources in the trusting domain based on the SID history attribute.

Only domain administrators can disable SID filtering. To disable SID filter quarantining for the trusting domain, type the following syntax at a command-prompt:

**Netdom trust** *TrustingDomainName* **/domain:** *TrustedDomainName* **/quarantine:**No **/userD:***domainadministratorAcct***/passwordD:***domainadminpwd*

To enable SID filter quarantining, set the **/quarantine:** command-line option to **Yes**. For more information about Netdom.exe, see Active Directory support tools.

You can enable or disable SID filter quarantining only from the trusting side of the trust. If the trust is a two-way trust, you can also disable SID filter quarantining in the trusted domain by using the domain administrator's credentials for the trusted domain and reversing the *TrustingDomainName* and *TrustedDomainName* values in the command-line syntax.

**Notes**

- To further secure your forest, you should consider enabling SID filter quarantining on all existing external trusts that were created by domain controllers running Windows 2000 Service Pack 3 (or earlier). You can do this by using Netdom.exe to enable SID filtering on existing external trusts, or by recreating these external trusts from a domain controller running Windows Server 2003 or Windows 2000 Service Pack 4 (or later).

- You cannot turn off the default behavior that enables SID filter quarantining for newly created external trusts.

- External trusts created from domain controllers running Windows 2000 Service Pack 3 (or earlier) do not enforce SID filter quarantining by default.

- Domain controllers running Windows NT Server 4.0 do not take part in the trust creation process when existing domain controllers in the same domain are running Windows 2000 or Windows Server 2003.

- You can enable or disable SID filter quarantining only for trusts that extend beyond forest boundaries such as external and forest trusts. For more information about SID filtering and forest trusts, see Forest trusts.

**Allowing SID history to traverse forest trusts**

If you are migrating users from one domain to another in different forests, you may want to allow the migrated users to access resources in their original forest by using their migrated (SID history) credentials. The default SID filtering that is applied to forest trusts prevents user-resource-access requests from traversing the trusts with the credentials of the original domain. If you want to make it possible for users to use the credentials that were migrated from their original domain, you can allow SID history to traverse forest trusts by using the **netdom** command.

Only domain administrators or enterprise administrators can modify SID filtering settings. To allow SID history credentials to traverse a trust relationship between two forests, type a command using the following syntax at a command prompt, and then press ENTER:

**Netdom trust** *TrustingDomainName* **/domain:** *TrustedDomainName* **/enablesidhistory:**Yes **/usero:***domainadministratorAcct***/passwordo:***domainadminpwd*

To re-enable the default SID filtering setting across forest trusts, set the **/enablesidhistory:** command-line option to **No**. For more information about Netdom, see "Domain and Forest Trust Tools and Settings."

| **Note** |
| --- |
| The same security considerations for removing SID filter quarantining from external trusts apply to allowing SID history to traverse forest trusts. |

# When to create a shortcut trust

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**When to create a shortcut trust**

Shortcut trusts are one-way or two-way, transitive trusts that can be used when administrators need to optimize the authentication process. Authentication requests must first travel a trust path between domain trees, and in a complex forest this can take time, which can be reduced with shortcut trusts. A trust path is the series of domain trust relationships that must be traversed in order to pass authentication requests between any two domains. For more information about trust paths, see Trust direction.

Shortcut trusts are necessary when many users in a domain regularly log on to other domains in a forest. For example, using the following figure as an example, you could form a shortcut trust between domain B and domain D or domain A and domain 1 and so on.

Shortcut trusts effectively shorten the path traveled for authentication's made between domains located in two separate trees.

For more information about how to create a shortcut trust, see Create a shortcut trust.

**Using one-way trusts**

A one-way, shortcut trust established between two domains located in separate domain trees can reduce the time needed to fulfill authentication requests, but in only one direction. For example, when a one-way, shortcut trust is established between domain A and domain B, authentication requests made in domain A to domain B can utilize the new one-way trust path. However, authentication requests made in domain B to domain A will still need to travel the longer trust path.

**Using two-way trusts**

A two-way, shortcut trust established between two domains located in separate domain trees will reduce the time needed to fulfill authentication requests originating in either domain. For example, when a two-way trust is established between domain A and domain B, authentication requests made from either domain to the other can utilize the new, two-way trust path.

# When to create a realm trust

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**When to create a realm trust**

A realm trust can be established between any non-Windows Kerberos V5 realm and a Windows Server 2003 domain. This trust relationship allows cross-platform interoperability with security services based on other Kerberos V5 versions such as UNIX and MIT implementations. Realm trusts can switch from nontransitive to transitive and back. Realm trusts can also be either one-way or two-way.

For more information about how to create a realm trust, see Create a realm trust.

# When to create a forest trust

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**When to create a forest trust**

A forest trust can only be created between a forest root domain in one Windows Server 2003 forest and a forest root domain in another Windows Server 2003 forest. Creating a forest trust between two Windows Server 2003 forests provides a one-way or two-way, transitive trust relationship between every domain residing within each forest. Forest trusts are useful for Application Service Providers, companies undergoing mergers or acquisitions, collaborative business extranets, and companies seeking a solution for administrative autonomy.

For more information about creating forest trusts, see Checklist: Creating a forest trust.

| **Note** |
| --- |
| You should not enable SID filter quarantining on forest trusts, that is, by using the **netdom** command with the **/quarantine:yes** option. However, if you have migrated users from one Windows Server 2003 forest to another and the migrated users need access to resources in the former domain, you can relax the default SID filtering that is applied to a forest trust by using the **netdom** command with the **/enablesidhistory:yes** option. Using that command on a forest trust reduces the level of SID filtering on the forest trust. So, ensure that you trust the administrators of the trusted domain, as well as their security practices. |

**Using one-way forest trusts**

A one-way, forest trust between two forests allows members of the trusted forest to utilize resources located in the trusting forest. However, the trust operates in only one direction. For example, when a one-way, forest trust is created between forest A (the trusted forest) and forest B (the trusting forest), members of forest A can access resources located in forest B, but members of forest B cannot access resources located in forest A using the same trust.

**Using two-way forest trusts**

A two-way, forest trust between two forests allows members from either forest to utilize resources located in the other forest; domains in each respective forest trust domains in the other forest implicitly. For example, when a two-way, forest trust is established between forest A and forest B, members of forest A can access resources located in forest B, and members of forest B can access resources in forest A, using the same trust.

# Forest trusts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Forest trusts**

In a Windows Server 2003 forest, you can link two disjoined Windows Server 2003 forests together to form a one-way or two-way, transitive trust relationships. A two-way, forest trust is used to form a transitive trust relationship between every domain in both forests.

Forest trusts can provide the following benefits:

- Simplified management of resources across two Windows Server 2003 forests by reducing the number of external trusts necessary to share resources.
- Complete two-way trust relationships with every domain in each forest.
- Use of user principal name (UPN) authentication across two forests.
- Use of both the Kerberos V5 and NTLM authentication protocols to improve the trustworthiness of authorization data transferred between forests.
- Flexibility of administration. Administrative tasks can be unique to each forest.

Forest trusts can only be created between two forests and cannot be implicitly extended to a third forest. This means that if a forest trust is created between forest 1 and forest 2, and a forest trust is also created between forest 2 and forest 3, forest 1 will not have an implicit trust with forest 3. For more information about the requirements needed for a forest trust, see When to create a forest trust.

**Notes**

- In a Windows 2000 forest, if users in one forest need to access resources in another forest, an administrator can create an external trust relationship between the two domains. External trusts can be one-way or two-way and are nontransitive, and therefore, limit the ability for trust paths to extend to other domains. For more information about external trusts, see Trust types.
- All trusts in Windows Server 2003 Active Directory use security identifier (SID) filtering to some degree. External trusts are quarantined by default, which prevents any domain SIDs other than those of the quarantined trusted domain from traversing the trust relationship. SID filtering is used to prevent attacks from malicious users who might try to grant elevated user rights to another user account. SID filtering on forest trusts does not prevent migrations to domains within the same forest from using SID history and will not affect your universal group access control strategy. For more information about SID filtering, see When to create an external trust.

**Managing a multiple forest environment**

Forest trusts help you to manage a segmented Active Directory infrastructure within your organization by providing support for accessing resources and other objects across multiple forests. For more information about accessing resources across multiple forests, see Accessing resources across forests.

Because each forest is administered separately, adding additional forests to your organization increases your organization's management needs. For more information, see Creating a new forest.

Reasons to create multiple forests in your organization include:

- To secure data within each forest. Sensitive data can be protected so that only users within that forest can access it.
- To isolate directory replication within each forest. Schema changes, configuration changes, and the addition of new domains to a forest only have forest-wide impact within that forest, not on a trusting forest.

**Delegating forest-wide administrative control**
Active Directory data that is stored in the schema and configuration containers is replicated to every domain controller in the forest. Since changes to the schema and configuration containers will affect all domains in the forest, administrative control for forest-wide changes should be entrusted to highly trained or experienced administrators. All domain data contained in the forest root domain should also be regarded as highly sensitive data.

The following groups provide forest-wide administrative control in each forest:

- Enterprise Admins
- Domain Admins (in the forest root domain)
- Schema Admins

Since membership in any of these groups can affect forest-wide behavior, add users with caution. As a security best practice, avoid adding users from another forest to any of these forest-wide administrative groups. For more information about these groups, see Default groups.

**Synchronizing data across forests**
You can synchronize global address lists (GALs) and objects across forests using Microsoft Metadirectory Services (MMS) or another supported synchronization tool. Common data types that need synchronization across forests include:

- GALs (Exchange)
- Public folders
- Directory objects

Synchronizing this data across forests will help end users view address lists and other data the same way as they do when viewing this information within their own forest.

For more information about MMS, see Microsoft Metadirectory Services.

# Accessing resources across domains

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Accessing resources across domains**

Since two or more Active Directory domains within the same forest are implicitly connected by two-way, transitive trusts, authentication requests made from one domain to another are successfully routed in order to provide a seamless coexistence of resources across domains. Users can only gain access to resources in other domains after first being authenticated in their own domain.

Domain controllers running Windows 2000 or Windows Server 2003 authenticate users and applications using one of two authentication protocols: Kerberos V5 or NTLM. For more information about Kerberos authentication, see Kerberos V5 authentication. For more information about NTLM authentication, see NTLM authentication. For more information about the Active Directory authentication process, see Access control in Active Directory.

Once authenticated, the user can attempt to gain access to resources from any domain in the forest using the Active Directory authorization process. For more information about the Active Directory authorization process, see Security information for Active Directory.

To access a shared resource in another domain using Kerberos, a user's workstation first requests a ticket from a domain controller in its account domain to the server (hosting the resource) in the trusting domain. This ticket is then issued by an intermediary trusted by the workstation and the server. The workstation presents this trusted ticket to the server in the trusting domain for authentication.

The following figure and corresponding steps provide a detailed description of the Kerberos authentication process that is used when a computer running Windows 2000 Professional, Windows 2000 Server, Windows XP Professional, or a member of the Windows Server 2003 family attempts to access resources from a server located in another domain.

1. User1 logs on to Workstation1 using credentials from the child1.microsoft.com domain. As part of this process, the authenticating domain controller issues User1 a ticket-granting ticket (TGT). This ticket is required to be authenticated to resources. The user then attempts to access a shared resource (\\fileserver1\share) on a file server located in the child2 domain.

2. Workstation1 contacts the Key Distribution Center (KDC) on a domain controller in its domain (ChildDC1) and requests a service ticket for the FileServer1 service principal name (SPN).

3. ChildDC1 does not find the SPN in its domain database and queries the global catalog to see if any domains in the forest contain this SPN. The global catalog sends the requested information back to ChildDC1.

4. ChildDC1 sends the referral to Workstation1.

5. Workstation1 contacts a domain controller in ForestRootDC1 (its parent domain) for a referral to a domain controller (ChildDC2) in the Child2 domain. ForestRootDC1 sends the referral to Workstation 1.

6. Workstation1 contacts the KDC on ChildDC2 and negotiates the ticket for the user to gain access to FileServer1.

7. Now that Workstation1 has a service ticket, it sends the service ticket to FileServer1, which reads the user's security credentials and constructs an access token accordingly.

Each domain has its own set of security policies that do not cross from one domain to another. For more information, see Domains.

**Planning your access control strategy for multiple domains**
It is recommended that you carefully plan the most efficient access control strategy for your organization's resource needs. Your design and implementation of security groups throughout each domain in a single forest will be an important factor to consider during your planning. For information about planning an access control strategy for multiple forests, see Accessing resources across forests.

It is important to understand the following security group concepts before you begin the planning process:

- **Security groups.** User rights can be applied to groups in Active Directory while permissions can be assigned to security groups on member servers hosting a resource. For more information, see Group types.

- **Group nesting.** The ability to nest security groups is dependent on group scopes and domain functionality. For more information, see Nesting groups.

- **Group scope.** Group scope helps determine the domain-wide and forest-wide access boundaries of security groups. For more information, see Group scope.

- **Domain functionality.** The domain functional level of the trusting and trusted domains can affect group functionality such as group nesting. For more information, see Domain and forest functionality.

Once you have gained a thorough understanding of security group concepts, determine the resource needs of each department and geographical division to assist you with the planning effort.

**Best practices for controlling access to shared resources across domains**
By carefully using domain local, global, and universal groups, administrators can more effectively control access to resources located in other domains. Consider the following best practices:

- Organize domain users based on administrative needs, such as their locations or departments, and then create a global group, and add the appropriate user accounts as members.

  For example, add all employee user accounts in the Sales department to the Sales Department global group, and add all employee user accounts in the Accounting Department to the Accounting Department global group.

- Create a domain local group, and add all global groups from the other domains that need the same access to a resource in your domain.

  For example, employees in the Sales Department and Accounting Department global groups located in DomainA use similar print resources located in DomainB. To make future administration changes more flexible, create a domain local group called Print Resources in DomainB, and add as members both the Sales Department and Accounting Department global groups in DomainA.

- Assign the required permissions on the shared resource to the domain local group.

  For example, assign permissions to the Print Resources domain local group located in DomainB so that its members, including the Sales Department and Accounting Department groups from DomainA, can access the printer located in DomainB.

**Selective authentication between domains in an external trust**

Using Active Directory Domains and Trusts, you can determine the scope of authentication between two domains that are joined by an external trust. You can set selective authentication differently for outgoing and incoming external trusts. With selective trusts, administrators can make flexible access control decisions between external domains. For more information about how to set selective authentication, see Select the scope of authentication for users.

If you use domain-wide authentication on the incoming external trust, users in the second domain would have the same level of access to resources in the local domain as users who belong to the local domain. For example, if DomainA has an incoming external trust from DomainB and domain-wide authentication is used, any user from DomainB would be able to access any resource in DomainA (assuming that they have the required permissions).

If you set selective authentication on an incoming external trust, you need to manually assign permissions on each resource to which you want users in the second domain to have access. To do this, set a control access right *Allowed to authenticate* on an object for that particular user or group from the external domain.

When a user authenticates across a trust with the **Selective authentication** option enabled, an *Other Organization*security ID (SID) is added to the user's authorization data. The presence of this SID prompts a check on the resource domain to ensure that the user is allowed to authenticate to the particular service. Once the user is authenticated, if the *Other Organization* SID is not already present, then the server adds the *This Organization* SID. Only one of these special SIDs can be present in an authenticated user's context. For more detailed information about how selective authentication works, see Security Considerations for Trusts.

Administrators in each domain can add objects from one domain to access control lists (ACLs) on shared resources in the other domain. You can use the ACL editor to add or remove objects residing in one domain to ACLs on resources in the other domain. For more information about how to set permissions on resources, see Set permissions on a shared resource.

For information about setting authentication restrictions for multiple forests, see Accessing resources across forests.

# Accessing resources across forests

Updated: February 21, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Accessing resources across forests**

When two Windows Server 2003 forests are connected by a forest trust, authentication requests made using the Kerberos V5 or NTLM protocols can be routed between forests to provide access to resources in both forests. For more information about routing authentication requests across forests, see Routing name suffixes across forests.

Before authentication protocols can follow the forest trust path, the service principal name (SPN) of the resource computer must be resolved to a location in the other forest. An SPN can be one of the following:

- Domain Name System (DNS) name of a host
- DNS name of a domain
- Distinguished name of a service connection point object

When a workstation in one forest attempts to access data on the resource computer in another forest, Kerberos contacts the domain controller for a service ticket to the SPN of the resource computer. Once the domain controller queries the global catalog and identifies that the SPN is not in the same forest as the domain controller, the domain controller sends a referral for its parent domain back to the workstation. At that point, the workstation queries the parent domain for the service ticket and follows the referral chain until it gets to the domain where the resource is located.

The following figure and corresponding steps provide a detailed description of the Kerberos authentication process that is used when computers running Windows 2000 Professional, Windows XP Professional, Windows 2000 Server, or a member of the Windows Server 2003 family attempt to access resources from a computer located in another forest.

1. User1 logs on to Workstation1 using credentials from the child.microsoft.com domain. The user then attempts to access a shared resource on FileServer1 located in the msn.com forest.

2. Workstation1 contacts the Key Distribution Center (KDC) on a domain controller in its domain (ChildDC1) and requests a service ticket for the FileServer1 SPN.

3. ChildDC1 does not find the SPN in its domain database and queries the global catalog to see if any domains in the microsoft.com forest contain this SPN. Since a global catalog is limited to its own forest, the SPN is not found. The global catalog then checks its database for information about any forest trusts that are established with its forest, and, if found, it compares the name suffixes listed in the forest trust trusted domain object (TDO) to the suffix of the target SPN to find a match. Once a match is found, the global catalog provides a routing hint back to ChildDC1.

4. ChildDC1 sends a referral for its parent domain back to Workstation1.

5. Workstation1 contacts a domain controller in ForestRootDC1 (its parent domain) for a referral to a domain controller (ForestRootDC2) in the forest root domain of the msn.com forest.

6. Workstation1 contacts ForestRootDC2 in the msn.com forest for a service ticket to the requested service.

7. ForestRootDC2 contacts its global catalog to find the SPN, and the global catalog finds a match for the SPN and sends it back to ForestRootDC2.

8. ForestRootDC2 then sends the referral to child.msn.com back to Workstation1.

9. Workstation1 contacts the KDC on ChildDC2 and negotiates the ticket for User1 to gain access to FileServer1.

10. Now that workstation1 has a service ticket, it sends the server service ticket to FileServer1, which reads User1's security credentials and constructs an access token accordingly.

When a forest trust is first established, each forest collects all of the trusted namespaces in its partner forest and stores the information in a TDO. Trusted namespaces include domain tree names, user principal name (UPN) suffixes, service principal name (SPN) suffixes, and security ID (SID) namespaces used in the other forest. TDO objects are replicated to the global catalog. For more information about TDOs, see Trusts.

**Routing hints**

Routing hints are only used when all traditional authentication channels (local domain controller and then global catalog) have failed to produce a location of a SPN. Routing hints help direct authentication requests toward the destination forest.

When an SPN cannot be located in the domain from where the network logon request originated or from the global catalog database, the global catalog checks the forest trust TDO for trusted name suffixes located in the other forest that might match the suffix in the SPN. If a match is found, the forest root domain returns a routing hint back to the original source computer so that it can continue the SPN location process in the other forest.

### Notes

- Routing hints can only reference trusted name suffixes that are listed in the TDO for its forest trust. They do not verify the name suffix before sending the hint back to the original source computer.

- Accessing NetBIOS names and Kerberos delegation across forest trusts is not supported. NTLM is fully supported and cannot be disabled.

**Planning your access control strategy for multiple forests**

It is recommended that you carefully plan the most efficient access control strategy for your organization's resource needs. Your design and implementation of security groups throughout each forest will be an important factor to consider during your planning. For information about planning an access control strategy for multiple domains, see Accessing resources across domains.

It is important to understand the following security group concepts before you begin the planning process:

- **Security groups.** User rights can be applied to groups in Active Directory while permissions can be assigned to security groups on member servers hosting a resource. For more information, see Group types.

- **Group nesting.** The ability to nest security groups is dependent on groups scopes and domain functionality. For more information, see Nesting groups.

- **Group scope.** Group scope helps determine the domain-wide and forest-wide access boundaries of security groups. For more information, see Group scope.

- **Domain functionality.** The domain functional level of the trusting and trusted domains can affect group functionality such as group nesting. For more information, see Domain and forest functionality.

Once you have gained a thorough understanding of security group concepts, determine the resource needs of each department and geographical division to assist you with the planning effort.

**Best practices for using security groups across forests**

By carefully using domain local, global, and universal groups, administrators can more effectively control access to resources located in other forests. Consider the following best practices:

- To represent the sets of users who need access to the same types of resources, create role-based global groups in every domain and forest that contains these users. For example, users in the Sales Department in ForestA require access to an order-entry application that is a resource in ForestB. Account Department users in ForestA require access to the same application, but these users are in a different domain. In ForestA, create the global group SalesOrder and add users in the Sales Department to the group. Create the global group AccountsOrder and add users in the Accounting Department to that group.

- To group the users from one forest who require similar access to the same resources in a different forest, create universal groups that correspond to the global group roles. For example, in ForestA, create a universal group called SalesAccountsOrders and add the global groups SalesOrder and AccountsOrder to the group.

  | **Note** |
  | --- |
  | Universal groups are not available as security groups in Windows 2000 Server mixed-mode domains or in Windows Server 2003 domains that have a domain functional level of Windows 2000 mixed. They are available as distribution groups. |

- To assign permissions to resources that are to be accessed by users from a different forest, create resource-based domain local groups in every domain and use these groups to assign permissions on the resources in that domain. For example, in ForestB, create a domain local group called OrderEntryApp. Add this group to the access control list (ACL) that allows access to the order entry application, and assign appropriate permissions.

- To implement access to a resource across a forest, add universal groups from trusted forests to the domain local groups in the trusting forests. For example, add the SalesAccountsOrders universal group from ForestA to the OrderEntryApp domain local group in ForestB.

When a new user account needs access to a resource in a different forest, add the account to the respective global group in the domain of the user. When a new resource needs to be shared across forests, add the appropriate domain local group to the ACL for that resource. In this way, access is enabled across forests for resources on the basis of group membership.

For more information, see Set permissions on a shared resource.

**Selective authentication between forests**

Using Active Directory Domains and Trusts, you can determine the scope of authentication between two forests that are joined by a forest trust. You can set selective authentication differently for outgoing and incoming forest trusts. With selective trusts, administrators can make flexible forest-wide access control decisions. For more information about how to set selective authentication, see Select the scope of authentication for users.

If you use forest-wide authentication on an incoming forest trust, users from the outside forest have the same level of access to resources in the local forest as users who belong to the local forest. For example, if ForestA has an incoming forest trust from ForestB and forest-wide authentication is used, users from ForestB would be able to access any resource in ForestA (assuming they have the required permissions).

If you decide to set selective authentication on an incoming forest trust, you need to manually assign permissions on each computer in the domain as well as the resources to which you want users in the second forest to have access. To do this, set a control access right *Allowed to authenticate* on the computer object that hosts the resource in Active Directory Users and Computers in the second forest. Then, allow user or group access to the particular resources you want to share.

When a user authenticates across a trust with the **Selective authentication** option enabled, an *Other Organization* security ID (SID) is added to the user's authorization data. The presence of this SID prompts a check on the resource domain to ensure that the user is allowed to authenticate to the particular service. Once the user is authenticated, then the server to which he authenticates adds the *This Organization* SID if the *Other Organization* SID is not already present. Only one of these special

SIDs can be present in an authenticated user's context. For more detailed information about how selective authentication works, see Security Considerations for Trusts.

Administrators in each forest can add objects from one forest to access control lists (ACLs) on shared resources in the other forest. You can use the ACL editor to add or remove objects residing in one forest to ACLs on resources in another forest. For more information about how to set permissions on resources, see Set permissions on a shared resource.

For information about setting authentication restrictions for external domains, see Accessing resources across domains.

# Routing name suffixes across forests

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing name suffixes across forests**

Name suffix routing is a mechanism used to manage how authentication requests are routed across Windows Server 2003 forests that are joined together by forest trusts. To simplify administration of authentication requests, when a forest trust is initially created, all unique name suffixes are routed by default. A unique name suffix is a name suffix within a forest, such as a user principal name (UPN) suffix, service principal name (SPN) suffix, or DNS forest or domain tree name, that is not subordinate to any other name suffix. For example, the DNS forest name microsoft.com is a unique name suffix within the microsoft.com forest.

Forests can contain multiple unique name suffixes, and all children of unique name suffixes are routed implicitly. In Active Directory Domains and Trusts, name suffixes appear with an asterisk (*) at the beginning because of this. For example, if your forest uses *.microsoft.com as a unique name suffix, then authentication requests for all children of microsoft.com (*.child.microsoft.com) will be routed because the child domains are part of the microsoft.com name suffix.

If a forest trust exists between two forests, then name suffixes that do not exist in one forest can be used to route authentication requests to a second forest. When a new child name suffix (*.child.widgets.com) is added to a unique name suffix (*.widgets.com), the child name suffix will inherit the routing configuration of the unique name suffix to which it belongs. Any new unique name suffixes that are created after a forest trust has been established will be visible in the forest trust **Properties** dialog box after you verify the trust. However, routing for those new unique name suffixes will be disabled by default. For more information about how to verify a trust, see Verify a trust.

When a duplicate name suffix is detected, the routing for the newest name suffix will be disabled by default. For more information about how to route name suffixes, see Enable or disable an existing name suffix from routing. Administrators can use the forest trust **Properties** dialog box to manually prevent authentication requests for specific name suffixes from being routed to a forest.

### Notes

- Do not add the @ sign to the UPN suffix or a user name. When authentication requests are routed to a trusted forest, all characters before the first @ symbol are interpreted as the user name and everything after the first @ symbol as the UPN suffix.

- The Local Security Authority (LSA) will block routing to any UPN suffix that is not a valid DNS name. For example, adding an @ symbol to a UPN suffix will cause it to automatically be disabled.

**Collision detection**

When two Windows Server 2003 forests are linked by a forest trust, there is a possibility that unique name suffixes existing in one forest might collide with unique name suffixes located in the second forest. Collision detection guarantees that each name suffix will only be routed to a single forest.

Active Directory Domains and Trusts will detect a name suffix conflict when:

- The same Domain Name System (DNS) name is already in use.

- The same NetBIOS name is already in use.

- A domain security ID (SID) conflicts with another name suffix SID.

When a name suffix in a forest conflicts with a new forest trust partner or when a name suffix in an existing forest trust conflicts with a new forest trust partner, the name will be disabled in the new trust. For example, a conflict will occur if one forest is named widgets.com and the second forest is named sales.widgets.com. Despite the name suffix conflict, routing will still work for any other unique name suffixes in the second forest.

For another example, assume that the msn.com forest needs to establish a two-way, forest trust with the widgets.com forest. Both msn.com and widgets.com have identical UPN suffixes of microsoft.com. During the creation of the two-way, forest trust, the New Trust Wizard will detect and display the conflict between the two UPN name suffixes and then create the forest trust.

If Active Directory Domains and Trusts detects a name suffix conflict with a trust partner domain, access to that domain from outside the forest may be denied. However, access to the conflicted domain from within its forest will function normally.

For example, if the domain widgets.com exists in both the msn.com and microsoft.com forests, users within the msn.com forest will be able to access resources in widgets.com domain that resides in the msn.com forest. However, users in the msn.com forest will be denied access to resources in the widgets.com domain located in the microsoft.com forest.

Conflicts will be listed in Active Directory Domains and Trusts, in the forest trust **Properties** dialog box, on the **Name Suffix Routing** tab. If a name suffix conflict is detected during the creation of the forest trust, then the New Trust Wizard will prompt you to save a log file of the conflicts. You can also save a log file after a trust has been created. For more information about how to save this log file, see Change the routing status of a name suffix.

If a NetBIOS or domain SID conflict exists, Active Directory Domains and Trusts identifies the name suffixes routing status as enabled or disabled with exceptions, as appropriate. The details about where the conflict exists are listed in the log file.

You can also use the Netdom command-line tool to list all routed names and to enable and disable routing for NetBIOS names and SIDs. For example, a forest named microsoft.com has a forest trust with widgets.com and you also need to add a forest trust to msn.com. Both widgets.com and msn.com have child domains with the NetBIOS name of SALES (and DNS names of USsales.widgets.com and sales.msn.com).

After you create the new trust to msn.com, routing to the SALES domain name in msn.com will be disabled. If you need to use the name SALES to route to the msn.com forest but don't need to use it to the widgets.com forest, you can use Netdom to disable SALES in widgets.com, and then enable it in msn.com.

For information about Netdom, see Active Directory support tools.

# Understanding Sites and Replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding sites and replication**
This section covers:

- Sites overview
- Replication overview
- How replication works
- Replication within a site
- Replication between sites
- When to establish a single or separate sites
- Bandwidth
- Managing replication

# Sites overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sites overview**

Sites in Active Directory® represent the physical structure, or topology, of your network. Active Directory uses topology information, stored as site and site link objects in the directory, to build the most efficient replication topology. You use Active Directory Sites and Services to define sites and site links. A site is a set of well-connected subnets. Sites differ from domains; sites represent the physical structure of your network, while domains represent the logical structure of your organization.

**Using sites**

Sites help facilitate several activities within Active Directory, including:

- **Replication.** Active Directory balances the need for up-to-date directory information with the need for bandwidth optimization by replicating information within a site more frequently than between sites. You can also configure the relative cost of connectivity between sites to further optimize replication. For more information, see Replication between sites and Managing replication.

- **Authentication.** Site information helps make authentication faster and more efficient. When a client logs on to a domain, it first searches its local site for a domain controller to authenticate against. By establishing multiple sites, you can ensure that clients authenticate against domain controllers nearest to them, reducing authentication latency and keeping traffic off WAN connections.

- **Active Directory-enabled services.** Active Directory-enabled services can leverage site and subnet information to enable clients to locate the nearest server providers more easily. For information about services, see Services.

**Defining sites using subnets**

In Active Directory, a site is a set of computers well-connected by a high-speed network, such as a local area network (LAN). All computers within the same site typically reside in the same building, or on the same campus network. A single site consists of one or more Internet Protocol (IP) subnets. Subnets are subdivisions of an IP network, with each subnet possessing its own unique network address. A subnet address groups neighboring computers in much the same way that postal codes group neighboring postal addresses. The following figure shows several clients within a subnet that defines an Active Directory site.

Sites and subnets are represented in Active Directory by site and subnet objects, which you create through Active Directory Sites and Services. Each site object is associated with one or more subnet objects.

For information about creating sites, see Create a site.

For information about creating subnets, see Create a subnet.

For information about subnets, see "Introduction to TCP/IP" at the Microsoft Windows Resource Kits Web site.

**Assigning computers to sites**

Computers are assigned to sites based on their Internet Protocol (IP) address and subnet mask. Site assignment is handled differently for clients and member servers than for domain controllers. For a client, site assignment is dynamically determined by its IP address and subnet mask during logon. For a domain controller, site membership is determined by the location of its associated server object in Active Directory. For more information, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

For information about associating subnets with sites, see Associate a subnet with a site.

For information about establishing single or multiple sites, see When to establish a single or separate sites.

**Understanding sites and domains**

In Active Directory, sites map the physical structure of your network, while domains map the logical or administrative structure of your organization. This separation of physical and logical structure provides the following benefits:

- You can design and maintain the logical and physical structures of your network independently.
- You do not have to base domain namespaces on your physical network.
- You can deploy domain controllers for multiple domains within the same site. You can also deploy domain controllers for the same domain in multiple sites.

Multiple sites in a single domain

Single site with multiple domains

For more information about domains, see Domains.

# Replication overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Replication overview**
Except for very small networks, directory data must reside in more than one place on the network to be equally useful to all users. Through replication, the Active Directory® directory service maintains replicas of directory data on multiple domain controllers, ensuring directory availability and performance for all users. Active Directory uses a multimaster replication model, allowing you to make directory changes at any domain controller, not just at a designated primary domain controller. Active Directory relies on the concept of sites to help keep replication efficient, and on the Knowledge Consistency Checker (KCC) to automatically determine the best replication topology for the network.

**Organizing data for replication**
Data is stored on each domain controller in the directory store, which is divided logically into specific directory partitions. Each partition stores a different type of directory data, either domain data, forest schema data, forest configuration data, or application data. All domain controllers within a forest hold a replica of the schema and configuration partitions for that forest, and all domain controllers within a particular domain hold a replica of the domain partition for their domain. Application directory partitions hold directory data specific to a particular application and can be stored by domain controllers belonging to different domains. Changes to each directory partition are replicated to all other domain controllers that hold a copy of that partition. For more information, see Directory data store.

Replication also ensures the availability of the global catalog throughout the entire forest. The global catalog is a searchable directory store containing data about every object in all domains. The global catalog is stored by domain controllers for which the global catalog has been enabled. For more information, see Global catalog replication.

**Improving replication efficiency with sites**
To help make replication more efficient, Active Directory relies on sites. Sites, defined as groups of well-connected computers, determine how directory data is replicated. Active Directory replicates directory information within a site more frequently than among sites. This way, the best connected domain controllers, those most likely to need particular directory information, receive replicated updates first. The domain controllers in other sites also receive the changes, but less frequently, reducing network bandwidth consumption. For more information, see How replication works and Sites overview.

**Determining the replication topology**
The Knowledge Consistency Checker (KCC), a process running on each domain controller, automatically identifies the most efficient replication topology for your network, based on information you provide about your network in Active Directory Sites and Services. The KCC regularly recalculate the replication topology to adjust for any network changes that have occurred. The KCC of one domain controller within each site (the intersite topology generator) determines the intersite replication topology. For more information about the KCC, see Active Directory Replication Technologies.

**Replication enhancements in the Windows Server 2003 family**
The Microsoft® Windows Server 2003 family includes enhancements to make replication both more efficient, as well as more scalable across a larger number of domains and sites. These include refinements in memory usage, enhancements to the Windows 2000 spanning tree algorithm, a completely new spanning tree algorithm for Windows Server 2003 forests, and a new load balancing tool.

In a forest set to the Windows 2000 functional level, the replication enhancements provide gains in replication efficiency and scalability, even when sites and domains contain domain controllers running Windows 2000. If a site contains at least one domain controller running Windows Server 2003, then a domain controller running Windows Server 2003 assumes the intersite topology generator role for the site, allowing the enhancements to take effect.

In a forest set to the Windows Server 2003 functional level, the new Windows Server 2003 spanning tree algorithm goes into effect for larger gains in both efficiency and scalability. For example, using the original spanning tree algorithm from Windows 2000, one domain can contain up to 300 sites. With the new Windows Server 2003 algorithm, one domain can contain up to at least 3,000 sites. In the new algorithm, the intersite topology generator in each site uses a randomized selection process to determine the bridgehead servers for the site. This selection process more evenly distributes the bridgehead replication workload among domain controllers in a site, resulting in much better efficiency (particularly in hub sites with a number of domain controllers). By default, the randomized selection process takes place only when new connection objects are added to the site. However, a new tool, called **adlb.exe**, can be run to rebalance the load each time changes occur in the topology or in the number of domain controllers in the site. In addition, **adlb** can stagger schedules so that the outbound replication load for each server is spread out evenly across time. For more information about **adlb** and to download the tool, see the "Windows Server 2003 Active Directory Branch Office Planning and Deployment Guide."

# How replication works

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How replication works**
To keep directory data on all domain controllers consistent and up to date, Active Directory replicates directory changes on a regular basis. Replication occurs over standard network protocols, uses change tracking information to prevent unnecessary replication, and uses linked value replication to improve efficiency.

**Transferring replication data**
Active Directory uses remote procedure call (RPC) over Internet Protocol (IP) to transfer replication data between domain controllers. RPC over IP is used for both intersite and intrasite replication. To keep data secure while in transit, RPC over IP replication uses both authentication (using the Kerberos V5 authentication protocol) and data encryption.

When a direct or reliable IP connection is not available, replication between sites can be configured to use the Simple Mail Transfer Protocol (SMTP). However, SMTP replication functionality is limited, and requires an enterprise certification authority (CA). SMTP can only be used to replicate the configuration, schema and application directory partitions, and does not support the replication of domain directory partitions. For more information, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

**Preventing unnecessary replication**
Once a domain controller has processed a directory change from another domain controller successfully, it should not try to replicate those changes back to the domain controller that sent the change. In addition, a domain controller should avoid sending updates to another domain controller if the target domain controller has already received that same update from a different replication partner. To prevent such unnecessary replication, Active Directory uses change tracking information stored in the directory. For information about change tracking, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

**Resolving conflicting changes**
It is possible for two different users to make changes to the exact same object property and to have these changes applied at two different domain controllers in the same domain before replication of either change occurs. In such a case, both changes are replicated as new changes, creating a conflict. To resolve this conflict, domain controllers that receive these conflicting changes examine the attribute data contained within the changes, each of which holds a version and a timestamp. Domain controllers will accept the change with the higher version and discard the other change. If the versions are identical, domain controllers will accept the change with the more recent timestamp.

**Improving replication efficiency**
Introduced in the Windows Server 2003 family, linked value replication allows individual values of a multivalued attribute to be replicated separately. In Windows 2000, when a change was made to a member of a group (one example of a multivalued attribute with linked values) the entire group had to be replicated. With linked value replication, only the group member that has changed is replicated, and not the entire group. To enable linked value replication, you must raise the forest functional level to Windows Server 2003 . For more information about forest functional levels, see Domain and forest functionality. For more information about multivalued attributes, see Schema.

For more information about how replication works, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

# Replication within a site

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Replication within a site**

Active Directory handles replication within a site, or intrasite replication, differently than replication between sites because bandwidth within a site is more readily available. The Active Directory Knowledge Consistency Checker (KCC) builds the intrasite replication topology using a bidirectional ring design. Intrasite replication is optimized for speed, and directory updates within a site occur automatically on the basis of change notification. Unlike replication data travelling between sites, directory updates replicated within a site are not compressed.

For information about intersite replication, see Replication between sites and How replication works.

**Building the intrasite replication topology**

The Knowledge Consistency Checker (KCC) on each domain controller automatically builds the most efficient replication topology for intrasite replication, using a bidirectional ring design. This bidirectional ring topology attempts to create at least two connections to each domain controller (for fault tolerance) and no more than three hops between any two domain controllers (to reduce replication latency). To prevent connections of more than three hops, the topology can include shortcut connections across the ring. The KCC updates the replication topology regularly.

### Note

- The KCC actually creates a separate replication topology for each directory partition (schema, configuration, domain, application). Within a single site, these topologies are usually identical for all partitions hosted by the same set of the domain controllers.

**Determining when intrasite replication occurs**

Directory updates made within a site are likely to have the most direct impact on local clients, so intrasite replication is optimized for speed. Replication within a site occurs automatically on the basis of change notification. Intrasite replication begins when you make a directory update on a domain controller. By default, the source domain controller waits 15 seconds and then sends an update notification to its closest replication partner. If the source domain controller has more than one replication partner, subsequent notifications go out by default at 3 second intervals to each partner. After receiving notification of a change, a partner domain controller sends a directory update request to the source domain controller. The source domain controller responds to the request with a replication operation. The 3 second notification interval prevents the source domain controller from being overwhelmed with simultaneous update requests from its replication partners.

For some directory updates in a site, the 15 second waiting time does not apply and replication occurs immediately. Known as urgent replication, this immediate replication applies to critical directory updates, including the assigning of account lockouts and changes in the account lockout policy, the domain password policy, or the password on a domain controller account.

For more information about intrasite replication, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

# Replication between sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Replication between sites**
Active Directory handles replication between sites, or intersite replication, differently than replication within sites because bandwidth between sites is usually limited. The Active Directory Knowledge Consistency Checker (KCC) builds the intersite replication topology using a least-cost spanning tree design. Intersite replication is optimized for bandwidth efficiency, and directory updates between sites occur automatically based on a configurable schedule. Directory updates replicated between sites are compressed to preserve bandwidth.

For information about intrasite replication, see Replication within a site.

For information about site design, see "Designing the Site Topology" at the Microsoft Windows Resource Kits Web site.

**Building the intersite replication topology**
Active Directory automatically builds the most efficient intersite replication topology using information you provide (through Active Directory Sites and Services) about your site connections. The directory stores this information as site link objects. One domain controller per site, called the intersite topology generator, is assigned to build the topology. A least-cost spanning tree algorithm is used to eliminate redundant replication paths between sites. The intersite replication topology is updated regularly to respond to any changes that occur in the network. You can control intersite replication through the information you provide when you create your site links. For more information, see Managing replication.

**Determining when intersite replication occurs**
Active Directory preserves bandwidth between sites by minimizing the frequency of replication and by allowing you to schedule the availability of site links for replication. By default, intersite replication across each site link occurs every 180 minutes (3 hours). You can adjust this frequency to match your specific needs. Be aware that increasing this frequency increases the amount of bandwidth used by replication. In addition, you can schedule the availability of site links for use by replication. By default, a site link is available to carry replication traffic 24 hours a day, 7 days a week. You can limit this schedule to specific days of the week and times of day. You can, for example, schedule intersite replication so that it only occurs after normal business hours. For more information, see Configure site link replication frequency and Configure site link replication availability.

### Notes

- With certain restrictions, you can use the Simple Mail Transfer Protocol (SMTP) for replicating to sites that do not have a direct or reliable Internet Protocol (IP) connection. For more information, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

- Intersite replication through a firewall or virtual private network requires some special considerations. For more information, see Active Directory at the Microsoft Web site.

# When to establish a single or separate sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**When to establish a single or separate sites**
You can optimize the replication efficiency and reduce the administrative overhead of your network by establishing sites appropriately. The most effective number of sites depends on the physical design of your network. When you first create a new forest, a single, default Active Directory site (called Default-Site-First-Name) is created that represents your entire network. A forest or domain consisting of a single site can be very efficient for a single location network connected completely by high-speed bandwidth. If your forest or domain contains multiple geographic locations that communicate over low-speed wide area network (WAN) connections, establishing multiple sites gives you more detailed control of replication behavior, reduces authentication latency, and reduces network traffic on the WAN.

For information about sites, see Sites overview.

For information about designing a site topology, see "Designing the Site Topology" at the Microsoft Windows Resource Kits Web site.

**Why bandwidth is important**
Within a site, bandwidth affects how efficiently replication can work. The frequency with which intrasite replication occurs requires high-speed bandwidth to function most effectively. So before you a create new site, you should make sure that high-speed bandwidth connects all computers within the site candidate. Any area where domain controllers are connected by 10 megabits per second (Mbps) or more of bandwidth is a good site candidate.

**When to establish a single site**
If you have a single LAN consisting of a single subnet, or if your network contains multiple subnets connected by a high-speed backbone, establishing a single site replication topology can provide the following benefits:

- Simplified replication management
- Prompt directory updates between all domain controllers

A single site topology allows all replication on your network to occur as intrasite replication, which requires no manual replication configuration. A single site design also allows all domain controllers to remain very current with respect to directory changes, because directory updates are replicated almost immediately. For more information, see Replication within a site. For information about creating sites, see Create a site.

**When to establish multiple sites**
When your network consists of multiple geographic locations connected by a WAN, establishing separate sites for each location provides the following benefits:

- Efficient use of WAN bandwidth for replication
- Detailed control of replication behavior
- Reduction in authentication latency

Physically separate network locations typically communicate over WAN connections, which are most often characterized by low-speed bandwidth. By creating a separate site for each physical location on your network, you ensure that domain controllers communicating over WAN connections use intersite replication, which is specifically designed for efficiency on low bandwidth connections. For more information, see Replication between sites.

With multiple sites, you have more detailed control of replication behavior through several configurable intersite replication settings. These settings include the relative cost of different replication paths, the domain controllers associated with each site, the subnets associated with each site, the frequency of directory update transfers, and the availability of connections for use by replication. For more information, see Managing replication.

A network client logging on to a domain must contact a domain controller as part of the authentication process, first looking within its own site. If the site includes two or more physically separate network locations, the client may authenticate against a

domain controller across a WAN connection. Authentication across a WAN introduces a delay in the authentication process. By placing physically separate network locations into separate Active Directory sites, you can ensure that clients first attempt to authenticate against a domain controller in their own site.

# Bandwidth

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Bandwidth**

Bandwidth is the most important practical consideration affecting intrasite replication on your network. Although sites are conveniently defined by subnets, it is important to understand that the reason for this choice is that subnets are typically well-connected. This means that subnets are generally, but not always, an effective way to determine sites.

To organize your sites effectively, consider replication requirements and available connectivity. Find a balance that ensures domain controllers in the same site are sufficiently well-connected to handle the frequent exchange of directory information, while not exacting what you consider to be excessive costs (such as high financial expense or compromised network performance).

When considering bandwidth, you may want to combine several subnets into one site, or split one subnet among several sites, such as in the following instances:

- You have very poorly connected computers, including several domain controllers in one subnet. Create several smaller subnets that are better connected than they were as one large subnet. For this to be effective, each new subnet should contain a domain controller.

- You have several subnets that are all well-connected or you have fewer domain controllers than subnets, but you want several subnets to be in a single site. To do this, add multiple subnets to one site.

For more information about how bandwidth may affect the way you configure sites, see Replication between sites.

# Managing replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing replication**
Active Directory relies on site configuration information to manage and optimize the process of replication. Active Directory provides automatic configuration of these settings in some cases. In addition, you can configure site-related information for your network using Active Directory Sites and Services. Configurable information includes settings for site links, site link bridges, and bridgehead servers.

**Configuring site links**
You can use site link settings to control replication between sites. Configurable settings include the relative cost of each site link, the frequency of replication on each site link, and the schedule availability of each site link for replication. For information about site links, see Replication between sites.

**Site link cost**
The cost of a site link determines the relative preference of the Active Directory Knowledge Consistency Checker (KCC) for using a site link in the replication topology. The higher the cost of the site link, the lower will be the KCC's preference for using the site link. For example, if you have two site links, site link A and site link B, and you set the cost of site link A to 150 and the cost of site link B to 200, the KCC will prefer to use site link A in the replication topology. By default, the cost of a newly created site link is 100. For information about setting site link cost, see Configure site link cost. For information about the KCC, see Replication overview.

**Replication frequency**
The replication frequency of a site link determines how often replication occurs over that site link. By default, the replication frequency for a site link is 180 minutes, meaning that replication occurs over that site link every 180 minutes, or three hours. Using Active Directory Sites and Services, you can set the replication frequency from 15 minutes to 10,080 minutes (one week). A site link must be available for any replication to occur. If a site link is not available when the number of minutes between replication updates has passed, no replication will occur. For more information, see Configure site link replication frequency.

**Site link availability**
The availability schedule for a site link determines during which hours or days of the week a site link can be used for replication. By default, a site link is always available for replication, 24 hours a day and 7 days a week. You can change this schedule, for example, to exclude business hours during which your network is busy handling other types of traffic. Or, you can exclude particular days on which you do not want replication to occur. Scheduling information is ignored by site links that use the Simple Mail Transfer Protocol (SMTP) for replication. For more information, see Configure site link replication availability.

**Configuring site link bridges**
By default, all site links are bridged, or transitive. This allows any two sites that are not connected by an explicit site link to communicate directly, through a chain of intermediary site links and sites. One advantage to bridging all site links is that your network is easier to maintain because you do not need to create a site link to describe every possible path between pairs of sites.

Generally, you can leave automatic site link bridging enabled. However, you might want to disable automatic site link bridging and create site link bridges manually just for specific site links, in the following cases:

- Your network is not fully routed (not every domain controller can directly communicate with every other domain controller).
- You have a network routing or security policy in place that prevents every domain controller from being able to directly communicate with every other domain controller.
- Your Active Directory design includes a large number of sites. For more information, see the Active Directory Branch Office Planning Guide at the Microsoft Web site.

For more information about site link bridges and their affects on replication, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

For information about disabling automatic site link bridging, see Enable or disable site link bridges.

For information about creating a site link bridge manually, see Create a site link bridge.

**Configuring preferred bridgehead servers**

When the KCC constructs the intersite replication topology, it automatically assigns one or more bridgehead servers for each site to ensure that directory changes only need to be replicated across a site link one time. It is recommended that you allow the KCC to make the bridgehead server assignments. You can make the bridgehead server assignments manually through Active Directory Sites and Services. However, doing so can potentially disrupt replication if one of your manually assigned bridgehead servers becomes unavailable. For more information, see "Active Directory Replication" at the Microsoft Windows Resource Kits Web site.

For information about manually configuring a bridgehead server, see Designate a preferred bridgehead server.

# Understanding the Global Catalog

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding the global catalog**
This section covers:

- The role of the global catalog
- Global catalog replication
- Customizing the global catalog
- Global catalogs and sites

# The role of the global catalog

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The role of the global catalog**

A global catalog is a domain controller that stores a copy of all Active Directory objects in a forest. The global catalog stores a full copy of all objects in the directory for its host domain and a partial copy of all objects for all other domains in the forest, as shown in the following figure.

The partial copies of all domain objects included in the global catalog are those most commonly used in user search operations. These attributes are marked for inclusion in the global catalog as part of their schema definition. Storing the most commonly searched upon attributes of all domain objects in the global catalog provides users with efficient searches without affecting network performance with unnecessary referrals to domain controllers.

You can manually add or remove other object attributes to the global catalog by using the Active Directory Schema snap-in. For more information, see Customizing the global catalog.

A global catalog is created automatically on the initial domain controller in the forest. You can add global catalog functionality to other domain controllers or change the default location of the global catalog to another domain controller. For more information, see Enable or disable a global catalog.

A global catalog performs the following directory roles:

- **Finds objects**

  A global catalog enables user searches for directory information throughout all domains in a forest, regardless of where the data is stored. Searches within a forest are performed with maximum speed and minimum network traffic.

  When you search for people or printers from the Start menu or choose the Entire Directory option within a query, you are searching a global catalog. Once you enter your search request, it is routed to the default global catalog port 3268 and sent to a global catalog for resolution. For more information, see Finding directory information and "Finding information in Active Directory" at the Microsoft Windows Resource Kits Web site.

- **Supplies user principal name authentication**

  A global catalog resolves user principal names (UPNs) when the authenticating domain controller does not have knowledge of the account. For example, if a user's account is located in example1.microsoft.com and the user decides to log on with a user principal name of user1@example1.microsoft.com from a computer located in example2.microsoft.com, the domain controller in example2.microsoft.com will be unable to find the user's account, and will then contact a global catalog to complete the logon process. For more information, see Active Directory naming.

- **Supplies universal group membership information in a multiple domain environment**

Unlike global group memberships, which are stored in each domain, universal group memberships are only stored in a global catalog. For example, when a user who belongs to a universal group logs on to a domain that is set to the Windows 2000 native domain functional level or higher, the global catalog provides universal group membership information for the user's account at the time the user logs on to the domain.

If a global catalog is not available when a user logs on to a domain set to the functional level of Windows 2000 native or higher, the computer will use cached credentials to log on the user if the user has logged on to the domain previously. If the user has not logged on to the domain previously, the user can only log on to the local computer. However, if a user logs on as the Administrator in the domain (Builtin Administrator account), the user can always log on to the domain, even when a global catalog is not available.

For more information about universal groups, see Group scope. For more information about universal groups and replication, see Global catalog replication and Global catalogs and sites.

**Note**

- When there is only one domain in a forest, it is not necessary for users to obtain universal group memberships from a global catalog when logging on. This is because Active Directory can detect that there are no other domains in the forest and will prevent a query to the global catalog for this information.

- **Validates object references within a forest**

  A global catalog is used by domain controllers to validate references to objects of other domains in the forest. When a domain controller holds a directory object with an attribute containing a reference to an object in another domain, this reference is validated using a global catalog.

# Global catalog replication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Global catalog replication**

Replication of the global catalog ensures that users throughout the forest have fast access to information about every object in the forest. The default attributes that make up the global catalog provide a baseline of the most commonly searched attributes. These attributes are replicated to the global catalog as part of normal Active Directory replication.

The replication topology for the global catalog is generated automatically by the Knowledge Consistency Checker (KCC). However, the global catalog is replicated only to other domain controllers that have been designated as global catalogs. Global catalog replication is affected both by the attributes marked for inclusion in the global catalog, and by universal group memberships.

**Adding attributes**

Active Directory defines a base set of attributes for each object in the directory. Each object and some of its attributes (such as universal group memberships) are stored in the global catalog. Using the Active Directory Schema snap-in, you can specify additional attributes to be kept in the global catalog.

In Windows 2000 forests, extending the partial attribute set causes a full synchronization of all object attributes stored in the global catalog (for all domains in the forest). In a large, multi-domain forest, this synchronization can cause significant network traffic. Between domain controllers enabled as global catalogs that are running Windows Server 2003, only the newly added attribute is replicated. For more information about adding attributes to the global catalog, see Customizing the global catalog.

**Preventing unpredictable access to global catalog data**

Special security consideration should be given when specifying permissions on domain data that is also replicated to the global catalog. When a user connects to a global catalog, an impersonation token is created for the user, which is used in subsequent access control decisions on the global catalog. The user's universal, global and domain local group memberships are represented in this token. However, only domain local groups from the domain that the domain controller hosting the global catalog (to which the user has connected) belongs to and of which the user is a member show up in the user's token. Domain local groups in the user's domain (and in other domains) of which the user is a member do not show up in the access token.

A global catalog stores a replicated, read-only copy of all objects in the forest and a partial set of each object's attributes, including the security descriptor for each object. The security descriptor contains a discretionary access control list (DACL), which specifies permissions on the object. When a user connects to a global catalog and tries to access an object, an access check is performed based on the user's token and the object's DACL. Any permissions specified in the object's DACL for domain local groups that are not from the domain that the domain controller hosting the global catalog (to which the user has connected) belongs to, will be ineffective because only domain local groups from the global catalog's domain of which the user is a member are represented in the user's access token. As a result, a user may be denied access when access should have been granted, or allowed access when access should have been denied.

As a best practice, you should avoid using domain local groups when assigning permissions on Active Directory objects, or be aware of the implications if you do use them. To prevent unauthorized access to global catalog data, use global groups or universal groups instead. For information about global and universal groups, see Group scope.

**How universal groups affect global catalog replication**

Groups with universal scope, and their members, are listed exclusively in the global catalog. Groups with global or domain local scope are also listed in the global catalog, but their members are not. This reduces the size of the global catalog and the replication traffic associated with keeping the global catalog up to date. You can improve network performance by using groups with global or domain local scope for directory objects that will change frequently.

When you first create a universal group, you do so from any domain that is set to the domain functional level of Windows 2000 or higher. The universal group resides in the domain directory partition in which it was created and is also replicated to the global catalog. Updates to the group membership are thereafter replicated to both the domain and the global catalog.

For more information about domain functional levels, see Domain and forest functionality.

# Customizing the global catalog

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Customizing the global catalog**

There may be instances where you will need to customize the global catalog to include additional attributes. However, you will want to carefully consider your options as changes to attributes can impact network traffic. By default, the global catalog contains an object's most common attributes for every object in the entire forest, which applications and users can query. For example, you can find a user by first name, last name, e-mail address, or other common properties of a user account.

To add additional searchable attributes to the global catalog, administrators can use the Active Directory Schema snap-in. For more information about adding additional attributes to the global catalog, see Add an attribute to the global catalog.

When determining whether or not to add an attribute to the global catalog, consider only adding additional attributes that are frequently queried and referenced by users or applications across the enterprise. Also consider how frequently an attribute gets updated during replication. Attributes that are stored in the global catalog are replicated to every global catalog in the forest. The smaller the attribute, the lower the impact of that replication. If the attribute is large, but very seldom changes, it will have a smaller replication impact than a small attribute that changes often.

For more information about attribute definitions, see the Active Directory Programmer's Guide at the Microsoft Web site.

**Important**

- It is strongly recommended that you use global groups or universal groups instead of domain local groups when specifying permissions on domain directory partition objects replicated to the global catalog. For more information, see Global catalog replication.

**Notes**

- In Windows 2000, adding a new attribute to the global catalog causes a full synchronization of all of the domain data from all of the domains in the forest. In a large, multi-domain Windows 2000 forest, this synchronization can cause significant network traffic. Between domain controllers enabled as global catalogs that are running Windows Server 2003, only the newly added attribute is replicated.

- When deciding whether or not to include an attribute in the global catalog, remember that you are trading increased replication and increased disk storage on global catalogs for potentially faster query performance.

# Global catalogs and sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Global catalogs and sites**

To optimize network performance in a multiple site environment, consider adding global catalogs for select sites. In a single site environment, a single global catalog is usually sufficient to cover common Active Directory queries. The following table will help you determine whether your multiple site environment will benefit using additional global catalogs.

| Use a global catalog when | Advantage | Disadvantage |
|---|---|---|
| A commonly used application in the site utilizes port 3268 to resolve global catalog queries. | Performance improvement | Additional network traffic due to replication |
| A slow or unreliable WAN connection is used to connect to other sites. Use the same failure and load distribution rules that you used for individual domain controllers to determine whether additional global catalog servers are necessary in each site. | Fault tolerance | Additional network traffic due to replication |
| Users in the site belong to a Windows 2000 domain running in native mode. In this case, all users must obtain universal group membership information from a global catalog server. If a global catalog is not located within the same site all logon requests must be routed over your WAN connection to a global catalog located in another site.<br><br>If a domain controller running Windows Server 2003 in the site has universal group membership caching enabled, then all users will obtain a current cached listing of their universal group memberships. | Fast user logons | Additional network traffic due to replication |

**Note**

- Network traffic related to global catalog queries generally use more network resources than normal directory replication traffic.

**Universal group membership caching**

Due to available network bandwidth and server hardware limitations, it may not be practical to have a global catalog in smaller branch office locations. For these sites, you can deploy domain controllers running Windows Server 2003, which can store universal group membership information locally.

Information is stored locally once this option is enabled and a user attempts to log on for the first time. The domain controller obtains the universal group membership for that user from a global catalog. Once the universal group membership information is obtained, it is cached on the domain controller for that site indefinitely and is periodically refreshed. The next time that user attempts to log on, the authenticating domain controller running Windows Server 2003 will obtain the universal group membership information from its local cache without the need to contact a global catalog.

By default, the universal group membership information contained in the cache of each domain controller will be refreshed every 8 hours. To refresh the cache, domain controllers running Windows Server 2003 will send a universal group membership confirmation request to a designated global catalog. Up to 500 universal group memberships can be updated at once. Universal group membership caching can be enabled using Active Directory Sites and Services. Universal group membership caching is site specific and requires that all domain controllers running Windows Server 2003 be located in that site to participate. For more information about how to enable this option, see Cache universal group memberships.

The following list summarizes potential benefits for caching universal group memberships in branch office locations:

- Faster logon times since authenticating domain controllers no longer need to access a global catalog to obtain universal group membership information.

- No need to upgrade hardware of existing domain controllers to handle the extra system requirements necessary for

hosting a global catalog.

- Minimized network bandwidth usage since a domain controller will not have to handle replication for all of the objects located in the forest.

**Note**

- You might want to continue using a global catalog in branch office locations if an application in a site is sending global catalog queries to port 3268. Universal group membership caching does not intercept calls made to port 3268.

# Interoperating with DNS and Group Policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Interoperating with DNS and Group Policy**

This section covers:

- DNS integration
- Group Policy integration

# DNS integration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS integration**

Active Directory is integrated with DNS in the following ways:

- Active Directory and Domain Name System (DNS) have the same hierarchical structure.

  Although separate and implemented differently for different purposes, an organization's namespace for DNS and Active Directory have an identical structure. For example, microsoft.com is a DNS domain and an Active Directory domain. For more information, see Namespace planning for DNS.

- DNS zones can be stored in Active Directory.

  If you are using the Windows Server 2003 DNS Server service, primary zone files can be stored in Active Directory for replication to other Active Directory domain controllers. For more information, see Active Directory integration.

- Active Directory uses DNS as a locator service, resolving Active Directory domain, site, and service names to an IP address.

  To log on to an Active Directory domain, an Active Directory client queries their configured DNS server for the IP address of the LDAP service running on a domain controller for a specified domain. For more information about how Active Directory clients rely on DNS, see Locating a domain controller.

**Note**

- You can use **Dcdiag.exe** and **Netdiag.exe** to troubleshoot client computers that cannot locate a domain controller. These tools can help determine both server and client DNS misconfigurations. For more information, see article Q265706, "DCDiag/NetDiag Facilitate Join and DC Creation" in the Microsoft Knowledge Base. For a brief description of support tools, see Active Directory support tools.

While Active Directory is integrated with DNS and shares the same namespace structure, it is important to distinguish the difference between them:

- DNS is a name resolution service.

  DNS clients send DNS name queries to their configured DNS server. The DNS server receives the name query and either resolves the name query through locally stored files or consults another DNS server for resolution. DNS does not require Active Directory to function.

- Active Directory is a directory service

  Active Directory provides an information repository and services to make information available to users and applications. Active Directory clients send queries to domain controllers using the Lightweight Directory Access Protocol (LDAP). In order to locate a domain controller, an Active Directory client queries DNS. Active Directory requires DNS to function.

For a checklist on deploying DNS for Active Directory, see Checklist: Deploying DNS for Active Directory.

For information about configuring DNS servers for Active Directory, see Configure a DNS server for use with Active Directory.

# Group Policy integration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy integration**

Group Policy can be used to define default settings that will be automatically applied to user and computer accounts in Active Directory. Policy settings can be used to manage desktop appearance, assign scripts, redirect folders from local computers to network locations, determine security options and control what software can be installed on particular computers and what software is available to particular groups of users.

Here are a few examples of how Group Policy settings can be used in Active Directory:

- Set the minimum password length and the maximum length of time that a password will remain valid. This can be configured for an entire domain.
- Administrators can automatically install an application on every computer in a particular domain or on all computers assigned to a particular group in a particular site. For example, you could automatically install Microsoft Outlook on every computer in the domain and automatically install Microsoft Excel only on those computers belonging to the Accounting group in a particular site.
- Logon, logoff, startup, and shutdown scripts can be assigned based on the locations of the computer and user accounts in Active Directory.
- If members of a particular group often use different computers, administrators can install the necessary applications on each of those computers.
- Any user's My Documents folder can be redirected to a network location. Users can then gain access to their documents from any computer on the network.

Policy settings are stored in Group Policy objects. Group Policy settings from more than one Group Policy object can be applied to a particular site, domain, or organizational unit. For example, if a site contains three domains, one Group Policy object could control computer configurations for the entire site. A separate policy for each domain could determine specific security settings for the computers in each domain. If each domain contains an Accounting and a Marketing organizational unit, additional Group Policy objects could determine what software is installed on the computers used by the Accounting and Marketing groups throughout the entire site.

This ability to automatically configure and secure computers throughout your organization by selectively applied Group Policy objects is a very powerful administrative tool. For more information about controlling software installation with Group Policy and how to create a Group Policy object, see Group Policy (pre-GPMC).

You can use security groups to filter how Group Policy settings are applied to collections of users and computers belonging to a particular site, domain, or organizational unit. For more information about security groups, see Group types. For general information about Group Policy, see Group Policy overview.

# Understanding Schema

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding schema**
This section covers:

- Schema
- Schema classes and attributes
- Schema object names
- Deactivating a class or attribute
- Extending the schema

# Schema

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Schema**
The Active Directory schema contains the definitions for all objects in the directory. Every new directory object you create is validated against the appropriate object definition in the schema before being written to the directory. The schema is made up of object classes and attributes. The base (or default) schema contains a rich set of object classes and attributes to meet the needs of most organizations, and is modeled after the International Standards Organization (ISO) X.500 standard for directory services. Because it is extensible, you can modify and add classes and attributes to the base schema. However, you should carefully consider each change you make, because extending the schema affects the entire network. For more information, see Extending the schema.

**How directory objects are defined**
In the schema, an object class represents a category of directory objects, such as users, printers, or application programs, that share a set of common characteristics. The definition for each object class contains a list of the schema attributes that can be used to describe instances of the class. For example, the User class has attributes such as givenName, surname, and streetAddress. When you create a new user in the directory the user becomes an instance of the User class, and the information you enter about the user becomes instances of the attributes. For more information, see Schema classes and attributes.

**How the schema is stored**
Each forest can contain only one schema, which is stored in the schema directory partition. The schema directory partition, along with the configuration directory partition, is replicated to all domain controllers in a forest. However, a single domain controller, the schema master, controls the structure and content of the schema. For more information about the schema master, see Operations master roles.

**Schema cache**
To improve performance on schema operations (such as new object validation), each domain controller holds a copy of the schema in memory (in addition to the copy it holds on disk). This cached version is automatically updated (after a small time interval) each time you update the schema. Or, you can reload the updated schema to cache manually for immediate effect. For more information, see Reload the schema.

**Securing the schema**
Like every object in Active Directory, schema objects are protected from unauthorized use by access control lists (ACLs). By default, only members of the Schema Admins group have write access to the schema. So, to extend the schema you must be a member of the Schema Admins group. The only default member of the Schema Admins group is the administrator account in the root domain of the forest. You should restrict membership in the Schema Admins group because extending the schema improperly can have serious consequences to your network. For more information, see Access control in Active Directory and Default groups.

For more information about the schema, see "Active Directory Schema" at the Microsoft Windows Resource Kits Web site and at the Microsoft MSDN Web site.

# Schema classes and attributes

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Schema classes and attributes**

Every directory object you create is an instance of an object class contained in the schema. Each object class contains a list of associated attributes that determine the information the object can contain. Classes and attributes are defined independently, so that a single attribute can be associated with multiple classes. All schema classes and attributes are defined by the classSchema and attributeSchema objects, respectively.

**Classes**

ClassSchema objects are used to define classes in the schema. A classSchema object provides the template for building directory objects of that class. Examples of classSchema include *User* and *Server*. A classSchema object contains, among other things, the following information:

- Class type (structural, abstract, or auxiliary)
- Common name and Lightweight Directory Access Protocol (LDAP) display name
- Lists of the "must contain" and "may contain" attributes for instances of the object
- Relative distinguished name attribute
- A list of possible parent classes

**Class types**

Three different types of classes exist in the schema:

| Class type | Purpose |
|---|---|
| **Structural** | Used to instantiate objects (users, servers and so on) in the directory. |
| **Abstract** | Provides templates for deriving structural classes |
| **Auxiliary** | Contains predefined lists of attributes that can be included in structural and abstract classes. |

**Note**

- With the Windows Server 2003 family, the inetOrgPerson class is now a part of base schema. This class can be used as a security principal in the same manner as the user class.

**Attributes**

AttributeSchema objects are used to define attributes in the schema. An attributeSchema object determines the allowable contents and syntax for instances of that attribute in the directory. Examples of attributeSchema include *User-Principal-Name* and *Telex-Number*. An attributeSchema object contains, among other things, the following information:

- Common name and LDAP display name
- Syntax rules
- Data constraints (single versus multivalued, minimum, and maximum values)
- Whether and how the attribute is indexed

**Single and multivalued attributes**

Attributes can be single-valued or multivalued. An instance of a single-valued attribute can can only contain a single value. An

instance of a multivalued attribute can contain multiple values of uniform syntax. A multivalued attribute stores no information about ordering of the attributes it contains. Each value of a multivalue attribute must be unique.

**Indexed attributes**

Both multivalued and single valued attributes can be indexed to help improve the performance of queries on that attribute. (Indexing does not apply to classes.) Attributes are marked for indexing based on their schema definition. Indexing an attribute also allows users to use wildcards (*) as prefixes and suffixes when specifying a search string. When you mark an attribute as indexed, all instances of the attribute are added to the index, not just the instances that are members of a particular class. Indexing attributes, particularly multivalued attributes, can negatively affect replication and object creation time, as well as directory database size. So, it is recommended that you only index commonly used attributes. For more information, see Index an attribute in Active Directory.

For more information about the schema, see "Active Directory Schema" at the Microsoft Windows Resource Kits Web site and the Microsoft MSDN Web site.

# Schema object names

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Schema object names**
When extending the schema, you need to know how to reference schema objects. Both class and attribute schema objects can be referenced in several ways:

- Lightweight Directory Access Protocol (LDAP) display name
- common name
- object identifier

**LDAP display name**
The Active Directory Schema snap-in and other administrative tools display the LDAP display name of objects. Programmers and system administrators use LDAP display names to reference objects programmatically. The LDAP display name typically consists of two or more words combined. When the name consists of multiple words, subsequent words in the name are identified using capitalization. Example LDAP display names are mailAddress and machinePasswordChangeInterval. The LDAP display name is guaranteed to be unique for each object.

**Common name**
The common name is a more readable version of the LDAP display name. The common names of the two attributes used in the previous example are SMTP-Mail-Address and Machine-Password-Change-Interval. Common names are guaranteed to be unique within a container.

**Object identifier**
An object identifier (also known as OID) is issued by an issuing authority such as the International Organization for Standardization (ISO) or the American National Standards Institute (ANSI). For example, the object identifier for the SMTP-Mail-Address attribute is 1.2.840.113556.1.4.786. Every object identifier must be unique. For more information about ISO, see the International Organization for Standardization Web site.

When extending your schema, you can register new object identifiers through Microsoft. For more information, see the Microsoft Web site.

**Schema object naming rules**
To help standardize schema naming conventions, Microsoft strongly suggests that schema extensions adhere to naming rules for both the LDAP Display Name and the Common Name. To qualify as "Certified for Windows," an application that extends the schema must adhere to these naming rules. For more information, see the Active Directory chapter of the certification program documentation at the Microsoft Web site. See also the Active Directory Programmer's Guide at the Microsoft Web site.

**Message queuing aliases**
A message queuing alias is an object in Active Directory that can be used to reference queues which might not be listed in Active Directory. For example, a queuing alias can be used to reference a private queue within the context of a distribution list. You can create a queuing alias by using Active Directory Users and Computers. Using queuing aliases provides the following benefits:

- When a queuing alias object is deleted, the alias is automatically removed from all distribution lists that reference the alias.
- A queue referenced by a queuing alias can be changed without changing the alias.
- Queuing aliases can be used to reference a queue not listed in the directory service, including private queues or queues from another organization.
- Queuing aliases can be used to send http messages by referencing the destination queue using a direct format name.

A queuing alias object has a single attribute, a format name that references a queue. Queuing aliases can contain public,

private, and direct format names. The format name for the queue cannot exceed 255 characters. For more information, see Using Message Queuing.

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Deactivating a class or attribute

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deactivating a class or attribute**
Domain controllers running Windows Server 2003 do not permit the deletion of classes or attributes, but they can be deactivated if they are no longer needed or if there was an error in the original definition. A deactivated class or attribute is considered *defunct*. A defunct class or attribute is unavailable for use; however, it is easily reactivated.

If your forest has been raised to the Windows Server 2003 functional level, you can reuse the object identifier (governsId and attributeId values), the ldapDisplayName, and the schemaIdGUID that were associated with the defunct class or attribute. This allows you to change the object identifier associated with a particular class or attribute. The only exception to this is that an attribute used as a rdnAttId of a class continues to own its attributeId, ldapDisplayName, and schemaIdGuid values even after being deactivated (for example, those values cannot be reused).

If your forest has been raised to the Windows Server 2003 functional level, you can deactivate a class or attribute and then redefine it. For example, the Unicode String syntax of an attribute called SalesManager could be changed to Distinguished Name. Since Active Directory does not permit you to change the syntax of an attribute after it has been defined in the schema, you can deactivate the SalesManager attribute and create a new SalesManager attribute that reuses the same object identifier and LDAP display name as the old attribute, but with the desired attribute syntax. You must rename the deactivated attribute before it can be redefined.

For more information about forest functionality, see Domain and forest functionality.

**Notes**

- Classes and attributes added to the base schema can be deactivated without raising the forest functional level. However, they can be redefined only in forests raised to the Windows Server 2003 functional level or higher.
- Default schema attributes or classes in the base schema cannot be deactivated if bit 4 of the systemFlags attribute is set to 1. Only attributes or classes where bit 4 of the systemFlags attribute is equal to zero can be deactivated.

Object identifiers must be unique. Mistyping a number when entering an object identifier can cause a conflict between the invalid object identifier and a legitimate object identifier that is registered by an application. When installing an application that adds an attribute or class, the application may need to use the mistyped object identifier for one of its legitimate schema extensions. You can correct object identifier conflicts in forests that are set to the Windows Server 2003 functional level. To correct the conflict, deactivate the attribute or class with the incorrect object identifier. The application installation program will then be able to create the new attribute or class using the correct object identifier.

Before deactivating a class, consider the following:

- You can deactivate a class only if that class is not specified as a subClassOf, auxiliaryClass, systemAuxiliaryClass, possSuperiors, or systemPossSuperiors of any existing active class.
- You cannot use a defunct class in definitions of new classes, and you cannot add it to existing class definitions.
- You cannot create objects that are instances of the defunct class or modify existing instances of the class. However, the instances of the defunct class become available again for modification when the defunct class is reactivated.

Before deactivating an attribute, consider the following:

- You can deactivate an attribute only if the attribute is not specified as a systemMustContain, mustContain, systemMayContain, mayContain, or rdnAttId of any existing active class.
- You cannot use a defunct attribute in definitions of new classes, and you cannot add it to existing class definitions.
- You cannot read, modify, or delete instances of the defunct attribute present in existing objects. However, the instances of the defunct attribute become available when the defunct attribute is reactivated.

- To purge the directory of instances of an attribute you must delete the instances before deactivating the attribute.

Classes and attributes can be deactivated programmatically (recommended) or by using the Active Directory Schema snap-in. To deactivate a class or attribute using the Active Directory Schema snap-in, see Deactivate a class or attribute. For information about programmatically deactivating classes and attributes, see the Active Directory Programmer's Guide at the Microsoft Web site.

**Reactivating a class**
A defunct class can be reactivated. However, a defunct class cannot be reactivated unless the attributes referenced in its mustContain, systemMustContain, mayContain, and systemMayContain properties are active and the classes referenced in its subClassOf, auxiliaryClass, systemAuxiliaryClass, possSuperiors, and systemPossibleSuperiors properties are also active.

Further, a defunct class cannot be reactivated if the values of the following attributes collide with an already active attribute or class: ldapDisplayName, attributeId, governsId, or schemaIdGuid.

To reactive a defunct class, see Reactivate a class or attribute.

**Reactivating an attribute**
An defunct attribute can be reactivated. However, a defunct attribute cannot be reactivated if the values of the following attributes collide with an already active attribute or class: ldapDisplayName, attributeId, governsId, schemaIdGuid, or mapiId.

To reactive a defunct attribute, see Reactivate a class or attribute.

# Extending the schema

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Extending the schema**

When the set of classes and attributes in the base Active Directory schema do not meet your needs, you can extend the schema by modifying or adding classes and attributes. You should only extend the schema when absolutely necessary. The easiest way to extend the schema is through the Schema Microsoft Management Console (MMC) snap-in. You should always develop and test your schema extensions in a test lab before moving them to your production network.

**Before extending the schema**

Before extending the schema, review these key points:

| | |
|---|---|
| Check the base schema first | Verify that no existing class or attribute in the base schema meets your application or data needs. For the complete set of classes and attributes in the base schema, see the Microsoft Web site. |
| Review schema documentation | For detailed information about extending the schema, see the Active Directory Programmer's Guide at the Microsoft Web site and "Active Directory Schema" at the Microsoft Windows Resource Kits Web site. |
| Schema modifications are global | When you extend the schema, the changes apply to every domain controller in the entire forest. |
| Schema classes related to the system cannot be modified | You cannot modify default system classes (those classes required for Windows to run) within the schema. However, directory-enabled applications that modify the schema may add new classes that you can modify. |
| Schema extensions are not reversible | Attributes or classes cannot be removed after creation. At best, they can be modified or deactivated. For more information, see Deactivating a class or attribute. |
| Obtain valid object identifiers | Every class and attribute in the schema must have a unique and valid object identifier (also known as OID). Do not create arbitrary object identifiers or recycle old object identifiers. For information about obtaining valid object identifiers, see Schema object names. |
| Document your changes | If you do decide to extend the schema, be sure to document your changes. |

**How to extend the schema**

You can modify the schema through graphical user interface (GUI) tools, command-line tools, and through scripting. The easiest way to modify the schema is by using the Active Directory Schema snap-in in Microsoft Management Console (MMC), which is a GUI tool for schema management. For information about installing the Active Directory Schema snap-in, see Install the Active Directory Schema snap-in. Modifying the schema through scripting requires programming knowledge and familiarity with the Active Directory Service Interfaces (ADSI). For more information, see the Active Directory Programmer's Guide and Extending the Schema at the Microsoft MSDN Web site.

For more information about schema administration tools, see Administration tools for the Active Directory schema.

For more information about extending the schema, see Modify an existing schema class or attribute definition and Add a new schema class or attribute definition. For information about deactivation and reactivation, see Deactivating a class or attribute, Deactivate a class or attribute and Reactivate a class or attribute.

**Using a test forest**

A very simple way to avoid damaging or costly schema mistakes in your production forest is to first test your schema extensions on a test forest. By using a test environment, you can identify any potential problems in your plan before they affect your users and your production environment.

After making schema changes in a test forest, you can reinstall the default schema by demoting each domain controller in the test forest to which the schema changes have replicated. Then, use the Active Directory Installation Wizard to reinstall Active Directory on the servers. This procedure is practical only in a test environment.

# Deploying Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying Active Directory**
This section covers:

- Deployment resources
- Using the Active Directory Installation Wizard
- Creating an additional domain controller
- Creating a new domain tree
- Creating a new child domain
- Creating a new forest
- Upgrading from Windows NT or Windows 2000

# Deployment resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deployment resources**

To deploy domain controllers running Windows Server 2003, it is recommended that you use the *Microsoft Windows Server 2003 Deployment Kit*, which is available online at the Microsoft Windows Resource Kits Web site.

The online deployment kit includes case studies and the necessary information for deploying Windows Server 2003 Active Directory in networks that have domain controllers running Windows NT 4.0 or Windows 2000. For complete information, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003" at the Microsoft Windows Resource Kits Web site.

If your network includes branch offices, see "Designing the Site Topology" at the Microsoft Windows Resource Kits Web site. This online guide helps plan Active Directory deployment when there are branch office sites connected with slow network links.

For information about monitoring Active Directory, see "Monitoring Active Directory" at the Microsoft Windows Resource Kits Web site.

# Using the Active Directory Installation Wizard

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using the Active Directory Installation Wizard**
The Active Directory Installation Wizard installs and configures domain controllers, which provide network users and computers access to the Active Directory directory service. You can install Active Directory on any member server (except those with restrictive license agreements) using the Active Directory Installation Wizard. Using the wizard, you will define one of the following roles for the new domain controller:

- New forest (also a new domain)

  For a checklist about creating a new forest, see Checklist: Creating a new forest.

- New child domain

  For a checklist about creating a child domain, see Checklist: Creating a new child domain.

- New domain tree in an existing forest

  For a checklist about creating a new domain tree, see Checklist: Creating a new domain tree.

- An additional domain controller in an existing domain.

  For a checklist about creating an additional domain controller, see Checklist: Creating an additional domain controller in an existing domain.

Before using the Active Directory Installation Wizard, consider DNS configuration and support for existing applications.

**DNS configuration**
By default, the Active Directory Installation Wizard attempts to locate an authoritative DNS server for the new domain from its list of configured DNS servers that will accept a dynamic update of a service (SRV) resource record. If found, all the appropriate records for the domain controller are automatically registered with the DNS server after the domain controller is restarted.

If a DNS server that can accept dynamic updates is not found, either because the DNS server does not support dynamic updates or dynamic updates are not enabled for the domain, then the Active Directory Installation Wizard will take the following steps to ensure that the installation process is completed with the necessary registration of the SRV resource records:

1. The DNS service is installed on the domain controller and is automatically configured with a zone based on the Active Directory domain.

   For example, if the domain that you chose for your first domain in the forest is example.microsoft.com, then a zone rooted at the DNS domain name of example.microsoft.com is added and configured to use the DNS Server service on the new domain controller.

2. A text file containing the appropriate DNS resource records for the domain controller is created.

   The file called Netlogon.dns is created in the systemroot\System32\Config folder and contains all the records needed to register the resource records of the domain controller. Netlogon.dns is used by the Net Logon service and supports Active Directory on servers running non-Windows Server 2003 DNS.

   If you are using a DNS server that supports the SRV resource record but does not support dynamic updates (such as a UNIX-based DNS server or a Windows NT DNS server), you can import the records in Netlogon.dns into the appropriate primary zone file to manually configure the primary zone on that server to support Active Directory.

If no DNS servers are available on the network, you can choose the option to automatically install and configure a local DNS

server when you install Active Directory using the Active Directory Installation Wizard. The DNS server will be installed on the server on which you are running the wizard, and the server's preferred DNS server setting will be configured to use the new local DNS server.

Before running the Active Directory Installation Wizard, ensure that the authoritative DNS zone allows dynamic updates and that the DNS server hosting the zone supports the DNS SRV resource record. For more information, see Checklist: Verifying DNS before installing Active Directory.

For more information, see Configure a DNS server for use with Active Directory. For general information about DNS integration with Active Directory, see DNS integration.

**Support for existing applications**

On servers running Windows NT 4.0 and earlier, read access for user and group information is assigned to anonymous users so that existing applications and some non-Microsoft applications function correctly.

On servers running Windows 2000 and Windows Server 2003, members of the Anonymous Logon group have read access to this information only when the group is added to the Pre-Windows 2000 Compatible Access group.

Using the Active Directory Installation Wizard, you can choose if you want the Anonymous Logon group and the Everyone security groups to be added to the Pre-Windows 2000 Compatible Access group by selecting the **Permissions compatible with pre-Windows 2000 Server operating systems** option. To prevent members of the Anonymous Logon group from gaining read access to user and group information, choose the **Permissions compatible only with Windows Server 2003 operating systems** option.

When upgrading a domain controller from Windows 2000 to a Windows Server 2003 operating system, if the Everyone security group is already a member of the pre-Windows 2000 Compatible Access security group (indicating backward compatibility settings), the Anonymous Logon security group will be added as a member of the pre-Windows 2000 Compatible Access security group during the upgrade.

You can manually switch between the backward compatible and high-security settings on Active Directory objects by adding the Anonymous Logon security group to the pre-Windows 2000 Compatible Access security group using Active Directory Users and Computers. For more information about adding members to a group, see Add a member to a group. For more information about default groups, see Default groups and Special identities.

**Note**

- If you select the **Permissions compatible only with Windows Server 2003 operating systems** check box when installing Active Directory and find that your applications are not functioning correctly, try resolving the problem by manually adding the special group Everyone to the Pre-Windows 2000 Compatible Access security group, and then restarting the domain controllers in the domain. Once you have upgraded to applications compatible with the Windows Server 2003 family, you should return to the more secure Windows Server 2003 operating system configuration by removing the Everyone group from the Pre-Windows 2000 Compatible Access security group and restarting the domain controllers in the affected domain.

# Creating an additional domain controller

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating additional domain controllers**

If you already have one domain controller in a domain, you can add additional domain controllers to the domain to improve the availability and reliability of network services. Adding additional domain controllers can help provide fault tolerance, balance the load of existing domain controllers, and provide additional infrastructure support to sites.

More than one domain controller in a domain makes it possible for the domain to continue to function if a domain controller fails or must be disconnected. Multiple domain controllers can also improve performance by making it easier for clients to connect to a domain controller when logging on to the network. You can add additional domain controllers over the network or from backup media.

Before adding domain controllers you should thoroughly understand Active Directory and the requirements necessary to set up additional domain controllers in an existing domain. For more information, see Checklist: Creating an additional domain controller in an existing domain and Create an additional domain controller.

**Using backup media to create additional domain controllers**

With Windows 2000, the only way you can create an additional domain controller in an existing domain is by replicating the entire directory database to the new domain controller. With low network bandwidth or a large directory database, this replication can take hours or days to complete. With servers running Windows Server 2003, you can create an additional domain controller using a *restored backup* taken from a domain controller running Windows Server 2003. This backup can be stored on any backup media (tape, CD, or DVD) or a shared resource.

Using restored backup files to create an additional domain controller will greatly reduce the network bandwidth used when installing Active Directory over a shared resource; however, network connectivity is still necessary so that all new objects and recent changes to existing objects are replicated to the new domain controller.

It is recommended that you use the most recent backup available. Older backups require more network bandwidth for replication. The backup used cannot be older than the tombstone lifetime of the domain, which is set to a default value of 60 days (180 days in a forest that is created on a server running Windows Server 2003 with Service Pack 1 [SP1]).

If a domain controller that was backed up contained an application directory partition, it will not be restored on the new domain controller. To manually create an application directory partition on a new domain controller, see Create or delete an application directory partition.

When adding an additional domain controller using backup media, a System State backup taken only from a domain controllers running Windows Server 2003 can be used once it has been restored. For more information about how to restore a System State backup, see Restore System State data.

For general information about restoring backups, see Authoritative, primary, and normal restores.

# Creating a new domain tree

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating a new domain tree**

Create a new domain tree only when you need to create a domain whose DNS namespace is not related to the other domains in the forest. This means that the name of the tree root domain (and all of its children) does not have to contain the full name of the parent domain. A forest can contain one or more domain trees. For information about how to create a new domain tree, see Create a new domain tree.

Before you create a new domain tree, consider whether another forest is necessary. Multiple forests provide isolation of the schema and configuration directory partitions, separate security boundaries, administrative autonomy, and the flexibility to use an independent namespace design for each forest. Adding an additional forest does, however, increase the complexity and cost of implementing and maintaining your deployment. Therefore, the decision to create a new forest should not be made lightly. Create a forest where you have a specific deployment requirement. For example, create a forest when you need a separate security boundary or if you need to isolate schema changes. These requirements are not met by the creation of a new domain tree. For more information, see either Creating a new forest. or "Design Considerations for Delegation of Administration in Active Directory" on the Microsoft Web site.

# Creating a new child domain

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating a new child domain**

Create a new child domain when you want to create a domain that shares a contiguous namespace with one or more domains. This means that the name of the new domain contains the full name of the parent domain. For example, sales.microsoft.com would be a child domain of microsoft.com. As a best practice, you create new domains as children of the forest root domain.

You can create a new child domain by creating a new domain under a parent domain using the Active Directory Installation Wizard. For information about how to create a new child domain, see Create a new child domain.

After you create the child domain, you can create additional domain controllers in the child domain for fault tolerance and high availability of Active Directory. For more information, see Creating an additional domain controller.

# Creating a new forest

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating a new forest**

When you create the first domain controller in your organization, you are creating the first domain (also called the *forest root* domain) and the first forest.

The top-level Active Directory container is called a forest. A forest consists of one or more domains that share a common schema and global catalog. An organization can have multiple forests.

A forest is the security and administrative boundary for all objects that reside within the forest. In contrast, a domain is the administrative boundary for managing objects, such as users, groups, and computers. In addition, each domain has individual security policies and trust relationships with other domains.

Multiple domain trees within a single forest do not form a contiguous namespace; that is, they have noncontiguous DNS domain names. Although trees in a forest do not share a namespace, a forest does have a single root domain, called the forest root domain. The forest root domain is, by definition, the first domain created in the forest. The Enterprise Admins and Schema Admins groups are located in this domain. By default, members of these two groups have forest-wide administrative credentials.

**When to create a new forest**

A first step in the Active Directory design process is to determine how many forests your organization needs. For most organizations, a single forest design is the preferred model and the simplest to administer. However, a single forest may not be practical for every organization.

With a single forest, users do not need to be aware of directory structure because all users see a single directory through the global catalog. When adding a new domain to a forest, no additional trust configuration is required because all domains in a forest are connected by two-way, transitive trusts. In a forest with multiple domains, configuration changes need be applied only once to update all domains.

However, there are scenarios in which you might want to create more than one forest:

- **When upgrading a Windows NT domain to a Windows Server 2003 forest.** You can upgrade a Windows NT domain to become the first domain in a new Windows Server 2003 forest. To do this, you must first upgrade the primary domain controller in that domain. Then, you can upgrade backup domain controllers, member servers, and client computers at any time.

  You can also keep a Windows NT domain and create a new Windows Server 2003 forest by installing Active Directory on a member server running Windows Server 2003. For more information, see Upgrading from a Windows NT domain.

- **To provide administrative autonomy.** You can create a new forest when you need to segment your network for purposes of administrative autonomy. Administrators who currently manage the IT infrastructure for autonomous divisions within the organization may want to assume the role of forest owner and proceed with their own forest design. However, in other situations, potential forest owners may choose to merge their autonomous divisions into a single forest to reduce the cost of designing and operating their own Active Directory or to facilitate resource sharing. Another alternative is to provide for some delegation of administrative authority that enables the benefits of both approaches. For more information, see "Best Practice Active Directory Design for Managing Windows Networks" on the Microsoft Web site or "Design Considerations for Delegation of Administration in Active Directory", also available on the Microsoft Web site.

**Operations master roles in a new forest**

When you create the first forest in your organization, all five operations master roles are automatically assigned to the first domain controller in the forest. As new child domains are added to the forest, the first domain controller in each of the new child domains is automatically assigned the following roles:

- Relative identifier master

- Primary domain controller (PDC) emulator

- Infrastructure master

Because there can be only one schema master and one domain naming master in a forest, these roles remain in the forest root domain. In an Active Directory forest with only one domain and one domain controller, that domain controller owns all the operations master roles. For more information, see Operations master roles.

**Adding new domains to your forest**
A domain stores only the information about objects located in that domain, so by creating multiple domains within a new forest, you are partitioning or segmenting Active Directory to better serve a disparate user base.

The easiest domain structure to administer is a single domain within a single forest. When planning, you should start with a single domain and only add additional domains when the single domain model no longer meets your needs. For more information about creating domains, see Domains.

**Before creating a new forest**
Active Directory requires DNS to function and both share the same hierarchical domain structure. For example, microsoft.com is a DNS domain and an Active Directory domain. Because of the reliance that Active Directory has on DNS you must thoroughly understand Active Directory and DNS concepts before creating a new forest. For more information, see Checklist: Creating a new forest.

# Upgrading from Windows NT or Windows 2000

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrading from Windows NT or Windows 2000**
This section covers:

- Upgrading overview
- Upgrading from a Windows NT domain
- Upgrading from a Windows 2000 domain
- Converting groups

# Upgrading overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrading overview**

The Active Directory® directory service is compatible with Microsoft® Windows NT® and supports a mix of operations that support domain controllers running Windows NT 4.0, Windows® 2000, and Windows Server 2003. This allows you to upgrade domains and computers at your own pace, based on your organization's needs.

Active Directory supports the NTLM protocol used by Windows NT. This enables authorized users and computers from a Windows NT domain to log on and access resources in Windows 2000 or Windows Server 2003 domains. To clients running Windows 95, Windows 98, or Windows NT that are not running Active Directory client software, a Windows 2000 or Windows Server 2003 domain appears to be a Windows NT 4.0 domain. For more information, see Active Directory clients.

The upgrade to Active Directory can be gradual and performed without interrupting operations. If you follow domain upgrade recommendations, it should never be necessary to take a domain offline to upgrade domain controllers, member servers, or workstations. When upgrading a Windows NT domain, you must upgrade the primary domain controller first. You can upgrade member servers and workstations at any time after this. For more information, see Upgrading from a Windows NT domain.

Active Directory allows upgrading from any Windows NT 4.0 domain model and supports both centralized and decentralized models. The typical master or multiple-master domain model can be easily upgraded to an Active Directory forest.

# Upgrading from a Windows NT domain

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrading from a Windows NT domain**
See the following recommended steps for upgrading from a Windows NT domain.

**Plan and implement a namespace and DNS infrastructure**
Because Domain Name System (DNS) is required for Active Directory, ensure that you have designed a DNS and Active Directory namespace and have either configured DNS servers or are planning to use the Active Directory Installation Wizard to automatically install the DNS service. For more information, see DNS integration and Namespace planning for DNS.

**Determine forest functionality**
Forest functionality determines the type of Active Directory features that can be enabled within the scope of a single forest. Each forest functional level has a set of specific minimum requirements for the versions of operating systems that domain controllers throughout the forest can run. For example, the Windows Server 2003 forest functional level requires that all domain controllers run a product in the Windows Server 2003 family.

When you are upgrading your first Windows NT domain to become the first Windows Server 2003 domain, it is recommended that you set the forest functional level to the Windows Server 2003 interim forest functional level, which you will be prompted to set during the upgrade. This level contains all of the features used in the Windows 2000 forest functional level, including the following two important Active Directory replication enhancements:

- Improved replication efficiency and scalability. For more information, see Replication overview.
- Linked value replication for more efficient replication of group memberships. For more information, see How replication works.

For more information, see New features for Active Directory.

The Windows Server 2003 interim functional level is an option only when upgrading the first Windows NT domain to a new forest and can be manually configured after the upgrade. For more information about how to manually set this functional level, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003" at the Microsoft Windows Resource Kits Web site. The Windows Server 2003 interim forest functional level only supports domain controllers running Windows Server 2003 and Windows NT, not domain controllers running Windows 2000. You cannot install Active Directory on servers running Windows 2000 in a forest with the functional level set to Windows Server 2003 interim. For more information about forest functionality, see Domain and forest functionality.

**Upgrade the primary domain controller**
The first server you must upgrade is the primary domain controller (PDC) running Windows NT 4.0 or earlier. During the upgrade, the Active Directory Installation Wizard requires that you choose to join an existing domain tree or forest or create a new domain tree or forest. If you decide to join an existing domain tree, you must provide a reference to the desired parent domain. For more information, see Checklist: Creating a new forest, Checklist: Creating a new child domain, or Checklist: Creating a new domain tree.

The Active Directory Installation Wizard installs all the necessary components on the domain controller, such as the directory data store and the Kerberos V5 protocol authentication software. Once the Kerberos V5 protocol is installed, the installation process starts the authentication service and the ticket granting service.

If this is a new child domain, then a transitive trust relationship is established with the parent domain. Eventually, the domain controller from the parent domain copies all schema and configuration information to the new child domain controller. The existing Security Accounts Manager (SAM) objects will be copied from the registry to the new data store. These objects are security principals.

During the upgrade, container objects are created to contain the accounts and groups from the Windows NT domain. The container objects are named Users, Computers, and Builtin and are displayed as folders in Active Directory Users and Computers. User accounts and predefined groups are routed to the Users container. Computer accounts are routed to the Computers container. Built-in groups are routed to the Builtin container.

Existing Windows NT 4.0 and earlier groups are located in different folders depending on the nature of the group. Windows NT

4.0 and earlier built-in local groups (such as Administrators and Server Operators) are located in the Builtin container. Windows NT 4.0 and earlier global groups (such as Domain Admins), any user-created local groups, and global groups are located in the Users container.

The upgraded PDC can synchronize security principal changes to remaining backup domain controllers (BDCs) running Windows NT 4.0 or earlier. The upgraded PDC is recognized as the domain master by BDCs running Windows NT Server 4.0 or earlier.

The upgraded domain controller is a fully functional member of the forest. The new domain is added to the domain and site structure and all domain controllers receive the notification that a new domain has joined the forest.

**Upgrade any remaining backup domain controllers**
Once you have upgraded the PDC running Windows NT 4.0 or earlier, you can proceed to upgrade all remaining BDCs. During the upgrade process, you might want to remove one BDC from the network to guarantee a backup if any problems develop. This BDC will store a secure copy of your current domain database.

If any problems arise during the upgrade, you can remove all domain controllers running Windows Server 2003 from the production environment, and then bring the BDC back into your network and make it the new PDC. This new PDC will then replicate its data throughout the domain so that the domain is returned to its previous state.

The only drawback to this method is that all changes that were made while the safe BDC was offline are lost. To minimize this loss, you could periodically turn the safe BDC on and off again (when the domain is in a stable state) during the upgrade process to update its safe copy of the directory.

If a domain controller running Windows Server 2003 becomes unavailable and no other domain controllers running Windows Server 2003 exist in the domain, a BDC running Windows NT can be promoted to a PDC to fill the role for the offline domain controller running Windows Server 2003.

When upgrading Windows NT 4.0 and earlier domains, only one domain controller running Windows Server 2003 can create security principals (users, groups, and computer accounts). This single domain controller is configured as a PDC emulator master. The PDC emulator master emulates a Windows NT 4.0 or earlier PDC. For more information about the PDC emulator role, see Operations master roles.

**Complete the upgrade of the domain**
After you have upgraded all existing Windows NT 4.0 and earlier primary and backup domain controllers to a Windows Server 2003 operating system, and you have no plans to use Windows NT 4.0 and earlier domain controllers, you can raise the domain functional level from Windows 2000 mixed to Windows 2000 native. For more information about how to raise the domain functional level, see Raise the domain functional level.

Several things happen when you raise the domain functional level to Windows 2000 native:

- Domain controllers no longer support NTLM replication.
- The domain controller that is emulating the PDC operations master cannot synchronize data with a BDC running Windows NT 4.0 or earlier.
- Domain controllers running Windows NT 4.0 and earlier cannot be added to the domain. You can add new domain controllers running Windows 2000 or Windows Server 2003.
- Users and computers using previous versions of Windows begin to benefit from the transitive trusts of Active Directory and can access resources anywhere in the forest with the appropriate permissions. Although previous versions of Windows do not support the Kerberos V5 protocol, the pass-through authentication provided by the domain controllers allows users and computers to be authenticated in any domain in the forest. This enables users or computers to access resources in any domain in the forest for which they have the appropriate permissions.

Other than the enhanced access to any other domains in the forest, clients will not be aware of any changes in the domain.

After upgrading a Windows NT 4.0 domain to an Active Directory domain, it is recommended that you delete and recreate all previously existing trusts with Active Directory domains. Even though the domain has been upgraded, the trust remains a Windows NT 4.0 trust. Internet protocol security (IPSec) does not work over a Windows NT 4.0 trust.

**Install Active Directory client software on older client computers**
Computers running Active Directory client software can use Active Directory features, such as authentication, to access

resources in the domain tree or forest and to query the directory. By default, client computers running Windows 2000 Professional and Windows XP Professional have the client software built in and can access Active Directory resources normally.

Computers running previous versions of Windows (Windows 95, Windows 98, and Windows NT) require installation of the Active Directory client software before access to Active Directory resources is available. Without the client software, previous versions of Windows can only access the domain as if it were a Windows NT 4.0 and earlier domain, finding only those resources available through Windows NT 4.0 and earlier one-way trusts. For more information about the Active Directory client software, see Active Directory clients.

# Upgrading from a Windows 2000 domain

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrading from a Windows 2000 domain**
Before upgrading a domain controller running Windows 2000 to Windows Server 2003, or installing Active Directory on the first domain controller running Windows Server 2003, ensure that your server, your forest, and your domain are ready. This process involves checking the upgrade compatibility of your server, preparing the forest, and preparing the domain, all of which can be accomplished using command-line tools.

To check the upgrade compatibility of the server and to copy any updated Setup files, run the **winnt32** command, using the **winnt32 /checkupgradeonly** command. For more information about the **winnt32** command, see Winnt32.

To prepare the forest, run the **adprep** command on the schema operations master, using the **adprep /forestprep** command. Running **adprep** on the schema master will update the schema, which will in turn replicate to all of the other domain controllers in the forest. The time it takes to replicate these changes will vary, depending on the replication schedule for your organization.

After the changes made by **adprep /forestprep** have replicated to the infrastructure operations master, you are ready to prepare the domain. To prepare the domain, run **adprep** on the infrastructure operations master, this time using the **adprep /domainprep** command.

On Windows Server 2003 domain controllers with no service pack installed **adprep /domainprep** can cause significant replication traffic due to synchronization of the Group Policy objects (GPOs) in the SYSVOL shared folder.

Windows Server 2003 with Service Pack 1 (SP1) includes a new **adprep** command, **adprep /domainprep /gpprep**, which you can run separately from **adprep /domainprep** and which you can run anytime to synchronize the GPOs that are located in the SYSVOL shared folder.

Therefore, if you are upgrading a Windows 2000 Server environment to Windows Server 2003 with SP1, prepare the forest using **adprep /forestprep** and prepare each domain using **adprep /domainprep**. Then, when network conditions are optimal, use **adprep /domainprep /gpprep** to add inheritable access control entries (ACEs) to the GPOs in the SYSVOL shared folder and to synchronize the contents of the SYSVOL shared folder among the domain controllers in the domain.

The Adprep command-line tool is available from the I386 directory on the operating system installation CD.

**Important**

- You cannot upgrade domain controllers running Windows 2000 to Windows Server 2003 or Windows Server 2003 with SP1, or add domain controllers running Windows Server 2003 or Windows Server 2003 with SP1 to Windows 2000 domains, until you have used **adprep** to prepare the forest and the domains within the forest.

For more information about the enhancements to Adprep.exe in Windows Server 2003 with SP1, see article 324392, “Enhancements to Adprep.exe in Windows Server 2003 Service Pack 1 and in hotfix 324392,” in the Microsoft Knowledge Base.

For more information about how to prepare your forest and domains using Adprep.exe, see "Overview: Upgrading Windows 2000 Domain Controllers to Windows Server 2003" in article 325379, “How to Upgrade Windows 2000 Domain Controllers to Windows Server 2003,” in the Microsoft Knowledge Base.

Operations master roles
Adprep

# Converting groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Converting groups**

When you upgrade a primary domain controller (PDC) running Windows NT Server 4.0 or earlier to a server running Windows Server 2003, existing Windows NT groups are converted in the following ways:

- Windows NT local groups are converted to domain local groups on servers running Windows Server 2003.
- Windows NT global groups are converted to global groups on servers running Windows Server 2003.

Domain member computers running Windows NT can continue to display and access the converted groups. The groups appear to these clients as Windows NT 4.0 local and global groups. However, a Windows NT client cannot display members of groups or modify the member properties when that membership violates Windows NT group rules. For example, when a Windows NT client views the members of a global group on a server running Windows Server 2003, it does not view any other groups that are members of that global group.

**Converted groups and Microsoft Exchange**

Exchange allows users to arrange e-mail addresses in groups and distribution lists. When Exchange servers are upgraded to Active Directory, the Exchange distribution lists are converted to distribution groups with universal scope. The administrator can convert the group to a security group later, if desired, by using Active Directory Users and Computers to change the group properties. The messaging application programming interface (MAPI) enables computers running previous version Exchange clients to view the converted distribution group.

**Using converted groups with servers running Windows Server 2003**

Client computers that do not run Active Directory client software identify groups with universal scope on servers running Windows Server 2003 as having global scope instead. When viewing the members of a group with universal scope, the Windows NT client can only view and access group members that conform to the membership rules of global groups on servers running Windows Server 2003.

In a Windows Server 2003 domain that is set to a domain functional level of Windows 2000 native, all the domain controllers must be running on servers running Windows Server 2003. However, the domain can contain member servers that run Windows NT Server 4.0. These servers view groups with universal scope as having global scope and can assign groups with universal scope rights and permissions and place them in local groups.

In a Windows Server 2003 domain, a Windows NT Server 4.0 member server running Windows NT administrative tools cannot access domain local groups. However, you can work around this by using a server running Windows Server 2003 and using its Windows Server 2003 Administration Tools Pack to access the server running Windows NT Server 4.0. You can use the Administration Tools Pack to display the domain local groups and assign to them permissions to resources on the server running Windows NT Server 4.0.

# Administering Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Active Directory**
This section covers:

- Using Run as
- Using saved queries
- Managing Active Directory from MMC
- Managing Active Directory from the command line
- Finding directory information
- Administering other domains
- Delegating administration
- Publishing resources
- Managing COM+ partitions in Active Directory
- Managing COM+ partition sets in Active Directory

# Using Run as

Updated: April 20, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Run as**

Logging onto your computer using administrative credentials can pose a security risk to your computer and network. Therefore, as a security best practice, it is recommended that you do not log on to your computer with administrative credentials. Instead, you can use Run as to accomplish administrative tasks without having to log on to your computer with administrative credentials. For information about the security risks associated with being logged on as an administrator, see Why you should not run your computer as an administrator.

Using Run as, you can open and run a program using a different account and security context than the one you are logged on with. So, you can log on using a regular user account, then, using Run as, open an administrative program in the context of an administrative account. The administrative context is only used for that specific program and is only available until that program is closed.

It is especially important for domain administrators to use Run as to accomplish administrative tasks. Running your computer as a domain administrator in Active Directory makes your domain (and forest) vulnerable to Trojan horses and other security risks that target the logon sequence.

You can use Run as through the user interface or as a command-line tool.

- User interface

  The Run as feature built into the user interface is a shortcut that is accessed on the right-click menu for some programs (.exe), some Control Panel (.cpl) items, and Microsoft Management Console (MMC) (.msc) consoles. Run as will prompt you for a user account and password before starting a program, Control Panel item, or MMC console. Some programs and administrative tasks, such as upgrading the operating system or configuring system parameters, do not support Run as. These tasks require an interactive logon. For more information about how to use the Run as feature, see Run a program with administrative credentials.

- Command-line tool

  In addition to the built-in Run as feature, the **runas** command provides the same capabilities. For more information about the **runas** command, see Runas. You can also create a custom shortcut using the **runas** command. For more information about creating shortcuts, see Create a shortcut using the runas command.

| **Tip** |
| --- |
| For more options and examples, see the TechNet Wiki topic How to Run with Alternate Credentials and Open Elevated Command Prompts (http://social.technet.microsoft.com/wiki/contents/articles/how-to-run-with-alternate-credentials-and-open-elevated-command-prompts.aspx). |

# Using saved queries

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using saved queries**

Saved queries provide a quick and consistent way for administrators to access a common set of directory objects on which to perform specific tasks or to monitor. Saved queries use predefined LDAP strings to search only the specified domain partition, and searches can be narrowed down to a single container object. You can also create a customized saved query that contains a LDAP search filter. For more information about saving queries, see Create a saved query. For more information about LDAP search filters, see the Internet Engineering Task Force Web site and search for "Representation of LDAP Search Filters."

Active Directory Users and Computers provides a Saved Queries folder in which administrators can create, edit, save, and organize saved queries. Before saved queries, administrators were required to create custom ADSI scripts that would perform a query on common objects. This was an often lengthy process that required knowledge of how ADSI utilizes LDAP search filters to resolve a query.

All queries located in the Saved Queries folder are stored in Active Directory Users and Computers (dsa.msc). Once you have successfully created your customized set of queries you can copy the .msc file to other domain controllers running Windows Server 2003 (located in the same domain) and use the same set of saved queries. You can also export saved queries to an .xml file and import them into other Active Directory User and Computer consoles located on domain controllers running Windows Server 2003 (within the same domain). For more information about saving console files, see Saving consoles.

You can save queries to search for disabled user or computer accounts, number of days since the last user logon, users with non-expiring Passwords, and many other commonly used queries. Once a saved query is executed and the desired objects are displayed, each object can then be modified directly through a query results screen. You can then select multiple objects and perform a task on them. For example, you can use a drag-and-drop operation to move two or more displayed objects onto a group.

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Managing Active Directory from MMC

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing Active Directory from MMC**
The Active Directory administrative tools simplify directory service administration. You can use the standard tools or, using Microsoft Management Console (MMC), create custom tools that focus on single management tasks. You can combine several tools into one console. You can also assign custom tools to individual administrators with specific administrative responsibilities. For information about MMC, see Working with MMC console files.

The Active Directory administrative tools can only be used from a computer with access to a domain. The following Active Directory administrative tools are available on the Administrative Tools menu:

- Active Directory Users and Computers
- Active Directory Domains and Trusts
- Active Directory Sites and Services

You can also remotely administer Active Directory from a computer that is not a domain controller, such as a computer running Windows XP Professional. To do this, you must install the Windows Server 2003 Administration Tools Pack. For more information, see Windows Server 2003 Administration Tools Pack Overview.

The Active Directory Schema snap-in is an Active Directory administrative tool for managing the schema. It is not available by default on the Administrative Tools menu, and must be added manually. For more information, see Install the Active Directory Schema snap-in.

For advanced administrators and network support specialists, there are many command-line tools that can be used to configure, manage, and troubleshoot Active Directory. For more information, see Active Directory support tools.

You can also create scripts that use Active Directory Service Interfaces (ADSI). Several sample scripts are supplied on the operating system installation media. For more information about the sample scripts, see Using the Windows Deployment and Resource Kits. For more information about using ADSI, see Programming interfaces.

**Customizing how data is displayed in Active Directory administrative tools and snap-ins**
The Active Directory administrative tools, such as Active Directory Users and Computers, and the Windows shell extensions use display specifiers to dynamically create context menu items and property pages. Display specifiers permit localization of class and attribute names, context menus, and property pages, and also support new classes and attributes. You can add and modify classes and attributes in the schema and extend both the administrative tools and the Windows shell in many ways by modifying attributes in display specifiers. For more information the Active Directory schema and display specifiers, see the Active Directory programmer's Guide at the Microsoft Web site.

**Using Active Directory Users and Computers**
You can change how directory objects are displayed in Active Directory Users and Computers by selecting commands on the **View** menu of the console. Menu commands include the ability to toggle features on and off, such as the console tree, description bar, status bar, large icons, small icons, and so on.

When you start Active Directory Users and Computers and expand the domain node, several containers are displayed in the console tree. If you have just created a domain controller, the containers that are displayed by default are:

- **Builtin:** Contains objects that define the default built-in groups, such as Account Operators or Administrators.
- **Computers:** Contains Windows 2000, Windows XP, and Windows Server 2003 computer objects, including computer accounts that were originally created using application programming interfaces (APIs) that could not use Active Directory. Computer objects are moved to the Computer container when Windows NT domains are upgraded to Windows 2000 or a Windows Server 2003 operating system.
- **Domain Controllers:** Contains computer objects for domain controllers running Windows 2000 or Windows Server 2003.

- **Users:** Contains user accounts and groups that were originally created using APIs that could not use Active Directory. User accounts and groups are moved to the Users container when Windows NT domains are upgraded to Windows 2000 or a Windows Server 2003 operating system. You can use the Windows NT 4.0 User Manager (Usrmgr) tool to modify users and groups created using the APIs that could not use Active Directory.

When you select **Advanced Features** on the **View** menu, two additional folders are displayed in the console:

- **LostAndFound:** Contains objects whose containers were deleted at the same time that the object was created. If an object has been created in or moved to a location that is missing after replication, the lost object is added to the LostAndFound container. The LostAndFoundConfig container in the configuration directory partition serves the same purpose for forest-wide objects.

- **System:** Contains built-in system settings for the various system service containers and objects. For more information about the System container, see Using the Windows Deployment and Resource Kits.

When you select **Filter options** on the **View** menu, you can show all objects, show only selected objects, configure the number of items that can be displayed for each folder, or create custom filters using object attributes and LDAP queries.

**Starting Active Directory MMC consoles from the command-line**
Active Directory MMC consoles, including Active Directory Users and Computers (dsa.msc), Active Directory Domains and Trusts (domain.msc) and Active Directory Sites and Services (dssite.msc), provide command-line options that allow you to start a console focused on a particular domain or domain controller. The command-line options support both fully qualified domain names and NetBIOS names.

The command-line options are:

- **/domain=** *FullyQualifiedDomainName*

- **/domain=** *NetBIOSDomainName*

- **/server=** *FullyQualifiedDomainControllerName*

- **/server=** *NetBIOSDomainControllerName*

You can use these command-line options to run the Active Directory MMC consoles directly from the command line, or you can create a shortcut to start a console and add the appropriate command-line options to the shortcut. You can also use the command-line options with any custom consoles that you create. For more information about creating and saving console files, see Windows interface administrative tool reference A-Z: Microsoft Management Console.

Command-line examples:

- To start Active Directory Users and Computers focused on domain1, type:

  **dsa.msc /domain=***domain1*

- To start Active Directory Users and Computers focused on server1, type:

  **dsa.msc /server=***server1***.***domain1*

- To start Active Directory Sites and Services focused on server1, type:

  **dssite.msc /server=***server1***.***domain1*

- To start Active Directory Domains and Trusts focused on server1, type:

  **domain.msc /server=***server1***.***domain1*

**Notes**

- Do not use both a /domain and /server command-line option at the same time.
- The /domain options can only be used with Active Directory Users and Computers.

# Managing Active Directory from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing Active Directory from the command line**

The following command-line tools can be used to manage Active Directory.

| Name | Description |
|---|---|
| CSVDE | Import and export Active Directory data using comma-separated format. |
| Dsadd | Add users, groups, computers, contacts, and organizational units to Active Directory. |
| Dsmod | Modify an existing object of a specific type in the directory. The types of objects that can be modified are: users, groups, computers, servers, contacts, and organizational units. |
| Dsrm | Remove objects of the specified type from Active Directory. |
| Dsmove | Rename an object without moving it in the directory tree, or move an object from its current location in the directory to a new location within a single domain controller. (For cross-domain moves, use the Movetree command-line tool.) |
| Dsquery | Query and find a list of objects in the directory using specified search criteria. Use in a generic mode to query for any type of object or in a specialized mode to query for for selected object types. The specific types of objects that can be queried through this command are: computers, contacts, subnets, groups, organizational units, sites, servers and users. |
| Dsget | Display selected attributes of specific object types in Active Directory. Attributes of the following object types can be viewed: computers, contacts, subnets, groups, organizational units, servers, sites, and users. |
| LDIFDE | Ceate, modify, and delete directory objects. This tool can also be used to extend the schema, export Active Directory user and group information to other applications or services, and populate Active Directory with data from other directory services. |
| Ntdsutil | General purpose Active Directory management tool. Use Ntdsutil to perform database maintenance of Active Directory, to manage single master operations, and remove metadata left behind by domain controllers that were removed from the network without being properly uninstalled. |

Additional command-line tools are available in the Support tools folder of the product compact disc and from the Resource Kit

For information about other command-line tools, see Command-line reference A-Z. For more information about manageability, see Management Strategies and Tools.

# Finding directory information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Finding directory information**

Active Directory is designed to provide information to queries about directory objects from both users and programs. Administrators and users can easily search for and find information in the directory by using the Search command on the Start menu. Client programs can access information in Active Directory by using Active Directory Service Interfaces (ADSI).

One of the principal benefits of Active Directory is its rich store of information about network objects. Information published in Active Directory about users, computers, files, and printers is available to network users. This availability is controlled by security permissions to view information. For information about publishing information in the directory, see Publishing resources.

Everyday tasks on a network involve communication with other users and connection to published resources. These tasks require finding names and addresses to send mail or connect to shared resources. In this respect, Active Directory functions as a shared address book for the enterprise. For example, you can find a user by first name, last name, e-mail name, office location, or other properties of that person's user account. Finding information is optimized by use of the global catalog. For more information, see The role of the global catalog.

**Restricting directory information access**

In some cases, such as for security or privacy reasons, you may want to restrict access to certain directory information. Access control permissions provide you with detailed control over the visibility of information stored in Active Directory. Using permissions, you can ensure that only users who need particular directory information have access to it. For information on assigning permissions to Active Directory objects or properties, see Assign, change, or remove permissions on Active Directory objects or attributes. In addition, see Best practices for assigning permissions on Active Directory objects.

**Efficient search tools**

Administrators can use the advanced Find dialogs in Active Directory Users and Computers to perform management tasks with greater efficiency and to easily customize and filter data retrieved from the directory. For more information, see Search Active Directory.

Additionally, administrators can add objects to groups quickly and with minimal network impact by utilizing browse-less queries to help find likely members. For more information, see Add a member to a group.

# Administering other domains

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering other domains**
In an organization with more than one domain, it is often necessary to administer a domain other than the one to which you are currently logged on. For example, when creating trusts, the trust must be created in both the trusting and the trusted domain. You can do this through:

- Cooperation with those who have administrative credentials in another domain
- Logging on with a user account with the necessary permissions
- Using Run as to start an administrative tool targeted on the particular domain (recommended)

A secure method of controlling administrative access to a particular domain is to tightly control the number of accounts that are added to the Domain Admins group for that domain and the number of people aware of those accounts. Only members of the Domain Admins group (or Enterprise Admins group) can make broad administrative changes to the domain.

For example, if a domain administrator in one domain wanted to establish a shortcut trust with another domain, the domain administrator could establish the trust relationship in that domain by communicating with the domain administrator of the other domain, agreeing on a common strong password for the trust, and having the administrator of the other domain create the trust in that domain.

A more convenient, but less secure method of administering more than one domain is to logon interactively with a user account that has administrative credentials in both domains. For example, user accounts that are members of the Enterprise Admins security group have permission to administer every domain in the forest. Logging on to a computer with a user account that has broad administrative access is not recommended. For more information, see Why you should not run your computer as an administrator.

Run as, when used with the appropriate user name and password, can be used to securely administer domains in any forest in your organization. For more information, see Using Run as.

**Notes**

- It is a security best practice to never log on with an account that has more rights and permissions than you need for the task you are currently performing.
- It is also a security best practice to limit the scope of a particular administrator's rights and permissions to include only those tasks that the administrator commonly performs.
- You cannot administer a Windows Server 2003 domain or forest using the Windows 2000 Administrative Tools Pack. For more information, see Windows Server 2003 Administration Tools Pack Overview.

# Delegating administration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Delegating administration**

By delegating administration, you can assign a range of administrative tasks to the appropriate users and groups. You can assign basic administrative tasks to regular users or groups, and leave domain-wide and forest-wide administration to members of the Domain Admins and Enterprise Admins groups. By delegating administration, you can allow groups within your organization to take more control of their local network resources. You also help secure your network from accidental or malicious damage by limiting the membership of administrator groups.

You can delegate administrative control to any level of a domain tree by creating organizational units within a domain and delegating administrative control for specific organizational units to particular users or groups.

To decide what organizational units you want to create, and which organizational units should contain accounts or shared resources, consider the structure of your organization.

For example, you might want to create an organizational unit that enables you to assign a user the administrative control for all user and computer accounts in all branches of a department, such as Human Resources. Or, you might want to assign a user administrative control only to some resources within a department, for example, computer accounts. Another possible delegation of administrative control would be to assign a user the administrative control for the Human Resources organizational unit, but not any organizational units contained within the Human Resources organizational unit.

Active Directory defines specific permissions and user rights that can be used for the purposes of delegating or restricting administrative control. Using a combination of organizational units, groups, and permissions, you can define the most appropriate administrative scope for a particular person, which could be an entire domain, all organizational units within a domain, or a single organizational unit.

Administrative control can be assigned to a user or group by using the Delegation of Control Wizard or through the Authorization Manager console. Both of these tools allow you to assign rights or permissions to particular users or groups.

For example, a user can be given permissions to modify the Owner Of Accounts property, without being assigned the permissions to delete accounts in that organizational unit. The Delegation of Control Wizard, as its name suggests, allows you to delegate administrative tasks using a wizard that steps you through the entire process. The Authorization Manager is a Microsoft Management Console (MMC) console that also allows you to delegate administration. The Authorization Manager provides greater flexibility than the Delegation of Control Wizard, at the cost of greater complexity.

For more information about using the Delegation of Control Wizard, see To delegate control. For more information about using Authorization Manager, see Authorization Manager.

**Delegating administration safely**

Delegate administration carefully and document all your delegated assignments. Before you delegate any tasks, ensure adequate training for users who will be assigned administrative control of objects. To review Active Directory security concepts, including permissions and inheritance, see Access control in Active Directory.

For more information about delegating administration safely, see Designing the Active Directory Logical Structure.

**Customizing MMC consoles for specific groups**

You can use Microsoft Management Console (MMC) options to create a limited-use version of a snap-in such as Active Directory Users and Computers. This allows administrators to control the options available to groups to whom you have delegated administrative responsibilities by restricting access to operations and areas within that customized console.

For example, suppose you delegate the Manage Printers right to the PrintManagers group in the Manufacturing organizational unit. To simplify administration, you can create a custom console for use by members of the PrintManagers group containing only the Manufacturing organizational unit and restrict the scope of the console using the console modes.

For more information about customizing a console and using console modes, see Using custom consoles and Console access options.

This type of delegation is also enhanced by the Group Policy settings available for MMC. These settings enable the administrator to establish which MMC snap-ins can be run by a particular user. The settings can be inclusive, allowing a set of snap-ins to run, or exclusive, restricting the set of snap-ins to run.

For more information about Group Policy settings for MMC, see Setting Group Policy in MMC.

**Using Group Policy to publish and assign customized consoles**
Using Group Policy, you can distribute a customized console to specific groups in one of two modes: publishing or assigning. Publishing a customized console advertises the console to the members of a group specified in the Group Policy setting by adding the console to the list of available programs in Add or Remove Programs. The next time the members of the group open Add or Remove Programs they have the option to install the new console. Assigning (as opposed to publishing) a console forces the console to be automatically installed for all specified accounts.

To publish or assign a console, create or modify a Group Policy object and then apply it to the appropriate group of users. Then, use the Software Installation extension of the Group Policy snap-in to either publish or assign the console.

For more information, see Group Policy (pre-GPMC).

**Important**

- The console must be packaged before using the Software Installation snap-in. You can use a tool such as Windows Installer to package the customized console. Once this has been accomplished you can configure the Software Installation snap-in to publish or assign the newly created package. For more information about how to package an application, see Using the Windows Deployment and Resource Kits.

- If the customized console you are packaging uses a snap-in that is not installed on the destination workstation or server for the published or assigned user, you will need to include the snap-in file and the registration of the file in the package. You can either create a separate package that contains the snap-in or add the snap-in during the creation of the customized console package so that it will be properly installed on the computer every time a user installs the console package.

**Note**

- If a user is logged on to their computer at the time that a Group Policy object is applied to their account, the user will not see the published or assigned console until they log off and then log on again.

For more information about other Active Directory security issues, see Security overview.

# Publishing resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Publishing resources**
To help users locate the network resources they need, you can publish searchable information about these resources in Active Directory. Resources that can be published include users, computers, printers, shared folders, and network services. Some commonly used directory information, like user and computer names, is published by default when the objects are created. Other directory information, such as information about shared folders, must be published manually. For information about searching the directory, see Finding directory information.

Using access control permissions, you can control which users and groups can search and view published information. Access control permissions give you detailed control over directory information at both the resource and the property levels. For example, you can use permissions to prevent a particular group from viewing any user information published in the directory. Or, you can use permissions to allow that group to view user names, but no other user information. For an overview of permissions, see Access control overview. For information about assigning permissions to Active Directory objects and properties, see Assign, change, or remove permissions on Active Directory objects or attributes.

**Publishing users and computers**
User and computer accounts are added to the directory using Active Directory Users and Computers and are automatically published to the directory upon creation. Commonly used account information, such as account names, is published by default. Other information, such as account security information, is only visible to administrators. For information about creating new accounts, see Create a new user account and Create a new computer account.

**Publishing shared printers**
You can also publish information about shared printers in Active Directory. Information about printers shared from Windows NT must be published manually. Information about printers shared from the Windows Server 2003 family or the Windows 2000 Server family is published to the directory automatically when you create a shared printer. You use Active Directory Users and Computers to manually publish shared printer information. For more information about publishing printers, see Manually publish a printer in Active Directory.

**Publishing shared folders**
To help users find shared folders more easily, you can publish information about shared folders in Active Directory. You use Active Directory Users and Computers to manually publish shared folder information. For more information about publishing shared folders, see Publish a shared folder.

**Publishing services**
A service is an application that makes data or operations available to network users. Publishing a service in Active Directory enables users and administrators to move from a machine-centric view of the network to a service-centric view. By publishing a service, rather than computers or servers, administrators can focus on managing the service regardless of which computer is providing the service or where the computer is located.

Some services, such as Certificate Services, are automatically published in Active Directory when they are installed. Other services can be published in the directory using programming interfaces. For more information, see Programming interfaces. Administrators can manage published services using Active Directory Sites and Services. For more information about services and how to publish them, see the Service Publication page at the Microsoft Web site. (http://msdn.microsoft.com/)

**Categories of service information**
Binding and configuration information are the two types of service information frequently published using Active Directory:

- Binding information allows clients to connect to services that do not have well-known bindings and that conform to a service-centric model. By publishing the bindings for these kinds of services, connections can be automatically established with services. Machine-centric services are typically handled on a service-by-service basis and should not be published to the directory.

- Configuration information can be common across client applications. Publishing this sort of information allows you to distribute current configuration information for these applications to all clients in the domain. The configuration information is accessed by client applications as needed. This eases application configuration for users and gives you more control over application behaviors.

**Characteristics of service information**

Service information that you publish to the directory is most effective if it has the following characteristics:

- **Useful to many clients.** Information that is useful to a small set of clients or that is useful only in certain areas of the network should not be published. If not widely used, this information wastes network resources, since it is published to every domain controller in the domain.

- **Relatively stable and unchanging.** Although there may be exceptions to this rule, it generally makes sense to publish only service information that changes less frequently than two replication intervals. For intrasite replication, the maximum replication period is fifteen minutes, and for intersite replication, the maximum replication period is configured based on the replication interval of the site link used for the replication. Object properties that change more frequently create excessive demands on network resources. Property values may be out of date until updates are published, which can take as long as the maximum replication period. Consequently, having properties out of date for that period of time must not create unacceptable conditions.

  For example, some network services select a valid TCP port for use each time they are started. After selecting the port, the service updates Active Directory with this information, which is stored as the service connection point. Clients access the service connection point when they want to use the service, but if the new service connection point has not been replicated when the client requests it, the client will receive an outdated port, rendering the service temporarily inaccessible.

- **Well-defined, reasonable properties.** Information that is of a consistent form is easier for services to use. The information should be relatively small in size.

# Managing COM+ partitions in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing COM+ partitions in Active Directory**
COM+ partitions stored in Active Directory are used to map a local COM+ partition, which stores the actual COM+ *application*, to specific users or organizational units within your enterprise. COM+ applications are groups of COM components developed to work together to make use of COM+ services such as queuing, role-based security, and so on.

There are two types of COM+ partitions: COM+ partitions stored in Active Directory and local COM+ partitions stored on application servers. Using COM+ partitions stored in Active Directory, you can assign domain users and entire organizational units to applications stored in local COM+ partitions. Local COM+ partitions are application containers used to manage multiple instances of COM+ applications on a single application server.

A local COM+ partition can only store one instance of an application. In other words, if you needed to make two or more versions of the same application (AppX 1.0 and AppX 2.0) available to domain users, then you would need to create two separate local COM+ partitions on an application server and associate (or link) them with two separate COM+ partitions in Active Directory. For more information about associating COM+ partitions, see Managing COM+ partition sets in Active Directory.

Each COM+ partition is configured and managed separately, according to the specific needs of its users.

**Note**

- COM+ partitions in Active Directory are not available from domain controllers running Windows 2000.

# Managing COM+ partition sets in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing COM+ partition sets in Active Directory**
COM+ partition *sets* stored in Active Directory can contain one or more COM+ partitions and are used to assign one or more applications, residing on an application server, to domain users or organizational units. For more information about COM+ partitions, see Managing COM+ partitions in Active Directory.

Each COM+ partition set defines the COM+ partitions for which a domain user is permitted to access.

COM+ partition sets provide the following advantages to both administrators and application programmers:

- Administering distributed applications becomes much easier because you can tailor access of a particular set of domain users to a specific set of applications.

- Security policies can be applied to domain users and organizational units within each partition set.

Before assigning COM+ partition sets, you must first logically group one or more COM+ partitions into a single COM+ partition set. Once a COM+ partition set has been defined, you can make applications available throughout the domain by mapping COM+ partition sets to domain users or organizational units. To do this, you must perform tasks on both the domain controller where Active Directory resides and on the application server where the COM+ application is installed.

**Tasks to perform on a domain controller**
You must first create a COM+ partition within Active Directory by using Active Directory Users and Computers or, programmatically, by using Active Directory Service Interfaces (ADSI). For more information, see Create a COM+ partition in Active Directory. Once you have created and configured your COM+ partitions in Active Directory, you can use Component Services on an application server to associate a local COM+ partition with a COM+ partition stored in Active Directory.

After the COM+ partition is created and you have associated it with a local COM+ partition, you need to create a COM+ partition set. When creating a COM+ partition set, you can define the COM+ partitions that comprise that set. Creating a COM+ partition set is done either by using Active Directory Users and Computers or, programmatically, by using Active Directory Service Interfaces (ADSI). For more information, see Create a COM+ partition set in Active Directory.

Finally, you map domain users or organizational units to the newly created COM+ partition set. You can associate multiple users or organizational units with a COM+ partition set at one time instead of having to map multiple user identities or organizational units. For more information, see Map a user or organizational unit to a COM+ partition set.

**Tasks to perform on Application servers**
Using Component Services you can link a single COM+ application stored locally on an application server to a single COM+ partition stored in Active Directory. You can do this by creating a local COM+ partition on the application server, through Component Services, and changing the local COM+ partition ID to reflect the COM+ partition ID located in Active Directory.

Each COM+ partition in Active Directory has a general description, a unique name, and a unique partition ID. The partition ID is what associates the local COM+ partition to the COM+ partition defined in Active Directory. The COM+ partitions defined in Active Directory are intended to be unique across an enterprise. A local COM+ partition is necessary in order to store the COM+ application on an application server, which may also have multiple versions of a specific application installed.

You can define a local COM+ partition ID on the application server and then later revise the partition ID in Active Directory to match it. Or, you can define a COM+ partition ID in Active Directory and then later revise the partition ID on the application server to match the one in Active Directory.

**Note**

- Local COM+ partitions are sometimes referred to as Empty Partitions in the Component Services user interface.

# Active Directory Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

This section covers:

- Web resources
- Active Directory support tools
- Programming interfaces

# Web resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Web resources**

The following items provide links to more information on the Web related to Active Directory:

- For information about deploying Active Directory, see "Identifying an Active Directory Deployment Strategy" at the Microsoft Windows Resource Kits Web site.
- For information about domain trust, see "Domain Trust" at the Microsoft Windows Resource Kits Web site.
- For information about establishing domain trusts, see "Designing an Authorization Strategy" at the Microsoft Windows Resource Kits Web site.
- For information about monitoring Active Directory, see "Monitoring Active Directory" at the Microsoft Windows Resource Kits Web site.
- For information about delegating enterprise administrator operations, see "Delegating Enterprise Administrator Operations" at the Microsoft Windows Resource Kits Web site.
- For development information about Active Directory, see the Active Directory Programmer's Guide at the Microsoft Web site.
- For development information about Lightweight Directory Access Protocol (LDAP), see the Lightweight Directory Access Protocol API at the Microsoft Web site.
- For information about obtaining valid object identifiers, see Active Directory Naming Registration at the Microsoft Web site.
- For information about Request for Comments (RFCs) and Internet drafts, see the Internet Engineering Task Force Web site.

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Active Directory support tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory support tools**

Several additional tools that can be used to configure, manage, and debug Active Directory are available as command-line tools. These tools are known as the Support Tools and are available on the installation CD in the \Support\Tools folder.

**Note**

You can find downloadable versions of the Support Tools at the following locations:

- Windows Server 2003 Service Pack 1 32-bit Support Tools (http://go.microsoft.com/fwlink/?LinkId=70775)
- Windows Server 2003 Service Pack 2 32-bit Support Tools (http://go.microsoft.com/fwlink/?LinkId=168625)

**List and description of tools**

In addition, the Active Directory Migration Tool (ADMT) is available to help you migrate user accounts, groups, and computer accounts from Windows NT 4.0 domains to Active Directory domains. The Active Directory Migration Tool is a Microsoft Management Console (MMC) snap-in and is available on the installation compact disk in the \i386\ADMT folder.

| Tool | Description |
|---|---|
| Movetree | Move objects from one domain to another. |
| SIDWalk | Set the access control lists on objects previously owned by accounts that were moved, orphaned, or deleted. |
| LDP | Allows LDAP operations to be performed against Active Directory. This tool has a graphical user interface (GUI). |
| Dnscmd | Enables administrator to check presence of domain controller locator records in DNS, add or delete such records and perform configuration of DNS servers, zones and records. |
| DSACLS | View or modify the access control lists of directory objects. |
| Netdom | Batch management of trusts, joining computers to domains, verifying trusts and secure channels. |
| NETDiag | Check end to end network and distributed services functions. |
| NLTest | Check that the locator and secure channel are functioning. |
| Repadmin | Check replication consistency between replication partners, monitor replication status, display replication metadata, force replication events and knowledge consistency checker recalculation. |
| Replmon | Display replication topology, monitor replication status (including group policies), force replication events and knowledge consistency checker recalculation. This tool has a graphical user interface (GUI). |
| DSAStat | Compare directory information on domain controllers and detect differences. |
| ADSI Edit | A Microsoft Management Console (MMC) snap-in used to view all objects in the directory (including schema and configuration information), modify objects and set access control lists on objects. |
| SDCheck | Check access control list propagation and replication for specified objects in the directory. This tool enables an administrator to determine if access control lists are being inherited correctly and if access control list changes are being replicated from one domain controller to another. |
| ACLDiag | Determine whether a user has been assigned or denied access to a directory object. It can also be used to reset access control lists to their default state. |

| | |
|---|---|
| DFSUtil | Command-line utility for managing all aspects of Distributed File System (DFS), checking the configuration concurrency of DFS servers, and displaying the DFS topology. |
| Dcdiag | Analyzes the state of domain controllers in a forest or enterprise and reports any problems to assist in troubleshooting. |
| Active Directory Migration Tool (ADMT) | A Microsoft Management Console (MMC) snap-in used to migrate user accounts, groups, and computer accounts from Windows NT 4.0 domains to Active Directory domains (available on the installation compact disk in the \i386\ADMT folder). |

For more information, see Install Windows Support Tools and Using the Windows Deployment and Resource Kits.

# Programming interfaces

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Programming interfaces**

Active Directory Service Interfaces (ADSI) provides a simple, powerful, object-oriented interface to Active Directory. ADSI makes it easy for programmers and administrators to create directory programs by using high-level tools, such as Microsoft Visual Basic, without having to worry about the underlying differences between the different namespaces.

ADSI enables you to build or buy programs that give you a single point of access to multiple directories in your network environment, whether those directories are based on LDAP or another protocol. ADSI is fully scriptable for ease of use by administrators.

For more information about ADSI, see the Active Directory Programmer's Guide at the Microsoft Web site and the Using the Windows Deployment and Resource Kits.

Active Directory also provides support for Messaging Application Programming Interface (MAPI), so legacy MAPI programs will continue to work with Active Directory.

In addition, Active Directory supports the LDAP C API as a lower-level interface for C programmers. For more information, see the Lightweight Directory Access Protocol (LDAP) API at the Microsoft Web site.

# Active Directory Troubleshooting

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**

- Troubleshooting Active Directory
- Troubleshooting replication
- Troubleshooting schema
- Troubleshooting trusts

# Troubleshooting Active Directory

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting Active Directory**
What problem are you having?

- Cannot add or remove a domain.
- Cannot create security principals in Active Directory.
- Changes to group memberships are not taking effect.
- Clients without Active Directory client software installed fail to authenticate.
- Receiving "Domain not found," "Server not available," or "RPC server is unavailable" error messages.
- User is unable to log on locally to a domain controller.
- Cannot enable auditing.
- Cannot remove Active Directory from a domain controller.
- Cannot connect to a domain controller running Windows 2000.

**Cannot add or remove a domain.**
**Cause:** The domain naming master is not available. This may be caused by a network connectivity problem or an Active Directory Installation Wizard failure. It may also be due to a failure of the computer holding the domain naming master role. Or, the user who is attempting to add or remove the domain does not have the necessary administrative credentials.

**Solution:** Identify the computer holding the domain naming master role by using the command **netdom query fsmo** and repair or replace the domain naming master computer. It may be necessary to seize the domain naming master role. Or, resolve the network connectivity problem. If this does not help solve the issue, see article Q223787, "Flexible Single Master Operation Transfer and Seizure Process," in the Microsoft Knowledge Base.

**See also:** Diagnose Connections; Operations master roles; Responding to operations master failures; Transfer the domain naming master role; Seize the domain naming master role

**Cannot create security principals in Active Directory.**
**Cause:** The RID master is not available or failed to replicate. This may be caused by a network connectivity problem or may be due to a failure of the computer holding the RID master role. This behavior can also occur when the **Access this computer from the network** user right is not assigned to the appropriate groups on the RID master. Or, the user who is attempting to create the security principal does not have the necessary administrative credentials.

**Solution:** Identify the computer holding the RID master role by using the command **netdom query fsmo** and repair or replace the computer holding the RID master role. It may be necessary to seize the RID master role. Or, resolve the network connectivity problem. If this does not help solve the issue, see articles Q223787, "Flexible Single Master Operation Transfer and Seizure Process," and Q248410 "Err Msg: The Account-Identifier Allocator Failed To..." in the Microsoft Knowledge Base.

**See also:** Access this computer from the network; Diagnose Connections; Operations master roles; Responding to operations master failures; Transfer the RID master role; Seize the RID master role

**Changes to group memberships are not taking effect.**
**Cause:** The infrastructure master is not available. This may be caused by a network connectivity problem. It may also be due to a failure of the computer holding the infrastructure master role. Or, the user who is attempting to change group membership does not have the necessary administrative credentials.

**Solution:** Identify the computer holding the infrastructure master role by using the command **netdom query fsmo** and

repair or replace the computer holding the infrastructure master role. It may be necessary to seize the infrastructure master role.Or, resolve the network connectivity problem. If this does not help solve the issue, see article Q223787, "Flexible Single Master Operation Transfer and Seizure Process," in the Microsoft Knowledge Base.

**See also:** Diagnose Connections; Operations master roles; Responding to operations master failures; Transfer the infrastructure master role; Seize the infrastructure master role

**Clients without Active Directory client software installed fail to authenticate.**
**Cause:** The end user's password has expired and the primary domain controller (PDC) emulator master is not available. This may be caused by a network connectivity problem. It may also be due to a failure of the computer holding the PDC emulator master role.

**Solution:** Identify the computer holding the PDC emulator master role by using the command **netdom query fsmo** and repair or replace the computer holding the PDC emulator master role. It may be necessary to seize the PDC emulator master role. Or, resolve the network connectivity problem. If this does not help solve the issue, see articles Q223787, "Flexible Single Master Operation Transfer and Seizure Process," and Q239869, "How to Enable NTLM 2 Authentication for Windows 95, Windows 98, Windows NT Server 4.0, and Windows 2000 Advanced Server," in the Microsoft Knowledge Base.

**See also:** Diagnose Connections; Operations master roles; Responding to operations master failures; Transfer the PDC emulator role; Seize the PDC emulator role

**Receiving "Domain not found," "Server not available," or "RPC server is unavailable" error messages.**
**Cause:** Name registration or name resolution problem.

**Solution:** Verify that Domain Name System (DNS) is available and functioning correctly. Run the **Netdiag /debug** command on the server in question. This will evaluate the registration of NetBIOS, DNS, and services. If this does not help solve the issue, see article Q265706, "DCDiag/NetDiag Facilitate Join and DC Creation," in the Microsoft Knowledge Base.

**See also:** Active Directory support tools; Install Windows Support Tools

**User is unable to log on locally to a domain controller.**
**Cause:** The ability to log on locally to a domain controller is controlled by security policies, which are established in Group Policy settings.

**Solution:** In the default Domain Controller Policy object, assign the particular user or group the **Allow log on locally** user right. If this does not help solve the issue, see article Q234237, "Assign "Log On locally" Rights to Windows Domain Controller," in the Microsoft Knowledge Base.

**See also:** Allow log on locally; Logon rights; Permit users to log on locally to a domain controller

**Cannot enable auditing.**
**Cause:** For servers running Windows Server 2003, auditing must be enabled in the Group Policy object. Or, the user who is attempting to enable auditing does not have the necessary administrative credentials.

**Solution:** Run GPEdit.msc to enable auditing or monitoring of system events.

**See also:** Define or modify auditing policy settings for an event category

**Cannot remove Active Directory from a domain controller.**
**Cause:** The NTDS Settings object could not be properly removed. Or, the user who is attempting to remove the domain controller does not have the necessary administrative credentials.

**Solution:** Use the Ntdsutil command-line tool to manually remove the NTDS Settings object. If this does not help solve the issue, see article Q216498, "Remove Data in Active Directory After an Unsuccessful Demotion," in the Microsoft Knowledge Base.

**See also:** Delete extinct server metadata

**Cannot connect to a domain controller running Windows 2000.**
**Cause:** You are trying to connect to a domain controller running Windows 2000 that does not have Service Pack 3 or later installed.

**Solution:** Upgrade domain controllers running Windows 2000 to Service Pack 3 or later.

**See also:** Connecting to domain controllers running Windows 2000

# Troubleshooting replication

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting replication**

For more detailed replication troubleshooting information than is available here, and for additional information about functionality in the version of Dcdiag.exe that is included in Windows Support Tools that ship with Windows Server 2003 with Service Pack 1 (SP1), see Troubleshooting Active Directory Replication Problems on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=60980).

What problem are you having?

- Monitoring replication.
- Replication between sites is slow.
- Received Event ID 1311 in the directory service log.
- Received Event ID 1265 with error "DNS Lookup Failure," or "RPC server is unavailable" in the directory service log. Or, received "DNS Lookup Failure" or "Target account name is incorrect" from the repadmin command.
- Received Event ID 1265 "Access denied," in directory service log. Or, received "Access denied" from the repadmin command.
- Received "Access denied" from Active Directory Sites and Services when manual replication was attempted.
- Unable to connect to a domain controller running Windows 2000 from the Active Directory Sites and Services snap-in.
- Search for new and updated information about replication. Or, your question does not match any of those listed above.

**Monitoring replication.**

- **Cause:** You should monitor replication regularly to help you identify and fix problems before they grow.
- **Solution:** Regular monitoring is the key to good replication maintenance. Repadmin.exe and dcdiag.exe (both part of the Windows Support Tools) and the directory service event log (accessible through the Event Viewer) are the primary tools for monitoring replication.

  Repadmin is a command-line tool that report failures on a replication link between two replication partners. The following **repadmin** example displays the replication partners and any replication link failures for Server1 on the microsoft.com domain:

  **repadmin /showrepl** *server1***.microsoft.com**

  For a complete list of **repadmin** options, use the **?** option:

  **repadmin /?**

  Dcdiag is a command-line tool that can check the DNS registration of a domain controller, check to see that the security descriptors (SIDs) on the naming context heads have appropriate permissions for replication, analyze the state of domain controllers in a forest or enterprise, and more. The following **dcdiag** example checks for any replication errors between domain controllers:

  **dcdiag /test:replications**

  For a complete list of dcdiag options, use the **?** option:

**dcdiag /?**

The directory service log reports replication errors that occur after a replication link has been established. For information about viewing the directory service log, see View an event log.

Large enterprises may also want to use the Microsoft Operations Manager for automated monitoring of large numbers of domain controllers. For more information, see Active Directory Management Pack Technical Reference for Microsoft Operations Manager 2005 on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=38341).

**See also:** Event Viewer; Install Windows Support Tools; Technical support options

**Replication between sites is slow.**

- **Cause:** The time required to replicate directory data between domain controllers is known as the replication latency. Replication latency can vary greatly, depending on the number of domain controllers, the number of sites, the available bandwidth between sites, replication frequency, and more.

- **Solution:**

  - Monitoring replication regularly is a good way to determine the normal replication latency on your network. With this knowledge, you can more easily determine if a problem is occurring. For more information, see the "Monitoring Replication" troubleshooting topic above.

  - Review the directory service log for any recent replication errors. Also, run **repadmin /showrepl** and review any resulting errors.

  - A good site topology design is important for replication efficiency. For information about site topology design guidelines, see When to establish a single or separate sites and Designing the Site Topology on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=4724).

  - A number of algorithm enhancements have been made to replication in the Windows Server 2003 operating systems to improve replication efficiency and scalability. Some of these enhancements take effect in a forest set to Windows 2000 functional level, while others require the Windows Server 2003 functional level. You will gain the greatest improvement from these enhancements by upgrading your forest to Windows Server 2003 functional level. Adlb.exe is a tool that can help improve replication efficiency even further in forests set to the Windows Server 2003 functional level. For more information about Adlb, see the Windows Server 2003 Active Directory Branch Office Planning and Deployment Guide on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=28523). For more information about forest functionality, see Domain and forest functionality.

**See also:** Replication overview; Replication between sites; Managing replication; Bandwidth; Checklist: Optimizing intersite replication

**Received Event ID 1311 in the directory service log.**

- **Cause:** The replication configuration information in Active Directory Sites and Services does not accurately reflect the physical topology of the network.

  Common causes of Event ID 1311 include:

  - One or more domain controllers are offline.

  - Bridgehead servers are online but experiencing errors replicating a required naming context between Active Directory sites.

  - Preferred bridgehead servers defined by administrators are online but do not host the required naming contexts.

- One or more sites are not contained in site links.
- Site links contain all sites but the site links are not all site links are interconnected.
- Preferred bridgeheads defined by the administrator are offline.

- **Solution:** To resolve an error in the configuration of replication:
  - Make sure all sites belong to at least one site link. For more information, see Add a site to a site link.
  - Make sure that the combination of site links you have created allows a path between all domain controllers containing a replica of a given directory partition. For example, if a directory partition is held by domain controllers in both Site A and Site C, make sure that Site A and Site C belong to a common site link, or that an intermediary site exists that has at least one site link in common with Site A and at least one site link in common with Site B.
  - Make sure that you have cleared the **Bridge all site links** check box in Active Directory Sites and Services if your network is not fully routed. Or, if your network is fully routed and you have cleared the **Bridge all site links** check box, you may need to select it again to allow full replication of a directory partition. For more information, see Enable or disable site link bridges.
  - If you have manually assigned preferred bridgehead servers, make sure these servers are not offline. (It is generally recommended that you allow Active Directory to select bridgehead servers automatically.)
  - Use Ping.exe and Network Monitor to verify connectivity through WAN links and across routers. For more information about Network Monitor, see Network Monitor overview.
  - You can also search the Microsoft Knowledge Base on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=4441) for new and updated information about Event ID 1311.

**See also:** Create a site link; Add a site to a site link; Enable or disable site link bridges; Install Windows Support Tools

**Received Event ID 1265 with error "DNS Lookup Failure," or "RPC server is unavailable" in the directory service log. Or, received "DNS Lookup Failure" or "Target account name is incorrect" from the repadmin command.**

- **Cause:** These messages are often the result of DNS problems. Active Directory replication depends on the following:
  - Each domain controller in the forest must register its CNAME record for the name *DsaGuid*._msdcs.*ForestName*. DsaGuid is the GUID of the NTDS Settings object of the domain controller (visible in Active Directory Sites and Services as the **DNS alias** property of the server object's NTDS settings). This record usually belongs to the _msdcs.*ForestName* zone or, if that zone does not exist, the *ForestName* zone.
  - Each advertising domain controller in the forest must register its A record in the appropriate zone for each domain in the forest.
  - The A record must map to the current IP address of the respective domain controller.
  - The records must have replicated to the DNS servers used by direct replication partners.
  - Each DNS zone must have the proper delegations to the child zones.
  - The IP configuration of the domain controllers must contain correct preferred and alternate DNS servers.

  DNS errors that are reported by the directory service log or by **repadmin /showrepl** mean that the destination domain controller could not resolve the GUID-based DNS name of its source replication partner.

- **Solution:** Do the following:

1. Verify CNAME and A records. At a command prompt, type the following:

   **dcdiag /test:connectivity**

2. If the CNAME and A records are missing, restart netlogon. At a command prompt, type the following:

   **net start netlogon**

3. Again, verify CNAME and A records, by repeating step 1.

4. If the records are still missing, verify IP configuration. Verify that the preferred and alternate DNS servers specified in the IP configuration of the source and destination domain controllers are correct.

5. If the client is configured correctly, verify that the zone is dynamic. At a command prompt, type the following:

   **dcdiag /test:registerindns /dnsdomain**

6. To verify that name resolution is the cause of the problem, ping the GUID-based name of the domain controller where replication failed. If it works, the next replication cycle should not return this error.

7. If the ping fails, further DNS troubleshooting is required. For more information, see Troubleshooting Domain Name System on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=62177).

**See also:** Nslookup; Ping; Troubleshooting DNS; Install Windows Support Tools

**Received Event ID 1265 "Access denied," in directory service log. Or, received "Access denied" from the repadmin command.**

- **Cause:** This error can occur if the local domain controller failed to authenticate against its replication partner when creating the replication link or when trying to replicate over an existing link. This typically happens when the domain controller has been disconnected from the rest of the network for a long time and its computer account password is not synchronized with its computer account password stored in the directory of its replication partner.

- **Solution:** Do the following:

1. Stop the Key Distribution Center (KDC) service using **net stop KDC**.

2. Purge the ticket cache on the local domain controller.

3. Reset the domain controller's account password on the primary domain controller (PDC) emulator master using **netdom /resetpwd**. (Netdom.exe is available in Windows Support Tools).

4. Synchronize the domain directory partition of the replication partner with the PDC emulator master

5. Manually force replication between the replication partner and the PDC emulator master.

6. Start the KDC on the local domain controller:

   **net start KDC**

**See also:** User and computer accounts; Net start; Install Windows Support Tools

**Received "Access denied" from Active Directory Sites and Services when manual replication was attempted.**

- **Cause:** Using Active Directory Sites and Services to force replication initiates replication on all common directory partitions between the replication partners. However, a user can only force manual replication for containers on which

they have been assigned the **Replication Synchronization** permission. The replication of other directory partitions will fail, causing the "Access Denied" error.

- **Solution:** The **repadmin** or **replmon** command-line tools from Windows Support Tools can be used to manually force the replication of a specific directory partition.

  Replication synchronization is a special permission. For more information about special permissions, see Set, view, change, or remove special permissions and Active Directory object permissions.

**See also:** Install Windows Support Tools; Force replication over a connection; Active Directory support tools

**Unable to connect to a domain controller running Windows 2000 from the Active Directory Sites and Services snap-in.**

- **Cause:** You are trying to connect to a domain controller running Windows 2000 that does not have Service Pack 3 or later installed.

- **Solution:** Upgrade domain controllers running Windows 2000 to Service Pack 3 or later.

**See also:** Connecting to domain controllers running Windows 2000; Managing Active Directory from MMC

**Search for new and updated information about replication. Or, your question does not match any of those listed above.**

- **Cause:** New and updated information is regularly published on the Microsoft Web site.

- **Solution:** Visit the following links for the latest information:

  - Searching the Knowledge Base on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=4441)

    Search the Microsoft Knowledge Base of technical support information and self-help tools for Microsoft products.

  - Product Support Services on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=281)

    Search FAQs by product, browse the product support newsgroups, and contact Microsoft Support.

  - Active Directory Collection in the Windows Server 2003 Technical Reference on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=4549)

    View detailed technical information about Active Directory replication and other technologies, including troubleshooting Active Directory replication.

  - Microsoft Windows Server TechCenter on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=34403)

    Search for troubleshooting information, service packs, patches, and downloads for your system. View the Technical Library for the latest product information, including deployment, operations, and technical reference.

  - Windows Server Community on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=832)

    The official online community for enthusiasts of the Windows server operating systems.

# Troubleshooting schema

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting schema**
What problem are you having?

- Unable to modify or extend the schema.
- Unable to add attributes to a class.
- Unable to connect to a domain controller running Windows 2000 from the Active Directory Schema snap-in.
- Unable to find or run the Active Directory Schema snap-in.
- Search for new and updated information. Or, your question does not match any of those listed above.

**Unable to modify or extend the schema.**
**Cause:** The schema operations master is not available. The domain controller that currently holds the schema master role is offline or network connectivity between you and the schema master is inoperable.

**Solution:** Restore the availability of the schema master by fixing the network connectivity problem or by transferring or seizing the schema master role.

**See also:** Diagnose Connections; Operations master roles; Responding to operations master failures; Transfer the schema master role; Seize the schema master role

**Cause:** The user trying to modify the schema does not belong to the Schema Admins group.

**Solution:** Add the correct user account to the Schema Admins group.

**See also:** Add a member to the Schema Admins group

**Cause:** There are syntax errors in the LDAP import format (LDIF) script.

**Solution:** Debug and fix the LDIF script then try the modification again.

**See also:** The Active Directory Programmer's Guide at the Microsoft Web site; Internet Engineering Task Force Web site

**Cause:** The domain controller holding the schema master role is running Windows 2000 and has not been enabled for schema changes.

**Solution:** Enable schema changes on the domain controller. For more information, see Enable schema changes on a schema master running Windows 2000.

**See also:** Domain and forest functionality; Operations master roles; The Active Directory Programmer's Guide at the Microsoft Web site

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here..

**Unable to add attributes to a class.**
**Cause:** The attributes cannot be associated with a class because the schema cache has not been updated.

**Solution:** Ensure that the schema cache is updated after an attribute is added before attempting to add the attribute to a class. For more information, see Reload the schema.

**Cause:** You are attempting to define a class on a domain controller that is not the schema operations master and the new attribute has not replicated in.

**Solution:** Always perform schema updates on the schema operations master.

**See also:** Using the Windows Deployment and Resource Kits; Extending the schema; The Active Directory Programmer's Guide at the Microsoft Web site.

**Unable to connect to a domain controller running Windows 2000 from the Active Directory Schema snap-in.**
**Cause:** You are trying to connect to a domain controller running Windows 2000 that does not have Service Pack 3 or later installed.

**Solution:** Upgrade domain controllers running Windows 2000 to Service Pack 3 or later.

**See also:** Connecting to domain controllers running Windows 2000

**Unable to find or run the Active Directory Schema snap-in.**
**Cause:** The Active Directory Schema snap-in has not been installed or registered.

**Solution:** For instructions on installing and registering the Active Directory Schema snap-in, see Install the Active Directory Schema snap-in.

**See also:** Managing Active Directory from MMC

**Search for new and updated information. Or, your question does not match any of those listed above.**
**Cause:** You can find new and updated information on the Microsoft Web site.

**Solution:** The Microsoft Web site contains the latest product support information. For information about where to look, see Using online resources.

For the latest Active Directory development information, see the Active Directory Programmer's Guide at the Microsoft Web site.

**See also:** Managing Active Directory from MMC; Using the Windows Deployment and Resource Kits; Technical support options

# Troubleshooting trusts

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting Trusts**
What problem are you having?

- Clients are unable to access resources in a domain outside of the forest.
- Trust errors between servers or workstations.
- Trust errors between Windows NT 4.0 and Active Directory domains.
- After upgrading a Windows NT 4.0 domain with existing trusts to Active Directory domains, you encounter various trust-related problems.
- Cannot connect to a domain controller running Windows 2000.

**Clients are unable to access resources in a domain outside of the forest.**
**Cause:** A failure has occurred on the external trust between the domains.

**Solution:** Reset and verify the trust between the domains. The PDC emulator master must be available for a trust to be successfully reset.

**See also:** Verify a trust; Operations master roles; When to create an external trust

**Trust errors between servers or workstations.**
**Cause:** Incorrect time synchronization between domain controllers or workstations, the server could be down, or the trust relationship could be broken.

**Solution:** Run Netdom to verify, reset, or establish the trust between computers. This command-line tool performs batch management of trusts, verifies trusts and secures channels between computers, and can join computers to domains.

**See also:** Install Windows Support Tools

**Trust errors between Windows NT 4.0 and Active Directory domains.**
**Cause:** Automatic trust password resets for the trust may not reach the PDC emulator master role holder.

**Solution:** Run Netdom to verify, reset, or establish trust between computers. This command-line tool performs batch management of trusts, verifies trusts and secures channels between computers, and can join computers to domains. If this does not help solve the issue, see article Q317178, "Windows NT 4.0 Domain Updates Trust Account Password on Non-PDC," in the Microsoft Knowledge Base.

**After upgrading a Windows NT 4.0 domain with existing trusts to Active Directory domains, you encounter various trust-related problems.**
**Cause:** When the domain has been upgraded, the existing trusts to Active Directory domains remain Windows NT 4.0 trusts. Internet Protocol Security (IPSec) cannot work over a Windows NT 4.0 trust. Or, trusts to other domains in the forest are no longer available.

**Solution:** After upgrading a Windows NT 4.0 domain to an Active Directory domain, it is recommended that you delete and recreate all previously existing trusts with Active Directory domains. If this does not solve the issue, see article Q275221, "Trusts Unavailable on Backup Domain Controllers After Upgrading the Windows NT Primary Domain Controller," in the Microsoft Knowledge Base.

**See also:** Install Windows Support Tools; Upgrading from a Windows NT domain

**Cannot connect to a domain controller running Windows 2000.**
**Cause:** You are trying to connect to a domain controller running Windows 2000 that does not have Service Pack 3 or later installed.

**Solution:** Upgrade domain controllers running Windows 2000 to Service Pack 3 or later.

**See also:** Connecting to domain controllers running Windows 2000

# Network Services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network services**
This section covers:

- Managing Core Network Services
- Managing Remote Connections
- Configuring Communication Links
- Configuring Communication Services
- Managing Bandwidth
- Integrating with Other Networks

# Managing Core Network Services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing core network services**
This section covers:

- TCP/IP Core Networking Service
- IP Version 6
- Internet Protocol Security (IPSec)
- DNS
- DHCP
- WINS

# TCP/IP Core Networking Service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP**
Transmission Control Protocol/Internet Protocol (TCP/IP) is a suite of standard protocols for connecting computers and building networks. TCP/IP is network protocol software provided with Microsoft® Windows® operating systems that implements and supports the TCP/IP protocol suite:

- Before you begin using TCP/IP with this computer, see Checklist: Configuring TCP/IP.
- To find features that have been moved in the Windows Server 2003 family, see New ways to do familiar tasks with TCP/IP.
- For tips about using TCP/IP, see Best practices for TCP/IP.
- For help with specific tasks, see TCP/IP How To....
- For general background information, see TCP/IP Concepts.
- For problem-solving instructions, see Troubleshooting TCP/IP.

The Windows Server 2003 family includes the latest version of Internet Protocol (IP), known as IP version 6. For more information, see IP Version 6.

# Checklist: Configuring TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Configuring TCP/IP**

| Step | Reference |
|---|---|
| Review TCP/IP concepts such as IP addressing, subnet masks, and default gateways. | Understanding TCP/IP |
| Review TCP/IP name resolution concepts and options for resolving NetBIOS and DNS names to IP addresses. | Name Resolution |
| Determine how computers on your network will obtain IP addresses. | DHCP |
| Determine how computers on your network will register and resolve NetBIOS names. | WINS |
| Determine how computers on your network will resolve and register DNS names. | DNS |
| Determine how this computer will be used with your TCP/IP network. | Configuring TCP/IP |
| Verify that network adapter hardware is installed, or install hardware if needed. | Hardware overview |
| Verify that network adapter hardware is installed, or install hardware if needed. | Configuring devices |
| Determine whether you will configure TCP/IP properties manually, dynamically, or automatically. | Configure TCP/IP |
| If you decide to manually configure TCP/IP, obtain and record the following TCP/IP information from your network administrator:<br>• IP address<br>• Subnet mask<br>• Default gateways<br>• DNS servers<br>• DNS domain<br>• WINS servers | |
| If you decide to manually configure TCP/IP, configure IP address, subnet mask, and default gateway settings. | Configure TCP/IP for static addressing |
| If you decide to manually configure TCP/IP, use WINS to obtain and resolve NetBIOS names. | Configure TCP/IP to use WINS |
| If you decide to manually configure TCP/IP, use DNS to obtain and resolve DNS names. | Configure TCP/IP to use DNS |
| (Optional) Configure additional or secondary methods to obtain and resolve NetBIOS names. | Advanced configuration |

| | |
|---|---|
| (Optional) Configure additional or secondary methods to obtain and resolve DNS names. | Advanced configuration |
| Use the **ipconfig /all** command to verify all current TCP/IP network configuration values. | Ipconfig |
| Use the **ping** command to verify that you have TCP/IP installed and working properly. | Test a TCP/IP configuration by using the ping command |
| Use the **nslookup** command to verify that you are able to obtain and resolve DNS names. | TCP/IP utilities; Verify DNS registration for domain controllers using the nslookup command |
| Review Internet Protocol security (IPSec) concepts, and then configure IPSec for TCP/IP. | Internet Protocol Security (IPSec) |

The Windows Server 2003 family includes the latest version of Internet Protocol (IP), known as IP version 6. For more information, see IP Version 6.

# New ways to do familiar tasks with TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar tasks**

The following table lists common tasks for configuring TCP/IP. The graphical user interface (GUI) for performing these tasks is different from the way it was in Windows NT Server 4.0 or Windows 2000.

Please choose your upgrade path:

- Windows NT 4.0 to a Windows Server 2003 operating system
- Windows 2000 to a product in a Windows Server 2003 operating system

**Windows NT 4.0 to a Windows Server 2003 operating system**

| If you want to | In Windows NT 4.0 | In this version of Windows |
|---|---|---|
| Configure TCP/IP | Use the **Protocols** tab of **Network** in Control Panel. | Open Network Connections and use the **Properties** of a connection. For more information, see Configure TCP/IP. |
| Add or remove TCP/IP | Use the **Protocols** tab of **Network** in Control Panel. | TCP/IP is installed by default and cannot be added or removed through the GUI. |

**Windows 2000 to a product in a Windows Server 2003 operating system**

| If you want to | In Windows 2000 | In this version of Windows |
|---|---|---|
| Configure TCP/IP | Use the **Properties** of a connection in Network and Dial-up Connections. | Open Network Connections and use the **Properties** of a connection. For more information, see Configure TCP/IP. |
| Add or remove TCP/IP | Use the **Properties** of a connection in Network and Dial-up Connections. | TCP/IP is installed by default and cannot be added or removed through the GUI. |

# Best practices for TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices**

- **If your network does not already use TCP/IP, develop a comprehensive IP addressing plan for your network.**

  You need to know the following information to help make a workable plan:

  1. How many physically separate network segments are contained within your network?
  2. How many host systems on each network segment will use TCP/IP?
  3. Will your network be connected to the Internet?

     - If so, will your network be directly connected to the Internet by using a router (which uses public addresses allocated by your Internet service provider), or will your network be indirectly connected to the Internet by using network address translation (NAT) or an application layer gateway such as a proxy server (which uses private addresses)?
     - If not, then it is technically possible to use any IP addressing scheme. However, it is highly recommended that you use private addresses so that an eventual connection to the Internet does not force you to renumber your network.

For more information about connecting a home or small office network to the Internet, see Internet Connection Sharing and network address translation.

- **If you are using private IP addressing, use addresses from the private address ranges reserved by the Internet Assigned Numbers Authority (IANA).**

  For more information, see Numbering your network.

- **Configure a default gateway on only one network adapter.**

  This practice reduces confusion and assures the results you intended. For information about configuring multiple gateways, see Default gateways.

# TCP/IP How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

- Configure TCP/IP
- Manage Routes
- Diagnose Connections

# Configure TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure TCP/IP**

- Install Simple TCP/IP Services
- Configure TCP/IP for dynamic addressing
- Configure TCP/IP for automatic addressing
- Configure TCP/IP for an alternate configuration
- Disable automatic address configuration
- Configure TCP/IP for static addressing
- Configure TCP/IP to use DNS
- Configure TCP/IP to use WINS
- Configure TCP/IP to use TCP/IP filtering

# Install Simple TCP/IP Services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install Simple TCP/IP Services**

1. Open Add or Remove Programs in Control Panel.
2. Click **Add/Remove Windows Components**.
3. In **Components**, click **Networking Services**, and then click **Details**.
4. In **Networking Services**, select the **Simple TCP/IP Services** check box, and then click **OK**.
5. Click **Next**.
6. If prompted, type the path where the distribution files are located, and then click **OK**.
7. Click **Finish**, and then click **Close**.

## Notes

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.
- To open a Control Panel item, click **Start**, click **Control Panel**, and then double-click the appropriate icon.
- Simple TCP/IP Services provide support for the optional TCP/IP protocol services listed in the following table.

| Protocol | Description | RFC |
|---|---|---|
| Character Generator (CHARGEN) | Sends data made up of the set of 95 printable ASCII characters. Useful as a debugging tool for testing or troubleshooting line printers. | 864 |
| Daytime | Returns messages containing the day of the week, month, day, year, current time (in *hh:mm:ss* format), and time-zone information. Some programs can use the output from this service for debugging or monitoring variations in system clock time or on a different host. | 867 |
| Discard | Discards all messages received on this port without response or acknowledgment. Can serve as a null port for receiving and routing TCP/IP test messages during network setup and configuration or, in some cases, can be used by programs as a message discard function. | 863 |
| Echo | Echoes back data from any messages it receives on this server port. Echo can be useful as a network debugging and monitoring tool. | 862 |
| Quote of the Day (QUOTE) | Returns a quotation as one or more lines of text in a message. Quotations are taken at random from the following file: *systemroot*\System32\Drivers\Etc\Quotes. A sample quote file is installed with the Simple TCP/IP Services. If this file is missing, the quote service fails. | 865 |

All of these protocol services are classified as elective Internet standards and are defined and described in the specified Request for Comments (RFC) document listed in the table. For more information about these protocol services, see the RFCs.

- Do not install Simple TCP/IP Services unless you specifically need this computer to support communication with other systems that use these protocol services.

- After Simple TCP/IP Services are installed, you cannot enable or disable the separate services individually.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

TCP/IP RFCs

# Configure TCP/IP for dynamic addressing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure TCP/IP for dynamic addressing**

1. Open Network Connections.
2. Right-click the network connection that you want to configure, and then click **Properties**.
3. On the **General** tab (for a local area connection) or the **Networking** tab (for all other connections), click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. Click **Obtain an IP address automatically**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- These instructions are only required if a static TCP/IP configuration was previously used. By default, computers running Windows Server 2003 operating systems attempt to obtain the TCP/IP configuration from a DHCP server on your network.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure TCP/IP for automatic addressing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure TCP/IP for automatic addressing**

1. Open Network Connections.
2. Right-click the network connection that you want to configure, and then click **Properties**.
3. On the **General** tab (for a local area connection) or the **Networking** tab (for all other connections), click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. Click **Obtain an IP address automatically**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- By default, TCP/IP is configured to use DHCP addressing. If a DHCP server is unavailable, then servers running Windows Server 2003 can use Automatic Private IP Addressing (APIPA) or the alternate configuration method to automate Internet Protocol (IP) configuration of network connections. For more information about these new features, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure TCP/IP for an alternate configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure TCP/IP for an alternate configuration**

1. Open Network Connections.
2. Right-click the network connection that you want to configure, and then click **Properties**.
3. On the **General** tab (for a local area connection) or the **Networking** tab (for all other connections), click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. On the **General** tab, click **Obtain an IP address automatically**.
5. On the **Alternate Configuration** tab, click **User configured**, and then type appropriate values for the following:
   - IP address
   - Subnet mask
   - Default gateway
   - Preferred and alternate DNS server
   - Preferred and alternate WINS server

**Notes**

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- The alternate configuration is used for computers that travel between a network with static IP addresses and one or more DHCP networks.
- Computers running Windows Server 2003 can use Automatic Private IP Addressing (APIPA) or the alternate configuration method to automate Internet Protocol (IP) configuration of network connections. For more information about these new features, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disable automatic address configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable automatic address configuration**

1. Open Registry Editor.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the **Last Known Good Configuration** startup option if problems are encountered after manual changes have been applied.

2. In Registry Editor, navigate to the following registry key:

   **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters**

3. Click the Parameters folder, and then click **Edit**.

4. Click **New**, and then click **DWORD Value**.

5. Type the following to create a new entry:

   **IPAutoconfigurationEnabled**

6. Right-click the new entry, and then click **Modify**.

7. In **Edit DWORD Value**, under **Value data**, ensure that the setting is **O**.

8. Exit Registry Editor, and restart the computer.

## Notes

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.

- To open Registry Editor, click **Start**, click **Run**, type **regedit**, and then click **OK**.

- If the **IPAutoconfigurationEnabled** entry is not present, a default value of **1** is assumed, which indicates that APIPA can be used.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure TCP/IP for static addressing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure TCP/IP for static addressing**

1. Open Network Connections.
2. Right-click the network connection you want to configure, and then click **Properties**.
3. On the **General** tab (for a local area connection) or the **Networking** tab (for all other connections), click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. Click **Use the following IP address**, and do one of the following:
   - For a local area connection, in **IP address**, **Subnet mask**, and **Default gateway**, type the IP address, subnet mask, and default gateway addresses.
   - For all other connections, in **IP address**, type the IP address.
5. Click **Use the following DNS server addresses**.
6. In **Preferred DNS server** and **Alternate DNS server**, type the primary and secondary DNS server addresses.

To configure advanced static address settings for a local area connection, click **Advanced**, and do one or more of the following:

To configure additional IP addresses:

1. On the **IP Settings** tab, in **IP addresses**, click **Add**.
2. In **TCP/IP Address**, type an IP address in **IP address** and a subnet mask in **Subnet mask**, and then click **Add**.
3. Repeat steps 1 and 2 for each IP address you want to add, and then click **OK**.

To configure additional default gateways:

1. On the **IP Settings** tab, in **Default gateways**, click **Add**.
2. In **TCP/IP Gateway Address**, type the IP address of the default gateway in **Gateway**. To manually configure a default route metric, clear the **Automatic metric** check box and type a metric in **Metric**.
3. Click **Add**.
4. Repeat steps 1 through 3 for each default gateway you want to add, and then click **OK**.

To configure a custom metric for this connection, clear the **Automatic metric** check box, and then type a metric value in **Interface metric**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure TCP/IP to use DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure TCP/IP to use DNS**

1. Open Network Connections.
2. Right-click the network connection you want to configure, and then click **Properties**.
3. On the **General** tab (for a local area connection) or the **Networking** tab (for all other connections), click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. If you want to obtain DNS server addresses from a DHCP server, click **Obtain DNS server address automatically**.
5. If you want to manually configure DNS server addresses, click **Use the following DNS server addresses**, and in **Preferred DNS server** and **Alternate DNS server**, type the preferred DNS server and alternate DNS server IP addresses.
6. To configure advanced DNS properties, click **Advanced**, click the **DNS** tab, and do one or more of the following:

- To configure an additional DNS server IP address:

Under **DNS server addresses, in order of use**, click **Add**.

In **TCP/IP DNS server**, type the IP address of the DNS server, and then click **Add**.

- To modify the resolution behavior for unqualified DNS names, do the following:

To resolve an unqualified name by appending the primary DNS suffix and the DNS suffix of each connection (if configured), click **Append primary and connection specific DNS suffixes**. If you also want to search the parent suffixes of the primary DNS suffix up to the second level domain, select the **Append parent suffixes of the primary DNS suffix** check box.

To resolve an unqualified name by appending the suffixes from a list of configured suffixes, click **Append these DNS suffixes (in order)**, and then click **Add** to add suffixes to the list.

- To configure a connection-specific DNS suffix, type the DNS suffix in **DNS suffix for this connection**.
- To modify DNS dynamic update behavior, do the following:

To use a DNS dynamic update to register the IP addresses of this connection and the primary domain name of the computer, select the **Register this connection's addresses in DNS** check box. This option is enabled by default. The primary domain name of the computer is the primary DNS suffix appended to the computer name and can be viewed as the full computer name on the **Computer Name** tab (available in System in Control Panel).

To use a DNS dynamic update to register the IP addresses and the connection-specific domain name of this connection, select the **Use this connection's DNS suffix in DNS registration** check box. This option is disabled by default. The connection-specific domain name of this connection is the DNS suffix for this connection appended to the computer name.

**Notes**

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

- To completely disable DNS dynamic update for all names on the computer, clear the **Register this connection's addresses in DNS** and **Use this connection's DNS suffix in DNS registration** check boxes for all connections in Network Connections.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure TCP/IP to use WINS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure TCP/IP to use WINS**

1. Open Network Connections.
2. Right-click the network connection you want to configure, and then click **Properties**.
3. On the **General** tab (for a local area connection) or the **Networking** tab (for all other connections), click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. Click **Advanced**, click the **WINS** tab, and then click **Add**.
5. In **TCP/IP WINS server**, type the IP address of the WINS server, and then click **Add**.
6. Repeat steps 4 and 5 for each WINS server IP address you want to add, and then click **OK**.
7. To enable the use of the Lmhosts file to resolve remote NetBIOS names, select the **Enable LMHOSTS lookup** check box. This option is enabled by default.
8. To specify the location of the file that you want to import into the Lmhosts file, click **Import LMHOSTS**, and then select the file in the **Open** dialog box.
9. To enable or disable NetBIOS over TCP/IP, do the following:
    - To enable the use of NetBIOS over TCP/IP, click **Enable NetBIOS over TCP/IP**.
    - To disable the use of NetBIOS over TCP/IP, click **Disable NetBIOS over TCP/IP**.
    - To have the DHCP server determine whether NetBIOS over TCP/IP is enabled or disabled, click **Default**. For more information, see Notes.

**Notes**

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- If you are using a DHCP server to allocate WINS server IP addresses, you do not need to add WINS server addresses.
- If you disable NetBIOS over TCP/IP, you might not be able to connect to computers that are running operating systems other than Windows 2000, Windows XP, or a Windows Server 2003 operating system.
- If you disable NetBIOS over TCP/IP, you cannot use broadcast-based NetBIOS name resolution to resolve computer names to IP addresses for computers on the same network segment. If your computers are on the same network segment, and NetBIOS over TCP/IP is disabled, you must install a DNS server and either have the computers register with DNS (or manually configure DNS records) or configure entries in the local Hosts file for each computer.
- The DHCP server determines whether NetBIOS over TCP/IP is enabled or disabled based on the value of the Microsoft vendor-specific DHCP option **Disable NetBIOS over TCP/IP (NetBT)**. This option either enables (set to **1**) or disables (set to **2**) NetBIOS over TCP/IP on the DHCP client computer. If the DHCP server does not send the **Disable NetBIOS**

**over TCP/IP (NetBT)** DHCP option during DHCP lease negotiation or TCP/IP is manually configured, NetBIOS over TCP/IP is enabled. For more information about the **Disable NetBIOS over TCP/IP (NetBT)** DHCP option, see Related Topics.

- You can no longer configure the NetBIOS scope ID on the **WINS** tab (previously available in Windows NT 4.0). To configure the NetBIOS scope ID, set the following registry value to the name of the scope ID that you want to use:

  **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\ScopeID**

  **Caution**

  - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

- For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure TCP/IP to use TCP/IP filtering

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure TCP/IP to use TCP/IP filtering**

1. Open Network Connections.
2. Right-click the network connection you want to configure, and then click **Properties**.
3. On the **General** tab (for a local area connection) or the **Networking** tab (for all other connections), click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. Click **Advanced**.
5. Click **Options**, click **TCP/IP filtering**, and then click **Properties**.
6. Do one of the following:
   - To enable TCP/IP filtering for all adapters, select the **Enable TCP/IP Filtering (All adapters)** check box.
   - To disable TCP/IP filtering for all adapters, clear the **Enable TCP/IP Filtering (All adapters)** check box.
7. Based on your requirements for TCP/IP filtering, configure TCP ports, UDP ports, or IP protocols for the allowed traffic.

## Notes

- To perform this procedure, you must be a member of the Administrators group or the Network Configuration Operators group on the local computer. For more information, see Default local groups and Default groups.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Routes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage routes**

- View the IP routing table
- Add a static IP route
- Remove a static IP route
- Enable the Routing and Remote Access service

# View the IP routing table

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the IP routing table**

1. Open Command Prompt.
2. At the command prompt, type:

   **route print**

**Note**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Route

# Add a static IP route

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a static IP route**

1. Open Command Prompt.

2. At the command prompt, type:

   **route add***destination***mask***subnetmaskgateway***metric***costmetric***if***interface*

   where:

| Static IP route entry | Definition |
|---|---|
| *destination* | Specifies either an IP address or host name for the network or host. |
| *subnetmask* | Specifies a subnet mask to be associated with this route entry. If *subnetmask* is not specified, 255.255.255.255 is used. |
| *gateway* | Specifies either an IP address or host name for the gateway or router to use when forwarding. |
| *costmetric* | Assigns an integer cost metric (ranging from 1 through 9,999) to be used in calculating the fastest, most reliable, and/or least expensive routes. If *costmetric* is not specified, 1 is used. |
| *interface* | Specifies the interface to be used for the route that uses the interface number. If an interface is not specified, the interface to be used for the route is determined from the gateway IP address. |

   For example, to add a static route to the 10.0.0.0 network that uses a subnet mask of 255.0.0.0, a gateway of 192.168.0.1, and a cost metric of 2, you type the following at a command prompt:

   **route add 10.0.0.0 mask 255.0.0.0 192.168.0.1 metric 2**

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To make a static route persistent, you can either enter **route add** commands in a batch file that is run during system startup or use the **-p** option when adding routes.

- Routes added by using the **-p** option are stored in the registry under the following key:

  **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip \Parameters\PersistentRoutes**

- All symbolic names used for *destination* or *gateway* are looked up in the network and computer name database files (Networks and Hosts), which are stored in the local *systemroot*\System32\Drivers\Etc folder.

- If a route addition fails, you can use the **tracert** command to verify that the gateway specified is directly reachable from the same subnet as this computer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your

account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove a static IP route

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove a static IP route**

1. Open Command Prompt.

2. At the command prompt, type:

   **route delete***destination*

   where:

   *destination* specifies either an IP address or network name for the remote TCP/IP host computer or network.

   For example, to delete a static route to the 10.0.0.0 network, you type the following at a command prompt:

   **route delete 10.0.0.0**

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- All symbolic names used for *destination* are looked up in the network database file Networks, which is stored in the local *systemroot*\System32\Drivers\Etc folder.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable the Routing and Remote Access service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable the Routing and Remote Access service**

1. If this server is a member of an Active Directory domain and you are not a domain administrator, instruct your domain administrator to add the computer account of this server to the **RAS and IAS Servers** security group in the domain of which this server is a member. The domain administrator can add the computer account to the **RAS and IAS Servers** security group by using Active Directory Users and Computers or with the **netsh ras add registeredserver** command. If this server is using local authentication or is authenticating against a RADIUS server, skip this step.

2. Open Routing and Remote Access.

3. By default, the local computer is listed as a server.

   To add another server, in the console tree, right-click **Server Status**, and then click **Add Server**.

   In the **Add Server** dialog box, click the applicable option, and then click **OK**.

4. In the console tree, right-click the server you want to enable, and then click **Configure and Enable Routing and Remote Access**.

5. Follow the instructions in the Routing and Remote Access Server Setup Wizard.

### Note

- To perform this procedure, you must be a member of the Administrators group. As a security best practice, consider using the Run As command rather than logging on with administrative credentials. If you have logged on with administrative credentials, you can also open Routing and Remote Access by clicking **Start**, clicking **Control Panel**, double-clicking **Administrative Tools**, and then double-clicking **Routing and Remote Access**. For more information, see Default local groups, Default groups, and Using Run as.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Diagnose Connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Diagnose connections**

- Test a TCP/IP configuration by using the ping command
- Test TCP/IP connections by using the ping and net view commands
- Trace a path by using the tracert command
- View the NetBIOS name table by using the nbtstat command
- Release and refresh NetBIOS names by using the nbtstat command
- View the Address Resolution Protocol (ARP) cache
- Add a static ARP cache entry
- View current TCP/IP protocol and connection statistics

# Test a TCP/IP configuration by using the ping command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test a TCP/IP configuration by using the ping command**

1. To quickly obtain the TCP/IP configuration of a computer, open Command Prompt, and then type **ipconfig**. From the display of the **ipconfig** command, ensure that the network adapter for the TCP/IP configuration you are testing is not in a **Media disconnected** state. For more information, see Notes.

2. At the command prompt, ping the loopback address by typing **ping 127.0.0.1**.

3. Ping the IP address of the computer.

4. Ping the IP address of the default gateway.

   If the **ping** command fails, verify that the default gateway IP address is correct and that the gateway (router) is operational.

5. Ping the IP address of a remote host (a host that is on a different subnet).

   If the **ping** command fails, verify that the remote host IP address is correct, that the remote host is operational, and that all of the gateways (routers) between this computer and the remote host are operational.

6. Ping the IP address of the DNS server.

   If the **ping** command fails, verify that the DNS server IP address is correct, that the DNS server is operational, and that all of the gateways (routers) between this computer and the DNS server are operational.

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- The **ipconfig** command is the command-line equivalent to the **winipcfg** command, which is available in Windows 95, Windows 98, Windows 98 Second Edition, and Windows Millennium Edition. Computers running Windows XP or Windows Server 2003 operating systems do not include a graphical equivalent of the **winipcfg** command, however, you can get equivalent functionality for viewing and renewing an IP address by opening Network Connections, right-clicking a network connection, clicking **Status**, and then clicking the **Support** tab.

- If the **ipconfig** command displays **Media disconnected**, the network cable is not plugged in to the network adapter.

- If the **ping** command is not found or the command fails, you can use Event Viewer to check the system log and look for problems reported by Setup or the Internet Protocol (TCP/IP) service.

- The **ping** command uses Internet Control Message Protocol (ICMP) Echo Request and Echo Reply messages. Packet filtering policies on routers, firewalls, or other types of security gateways might prevent the forwarding of this traffic.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test TCP/IP connections by using the ping and net view commands

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test TCP/IP connections by using the ping and net view commands**

1. To test TCP/IP connectivity by using the Ping command, use the display of the **ipconfig** command to ensure that your network adapter is not in a **Media disconnected** state. For more information, see Notes.

2. Open Command Prompt, and then ping the desired host using its IP address.

   If the **ping** command fails with a "Request timed out" message, verify that the host IP address is correct, that the host is operational, and that all of the gateways (routers) between this computer and the host are operational.

3. To test host name resolution by using the **ping** command, ping the desired host using its host name.

   If the **ping** command fails with an "Unable to resolve target system name" message, verify that the host name is correct and that the host name can be resolved by your DNS server.

4. To test TCP/IP connectivity by using the **net view** command, open Command Prompt, and then type **net view ***ComputerName*. The **net view** command lists the file and print shares by establishing a temporary connection. If there are no file or print shares on the specified computer, the **net view** command displays a "There are no entries in the list" message.

   If the **net view** command fails with a "System error 53 has occurred" message, verify that *ComputerName* is correct, that the computer is operational, and that all of the gateways (routers) between this computer and the computer are operational.

   If the **net view** command fails with a "System error 5 has occurred. Access is denied." message, verify that you are logged on using an account that has permission to view the shares on the remote computer.

   To further troubleshoot this connectivity problem, do the following:

   - Use the **ping** command to ping *ComputerName*.

     If the **ping** command fails with an "Unable to resolve target system name" message, then *ComputerName* cannot be resolved to its IP address.

   - Use the **net view** command and the IP address of the computer, as follows:

     **net view ***IPAddress*

     If the **net view** command succeeds, then *ComputerName* is being resolved to the wrong IP address.

     If the **net view** command fails with a "System error 53 has occurred" message, the remote computer might not be running the File and Printer Sharing for Microsoft Networks service.

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- The **ipconfig** command is the command-line equivalent to the **winipcfg** command, which is available in Windows 95,

Windows 98, and Windows Millennium Edition. Computers running Windows XP or a Windows Server 2003 operating system do not include a graphical equivalent of the **winipcfg** command, however, you can get equivalent functionality for viewing and renewing an IP address by opening Network Connections, right-clicking a network connection, clicking **Status**, and then clicking the **Support** tab.

- If the **ipconfig** command displays **Media disconnected**, the network cable is not plugged in to the network adapter.

- If the **ipconfig** command only yields the message **Windows IP Configuration**, and then returns you to the command prompt, you should check to see if your network adapter has been disabled. For more information, see **To make a local area connection** in Related Topics

- If the **ping** command is not found or the command fails, you can use Event Viewer to check the system log and look for problems reported by Setup or the Internet Protocol (TCP/IP) service.

- The **ping** command uses Internet Control Message Protocol (ICMP) Echo Request and Echo Reply messages. Packet filtering policies on routers, firewalls, or other types of security gateways might prevent the forwarding of this traffic.

- The procedure for testing TCP/IP connections using the **net view** command assumes that you are using only the TCP/IP protocol suite. If additional protocols are installed, such as the NWLink IPX/SPX/NetBIOS Compatible Transport Protocol, **net view** might work correctly when there are problems resolving names and making connections with TCP/IP because **net view** attempts a connection using all installed protocols. Even if the **net view** connection with TCP/IP fails, **net view** might successfully connect to the NWLink IPX/SPX/NetBIOS Compatible Transport Protocol.

- The IPX/SPX protocol is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Trace a path by using the tracert command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To trace a path by using the tracert command**

- Open Command Prompt, and type the following:

  **tracert***HostName*

  Or, type **tracert** *IPAddress*

  where *HostName* or *IPAddress* is the host name or IP address, respectively, of the remote computer.

  For example, to trace the path from this computer to www.microsoft.com, type the following at a command prompt:

  **tracert www.microsoft.com**

  If you do not want the tracert command to resolve and display the names of all routers in the path, use the **-d** parameter. This expedites the display of the path. For example, to trace a path from this computer to www.microsoft.com without displaying the router names, type the following at a command prompt:

  **tracert -d www.microsoft.com**

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- The **tracert** command traces the path by sending Internet Control Message Protocol (ICMP) Echo Request and Echo Reply messages (similar to the **ping** command) to produce command-line report output about each router that is crossed and the roundtrip time (RTT) for each hop. Packet filtering policies on routers, firewalls, or other types of security gateways might prevent forwarding of this traffic.

- If **tracert** is unsuccessful, you can use the command output to help determine at which intermediate router forwarding failed or was slowed.

- For details about packet forwarding and packet loss at each router and link in the path, use the **pathping** command.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View the NetBIOS name table by using the nbtstat command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the NetBIOS name table by using the nbtstat command**

1. Open Command Prompt.

2. At the command prompt, type:

   **nbtstat -n**

   The NetBIOS local name table for this computer is displayed as command-line output. The name type is listed to indicate whether each name is a unique name or a group name. Also, the status for each name is given, indicating whether the name is registered or unregistered with the network.

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- The **nbtstat** command displays statistics and names information used by NetBIOS over TCP/IP (NetBT) connections. The **-n** option is used to list only local NetBIOS names for this computer. You can also use **nbtstat** to:

  - List the NetBIOS name table of a remote computer.

  - Display the contents of the NetBIOS names cache of this computer or a remote computer.

  - Manually load or reload the NetBIOS names cache by using entries in the Lmhosts file with a **#PRE** option.

  - List NetBIOS over TCP/IP sessions statistics.

  - Release and refresh NetBIOS names in WINS.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Release and refresh NetBIOS names by using the nbtstat command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To release and refresh NetBIOS names by using the nbtstat command**

1. Open Command Prompt.

2. At the command prompt, type:

   **nbtstat -RR**

   The progress of the release and refresh process is displayed as command-line output. This information indicates if all local NetBIOS names currently registered in WINS for this computer have released and renewed their registration with a WINS server.

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- NetBIOS names are registered with WINS and are normally released when the computer shuts down properly. If the computer did not properly shut down or could not contact a WINS server during shutdown and release its names, you can use this command to force a refresh and update in WINS of the local names for this computer. This is useful for mobile or portable computers that are moved between different locations on a network.

- You can also use the **nbtstat** command to:

  - List the NetBIOS names registered to this computer or a remote computer.

  - Display the contents of the NetBIOS names cache of this computer or a remote computer.

  - Manually load or reload the NetBIOS names cache by using entries in the Lmhosts file with a **#PRE** option.

  - List NetBIOS over TCP/IP sessions statistics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View the Address Resolution Protocol (ARP) cache

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the Address Resolution Protocol (ARP) cache**

1. Open Command Prompt.

2. At the command prompt, type **arp -a**.

   For example, if you recently used the **ping** command to test and verify connectivity from this computer to a host computer at IP address 10.0.0.99, the ARP cache displays the following entry:

```
Interface: 10.0.0.1 on Interface 0x1
  Internet Address      Physical Address      Type
  10.0.0.99             00-e0-98-00-7c-dc     dynamic
```

   In this example, the cache entry indicates that the remote host computer at 10.0.0.99 resolved to a media access control address of 00-e0-98-00-7c-dc assigned in the network adapter hardware of the remote computer. The media access control address is the address that your computer used to physically communicate with this remote TCP/IP host on your network.

**Notes**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To minimize ARP broadcast traffic on your network, a cache of hardware-to-software address mappings is maintained for future use. This cache contains the following two types of entries:

  - **Dynamic ARP cache entries**

    These entries are added and deleted automatically during normal use of TCP/IP sessions with remote computers. Dynamic entries age and expire from the cache if not reused within 2 minutes. If a dynamic entry is reused within 2 minutes, it may remain in the cache and age up to a maximum cache life of 10 minutes before being removed or requiring cache renewal by using the ARP broadcast process.

  - **Static ARP cache entries**

    These entries are added manually by using the **arp** command with the **-s** option. Static entries remain in the ARP cache until either the computer is restarted, or the interface is reinitiated. Examples of some of the events that cause an interface to be reinitiated are:

1. The interface is **Disabled**, and then **Enabled**.

2. The **Repair** feature is used.

3. The commands **ipconfig /release** and **ipconfig /renew** are given.

4. The computer awakes from a suspend or hibernation state.

5. You removed and replugged a network cable or moved a computer out of and back into wireless range.

6. ARP cache entries can be deleted manually by using the **arp** command with the **-d** option.

```
Example: arp -d 192.168.0.1
Removes ARP mappings for 192.168.0.1 on all interfaces.
```

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a static ARP cache entry

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a static ARP cache entry**

1. Open Command Prompt.

2. At the command prompt, type:

   **arp -s***ip_addressmac_address*

   where:

| | |
|---|---|
| *ip_address* | Specifies the IP address of a local (on the same subnet) TCP/IP node. |
| *mac_address* | Specifies the media access control address for a network adapter installed and used on the local TCP/IP node. |

   For example, to add a static ARP entry for a local TCP/IP node with an IP address of 10.0.0.200 that resolves to a media access control address of 00-10-54-CA-E1-40, type the following at a command prompt:

   **arp -s 10.0.0.200 00-10-54-CA-E1-40**

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- Static ARP entries can help speed access for hosts that are frequently used.

- Static ARP entries are valid only until your computer is restarted. To make static ARP cache entries persistent, you can add **arp** commands to a batch file that is run at system startup.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

- Using TCP/IP
- TCP/IP Resources

# TCP/IP Overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP overview**
This section covers:

- Security features
- Security information for TCP/IP
- TCP/IP defined
- TCP/IP background
- The TCP/IP model
- TCP/IP utilities
- New features for TCP/IP

# Security features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security features**
TCP/IP incorporates security features that provide protection of the TCP/IP data as it is sent on the network and configuration of the types of local host traffic that are processed.

**Internet Protocol security**
Internet Protocol security (IPSec) is a set of Internet standards that uses cryptographic security services to provide the following:

- Confidentiality

  IPSec traffic is encrypted. Captured IPSec traffic is unintelligible without knowledge of the encryption key.

- Authentication

  IPSec traffic is digitally signed with the shared encryption key so that the receiver can verify that it was sent by the IPSec peer.

- Data integrity

  IPSec traffic contains a cryptographic checksum that incorporates the encryption key. The receiver can verify that the packet was not modified in transit.

For more information about IPSec, see Internet Protocol Security (IPSec).

**TCP/IP filtering**
With TCP/IP filtering, a feature known as TCP/IP Security in Microsoft® Windows NT® 4.0, you can specify exactly which types of incoming TCP/IP traffic are processed for each IP interface. This feature is designed to isolate the traffic that is processed by Internet or intranet servers in the absence of other TCP/IP filtering provided by the Routing and Remote Access service or other TCP/IP programs or services. TCP/IP filtering is disabled by default.

TCP/IP filtering is a set of filters for inbound local host TCP/IP traffic. Local host traffic is traffic that is processed by the host because the destination IP address of inbound TCP/IP traffic is addressed to an assigned interface addresses, appropriate subnet broadcast addresses, or a multicast address. TCP/IP filtering does not apply to routed traffic that is forwarded between interfaces.

With TCP/IP filtering, you can confine local host inbound TCP/IP traffic based on the:

- Destination TCP port
- Destination UDP port
- IP protocol

For information about configuring TCP/IP filtering, see Configure TCP/IP to use TCP/IP filtering.

# Security information for TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for TCP/IP**

TCP/IP internetworks are susceptible to a variety of possible attacks, from passive attacks (such as eavesdropping) to active attacks (such as denial-of-service attacks). For more information, see Security issues with IP and Security information for IPv6.

It is important to follow best practices for security when using IPv4 on your network. For more information, see Best practices for security.

The following are known security issues for IPv4:

- **The installation of an unauthorized router can cause the reconfiguration of clients and the rerouting of IPv4 traffic.**

  To communicate with IPv4 nodes on other network segments, IPv4 hosts use a default router, also called a default gateway. The IP address of the default router is statically configured or assigned through Dynamic Host Configuration Protocol (DHCP).

  A malicious user with physical access to the IPv4 network can cause a denial-of-service attack on IPv4 hosts by installing an unauthorized router on the network segment. The unauthorized IPv4 router can reroute link traffic and disrupt other network services.

  **Recommendation:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.

- **A computer can seize the IPv4 address of a computer or device on the same subnet, causing other network devices to create an incorrect entry in their ARP cache.**

  Nodes on an IPv4 subnet use Address Resolution Protocol(ARP) to resolve IP addresses used by TCP/IP-based software to media access control (MAC) addresses used by LAN hardware. The resolved link-layer address becomes an entry in the ARP cache on a node. If an IPv4 node spoofs the address of another node, it can cause other computers on the subnet to add a false entry to their ARP cache. All of the traffic that is intended for the computer with the spoofed IPv4 address instead goes to the computer of the attacker. In addition, the attacker can send traffic that will appear to have been generated by the spoofed computer.

  **Recommendation:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.

# TCP/IP defined

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP defined**
TCP/IP for is:

- Networking software based on industry-standard networking protocols.
- A routable, enterprise networking protocol that supports the connection of your Microsoft® Windows®-based computer to both LAN and WAN environments.
- Core technologies and utilities for connecting your Windows-based computer with dissimilar systems and sharing information.
- A foundation for gaining access to global Internet services, such as the World Wide Web and File Transfer Protocol (FTP) servers.
- A robust, scalable, cross-platform, client/server framework.

TCP/IP provides basic TCP/IP utilities that enable Windows-based computers to connect and share information with other Microsoft and non-Microsoft systems, including:

- Internet hosts
- Apple Macintosh systems
- IBM mainframes
- UNIX systems
- Open VMS systems
- Windows Server 2003 family
- Windows XP
- Windows 2000
- Windows NT®
- Windows Millennium Edition
- Windows 98
- Windows 95
- Windows for Workgroups
- LAN Manager
- Network-ready printers, such as HP LaserJet series printers that use HP JetDirect cards

**Note**

- The Windows Server 2003 family includes the latest version of Internet Protocol (IP), known as IP version 6. For more information, see IP Version 6.

# TCP/IP background

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP background**

Transmission Control Protocol/Internet Protocol (TCP/IP) is an industry-standard suite of protocols designed for large-scale internetworks that span LAN and WAN environments.

As the following timeline shows, the origins of TCP/IP began in 1969, when the U.S. Department of Defense (DoD) commissioned the Advanced Research Projects Agency Network (ARPANET).

The ARPANET was the result of a resource-sharing experiment. The purpose was to provide high-speed network communication links between various supercomputers located at various regional sites within the United States.

Early protocols such as Telnet (for virtual terminal emulation) and File Transfer Protocol (FTP) were first developed to specify basic utilities needed for sharing information across the ARPANET. As the ARPANET grew in size and scope, two other important protocols appeared:

- In 1974, Transmission Control Protocol (TCP) was introduced as a draft specification that described how to build a reliable, host-to-host data transfer service over a network.

- In 1981, Internet Protocol (IP) was introduced in draft form and described how to implement an addressing standard and route packets between interconnected networks.

On January 1, 1983, ARPANET began to require standard use of the TCP and IP protocols for all network traffic and essential communication. From this date forward, ARPANET started to become more widely known as the Internet and its required protocols started to become more widely known as the *TCP/IP protocol suite*.

The TCP/IP protocol suite is implemented in a variety of TCP/IP software offerings available for use with many computing platforms. Today, TCP/IP software remains widely in use on the Internet and is used often for building large routed private internetworks.

### Note

- The Microsoft® Windows Server 2003 family includes the latest version of the Internet Protocol (IP), known as IP version 6. For more information, see IP Version 6.

# The TCP/IP model

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The TCP/IP model**

TCP/IP is based on a four-layer reference model. All protocols that belong to the TCP/IP protocol suite are located in the top three layers of this model.

As shown in the following illustration, each layer of the TCP/IP model corresponds to one or more layers of the seven-layer Open Systems Interconnection (OSI) reference model proposed by the International Standards Organization (ISO).

The types of services performed and protocols used at each layer within the TCP/IP model are described in more detail in the following table.

| Layer | Description | Protocols |
|---|---|---|
| Application | Defines TCP/IP application protocols and how host programs interface with transport layer services to use the network. | HTTP, Telnet, FTP, TFTP, SNMP, DNS, SMTP, X Windows, other application protocols |
| Transport | Provides communication session management between host computers. Defines the level of service and status of the connection used when transporting data. | TCP, UDP, RTP |
| Internet | Packages data into IP datagrams, which contain source and destination address information that is used to forward the datagrams between hosts and across networks. Performs routing of IP datagrams. | IP, ICMP, ARP, RARP |
| Network interface | Specifies details of how data is physically sent through the network, including how bits are electrically signaled by hardware devices that interface directly with a network medium, such as coaxial cable, optical fiber, or twisted-pair copper wire. | Ethernet, Token Ring, FDDI, X.25, Frame Relay, RS-232, v.35 |

For more information about ARP, IP, ICMP, IGMP, UDP, and TCP, see Understanding TCP/IP.

**Note**

- The OSI reference model is not specific to TCP/IP. It was developed by the ISO in the late 1970s as a framework for describing all functions required of an open interconnected network. It is a widely known and accepted reference model in the data communications field and is used here only for comparison purposes.

# TCP/IP utilities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP utilities**

To assist with the management of TCP/IP, there are three types of TCP/IP-based utilities:

- Connectivity utilities that you can use to interact with and use resources on a variety of Microsoft® and non-Microsoft hosts, such as UNIX systems.
- Diagnostic utilities that you can use to detect and resolve networking problems.
- TCP/IP server software that provides printing and publishing services to TCP/IP-based Microsoft Windows® clients.

The following tables describe the TCP/IP-based utilities.

**Connectivity utilities**

| Utility | Description |
|---|---|
| Ftp | Transfers files of any size between computers running Windows Server 2003 operating systems and any computer running File Transfer protocol (FTP) server software. For more information, see Ftp. |
| Lpr | Sends print jobs to remote UNIX printers managed by Line Printer Daemon (LPD) print server software. For more information, see Lpr. |
| Rcp | Copies files between computers running Windows Server 2003 operating systems and computers running Remote Copy protocol (RCP) server software. For more information, see Rcp. |
| Rexec | Executes processes on remote computers. For more information, see Rexec. |
| Rsh | Runs commands on a computer running Remote Shell (RSH) server software. For more information, see Rsh. |
| Telnet | Uses terminal-based login to remotely access network devices that are running Telnet server software. For more information, see Telnet. |
| Tftp | Transfers small files between computers running Windows Server 2003 operating systems and computers running Trivial File Transfer protocol (TFTP) server software. For more information, see Tftp. |

**Diagnostic utilities**

| Utility | Description |
|---|---|
| Arp | Displays and modifies the Address Resolution protocol (ARP) cache. This cache is a local table used to resolve IP addresses to media access control addresses used on the local network. For more information, see Arp and Address Resolution Protocol (ARP). |
| Hostname | Returns the host name of the local computer. For more information, see Hostname. |
| Ipconfig | Displays the current TCP/IP configuration. Also used to manually release and renew TCP/IP configurations assigned by a DHCP server. For more information, see Ipconfig and Command-line utilities. |
| Lpq | Obtains print queue status information from computers running Line Printer Daemon (LPD) print server software. For more information, see Lpq. |
| Nbtstat | Displays the local NetBIOS name table, a table of NetBIOS names registered by local programs, and the NetBIOS name cache, a local cache listing of NetBIOS computer names that have been resolved to IP addresses. For more information, see Nbtstat and Release and refresh NetBIOS names by using the nbtstat command. |

| | |
|---|---|
| Netsh | Displays and administers TCP/IP protocol settings on the local computer or a remote computer. For more information, see Netsh commands for Interface IP. |
| Netstat | Displays TCP/IP protocol session information. For more information, see Netstat. |
| Nslookup | Checks records, domain host aliases, domain host services, and operating system information by querying DNS servers. For more information, see Nslookup and Verify DNS registration for domain controllers using the nslookup command. |
| Ping | Verifies configurations and tests IP connectivity. For more information, see Ping and Test a TCP/IP configuration by using the ping command. |
| Route | Displays or modifies the local routing table. For more information, see Route. |
| Tracert | Traces the route a packet takes to a destination. For more information, see Tracert and Trace a path by using the tracert command. |
| Pathping | Traces the route a packet takes to a destination and displays information on packet losses for each router in the path. Pathping can also be used to troubleshoot Quality of Service (QoS) connectivity. For more information, see Using the pathping command. |

**Server-based software**

| **Server software** | **Description** |
|---|---|
| TCP/IP Printing service | The TCP/IP Printing service offers an LPD printing service. This service allows UNIX computers to send print jobs to computers running Windows Server 2003 operating systems by using the Line Printer Remote (Lpr) utility for printing. |
| Internet Information Services | Internet Information Services (IIS) offers Web, Gopher, and FTP server software for providing TCP/IP-based publishing services. IIS is provided to offer an enterprise-ready Web server to use with an unlimited number of simultaneous connections. |
| Peer Web Services | Peer Web Services is provided with Windows XP Professional to provide Web-publishing services similar to those offered by IIS for serving fewer than 10 simultaneous connections. |

# New features for TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New features for TCP/IP**
TCP/IP includes the following new features for Microsoft® Windows Server 2003 family:

- IGMP version 3
- Alternate configuration
- Automatic determination of the interface metric
- IP version 6

**IGMP version 3**
Internet Group Management Protocol (IGMP) version 3, described in the Internet draft entitled "Internet Group Management Protocol, version 3," provides source-based multicast group membership reporting. Hosts can request to receive multicast traffic from specified sources or from all but a specific set of sources. Source-specific reporting prevents multicast-enabled routers from delivering multicast traffic to a subnet where there are no listening hosts. For more information, see Internet Group Management Protocol (IGMP).

**Alternate configuration**
Alternate configuration enables a computer to use an alternate, manually configured IP address configuration in the absence of a Dynamic Host Configuration Protocol (DHCP) server. You can use an alternate configuration when a computer is used on more than one network, at least one of the networks does not have a DHCP server, and automatic configuration is not wanted.

For example, if you have a laptop computer that you use both at the office and at home, it is useful to configure TCP/IP for an alternate configuration. At the office, the laptop uses a DHCP-allocated TCP/IP configuration. At home, where there is no DHCP server present, the laptop automatically uses the alternate configuration, which provides easy access to home network devices and the Internet and allow seamless operation on both networks, without the manual reconfiguration of TCP/IP settings.

Without an alternate configuration, TCP/IP uses Automatic Private IP Addressing (APIPA).

For more information, see Configure TCP/IP for an alternate configuration.

**Automatic determination of the routing metric**
By default, TCP/IP automatically determines the routing metric for the default gateway of each interface, based on the speed of its associated interface. If interfaces of different speeds are configured to use the same default gateway, the fastest interface has the lowest routing metric for its default route and is used to forward traffic to its default gateway. If there are multiple interfaces of the fastest speed, the interface that is listed first in the binding order is used to forward traffic to its default gateway. For more information, see The IP routing table.

Automatic determination of the interface metric is enabled by default through the **Automatic metric** check box on the **IP Settings** tab and when you manually configure default gateways in **Advanced TCP/IP Settings**. For more information, see Default gateways.

**IP version 6**
The Windows Server 2003 family includes the latest version of Internet Protocol (IP), known as IP version 6. For more information, see IP Version 6.

**Configuration Features**
TCP/IP includes several features that simplify configuration on a single subnet and optimize TCP performance in high-bandwidth network environments.

These features include support for:

- Automatic and alternate private address configuration
- Large TCP windows

- Better roundtrip time (RTT) estimation
- Selective acknowledgments
- ICMP router discovery
- DNS caching
- Disabling NetBIOS over TCP/IP

**Automatic and alternate private address configuration**
Use APIPA to automate TCP/IP address configuration for single-subnet networks that do not contain a DHCP server.

By default, computers running Windows Server 2003 operating systems first try to contact a DHCP server on the network to dynamically obtain configuration for each installed network connection.

- If a DHCP server is reached and the leased configuration is successful, TCP/IP configuration is completed.
- If a DHCP server is not reached, the computer checks for an alternate configuration. If an alternate configuration exists, then its settings are used to configure TCP/IP.
- If an alternate configuration does not exist, TCP/IP uses APIPA to automatically configure TCP/IP. When you use APIPA, a server running Windows Server 2003 determines an address in the reserved IP address range from 169.254.0.1 through 169.254.255.254. This address is used as a temporary IP address configuration until a DHCP server is located. The subnet mask is set to 255.255.0.0.

The APIPA range of IP addresses is reserved by the Internet Assigned Numbers Authority (IANA). Any IP addresses within this range are not used on the Internet.

APIPA eliminates IP address configuration for single-network small office or home office networks that are not connected to the Internet. For information about disabling APIPA, see Disable automatic address configuration.

**Large TCP windows**
Window size reflects the maximum number of packets that can be sent without waiting for positive acknowledgment. Large TCP windows improve TCP/IP performance when large amounts of data are in transit between the sender and receiver. In typical TCP-based communication, the maximum window size is usually fixed at the onset of connection and limited to 64 kilobytes.

With large window support, you can dynamically recalculate and scale the actual window size by using a TCP option as needed during longer sessions. With this option, more data packets are in transit on the network at one time, which increases throughput.

By default, computers running Windows Server 2003 operating systems only accept client requests for the large TCP windows option from TCP1323Opts-enabled computers that they are connecting with. TCP1323Opts-enabled computers make requests for the large TCP windows option during the initial three-way handshake. If you want your computer to be able to make requests for the large TCP windows option, you must enable TCP1323Opts in the registry. For more information about large TCP windows, see RFC 1323, "TCP Extensions for High Performance."

**Better RTT estimation**
TCP uses roundtrip time (RTT) to estimate the amount of time that is needed for roundtrip communication between a sender and a receiver. Servers running Windows Server 2003 support the use of the RFC 1323 TCP timestamp option to improve the way that RTT is estimated. By calculating more accurate RTT information more often, TCP uses better estimates for setting retransmission timers, which helps improve overall TCP speed and performance.

Improvements in estimating RTT help significantly over longer roundtrip network links, such as WANs that span continents or that use either wireless or satellite communication links.

By default, computers running Windows Server 2003 operating systems only accept client requests for the TCP timestamp option from TCP1323Opts-enabled computers that they are connecting with. TCP1323Opts-enabled computers make requests for the TCP timestamp option during the initial three-way handshake. If you want your computer to be able to make requests

for the TCP timestamp option, you must enable TCP1323Opts in the registry. For more information about TCP timestamp, see RFC 1323, "TCP Extensions for High Performance."

**Selective acknowledgments**
In typical TCP-based communication, acknowledgments are cumulative. TCP only acknowledges segments received that are contiguous with previously acknowledged segments. Noncontiguous segments--segments received out of sequence--are not explicitly acknowledged. TCP requires that segments are received and acknowledged within a brief time period, or the missing segment, and all subsequent segments that follow it, must be retransmitted.

Selective acknowledgments are a recent TCP option that allow the receiver to selectively notify and request that a sender resend only data that is actually missing. This results in smaller amounts of data that require retransmission and better use of network bandwidth.

For more information about selective acknowledgments, see RFC 2018, "TCP Selective Acknowledgment Options."

**ICMP router discovery**
Internet Control Message Protocol (ICMP) router discovery is the use of ICMP messages to discover the default gateway on a network segment when a default gateway is not manually configured or assigned by using DHCP. ICMP router discovery consists of two ICMP messages: the router solicitation and the router advertisement. A router solicitation is sent by a host to discover the routers on the network. A router advertisement is sent by a router in response to a router solicitation and periodically to notify hosts on the network that the router is still available. ICMP router discovery is disabled by default on TCP/IP for host computers running Windows XP or Windows Server 2003 operating systems, unless the host receives the perform router discovery option from a DHCP server.

You can configure a server running Windows Server 2003 and the Routing and Remote Access service to support ICMP router discovery as a router. For more information, see Routing Overview.

ICMP router discovery is described in RFC 1256, "ICMP Router Discovery Messages".

**DNS caching**
The Domain Name System (DNS) resolver in TCP/IP caches DNS name queries. You can view and flush the contents of the DNS cache by using the Ipconfig utility. For more information, see Client features and Flush and reset a client resolver cache using the ipconfig command.

**Disabling NetBIOS over TCP/IP**
With computers running Windows Server 2003 operating systems, you can disable NetBIOS over TCP/IP (NetBT) for each network connection. This feature is intended for computers that only use DNS name registration and resolution techniques and communicate by using the Client for Microsoft Networks and the File and Print Sharing for Microsoft Networks components with other computers where NetBT is disabled. Examples of disabling NetBT include computers in specialized or secured roles for your network, such as an edge proxy server or bastion host in a firewall environment, where NetBT support is not required or desired.

The following are considerations for disabling NetBT on computers running Windows Server 2003 operating systems:

- The computer no longer listens for traffic to the NetBIOS datagram service at User Datagram Protocol (UDP) port 138, the NetBIOS name service at UDP port 137, and the NetBIOS session service at Transmission Control Protocol (TCP) port 139.

- TCP/IP-based connections that use the Client for Microsoft Networks and the File and Print Sharing for Microsoft Networks components are only possible to other computers that have NetBT disabled. This affects the ability to browse the network to see network computers and to connect to file shares and network printers.

- NetBIOS name resolution techniques such as WINS, local subnet broadcasts, and the Lmhosts file are no longer used. All name resolution occurs through DNS queries and the Hosts file.

- If the computer needs to participate in WINS as a client, it must have NetBT enabled on at least one network connection.

- If a server running Windows Server 2003 needs to run the WINS service, it must have NetBT enabled on at least one private network connection.

For example, consider disabling NetBT if you have a server computer that has a connection to a private network and a connection to an external network, such as the Internet. In this case, NetBT is not required for the Internet connection. By

disabling NetBT on only the Internet connection, the dual-homed computer continues to function as either a WINS server or client for the internal network, and WINS clients are still serviced for connections made by using other physical network adapters installed on the computer.

You can disable NetBT on the **WINS** tab in the properties of the TCP/IP protocol. For more information, see Configure TCP/IP to use WINS. You can also disable NetBT through DHCP by using a Microsoft vendor-specific DHCP option. For more information, see "Dynamic Host Configuration Protocol" at the Microsoft Resource Kits Web site.

**Additional feature information**

For information about obtaining RFC documents, see TCP/IP RFCs.

# Understanding TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding TCP/IP**
This section covers:

- Core Protocols of TCP/IP
- IP Addressing and Routing
- Name Resolution

# Core Protocols of TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Core protocols of TCP/IP**
This section covers:

- Address Resolution Protocol (ARP)
- Internet Protocol (IP)
- Internet Control Message Protocol (ICMP)
- Internet Group Management Protocol (IGMP)
- User Datagram Protocol (UDP)
- Transmission Control Protocol (TCP)

# Address Resolution Protocol (ARP)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Address Resolution Protocol (ARP)**
Address Resolution Protocol (ARP) is a required TCP/IP standard defined in RFC 826, "Address Resolution Protocol (ARP)." ARP resolves IP addresses used by TCP/IP-based software to media access control addresses used by LAN hardware. ARP provides the following protocol services to hosts located on the same physical network:

- Media access control addresses are obtained by using a network broadcast request in the form of the question "What is the media access control address for a device that is configured with the enclosed IP address?"

- When an ARP request is answered, both the sender of the ARP reply and the original ARP requester record each other's IP address and media access control address as an entry in a local table called the ARP cache for future reference.

**Hardware addressing**
Hardware built for use on LANs must contain a unique address programmed into the device by the manufacturer. For Ethernet and Token Ring LAN hardware, this address is known as a media access control address.

Each media access control address identifies the device within its own physical network with a 6-byte number programmed into read-only memory (ROM) on each physical hardware device, such as a network adapter. Media access control addresses are typically displayed in hexadecimal (for example, 00-AA-00-3F-89-4A).

Authority and registration of media access control addresses are overseen by the Institute of Electrical and Electronics Engineers (IEEE). Currently, the IEEE registers and assigns unique numbers for the first three bytes of the media access control address to individual manufacturers. Each manufacturer can then assign the last three bytes of the media access control address to individual network adapters.

**How ARP resolves media access control addresses for local traffic**
The following illustration shows how ARP resolves IP addresses to hardware addresses for hosts on the same local network.

In this example, two TCP/IP hosts, Hosts A and B, are both located on the same physical network. Host A is assigned the IP address of 10.0.0.99 and Host B is assigned the IP address of 10.0.0.100.

When Host A tries to communicate with Host B, the following steps resolve Host B's software-assigned address (10.0.0.100) to Host B's hardware-assigned media access control address:

1. Based on the contents of the routing table on Host A, IP determines that the forwarding IP address to be used to reach Host B is 10.0.0.100. Host A then checks its own local ARP cache for a matching hardware address for Host B.

2. If Host A finds no mapping in the cache, it broadcasts an ARP request frame to all hosts on the local network with the question "What is the hardware address for 10.0.0.100?" Both hardware and software addresses for the source, Host A, are included in the ARP request.

   Each host on the local network receives the ARP request and checks for a match to its own IP address. If a host does not find a match, it discards the ARP request.

3. Host B determines that the IP address in the ARP request matches its own IP address and adds a hardware/software address mapping for Host A to its local ARP cache.

4. Host B sends an ARP reply message containing its hardware address directly back to Host A.

5. When Host A receives the ARP reply message from Host B, it updates its ARP cache with a hardware/software address mapping for Host B.

Once the media access control address for Host B has been determined, Host A can send IP traffic to Host B by addressing it to Host B's media access control address.

**How ARP resolves media access control addresses for remote traffic**
ARP is also used to forward IP datagrams to local routers for destinations that are not on the local network. In this situation, ARP resolves the media access control address of a router interface on the local network.

The following illustration shows how ARP resolves IP addresses to hardware addresses for two hosts on different physical networks connected by a common router.

In this example, Host A is assigned an IP address of 10.0.0.99 and Host B uses an IP address of 192.168.0.99. Router interface 1 is on the same physical network as Host A and uses the IP address 10.0.0.1. Router interface 2 is on the same physical network as Host B and uses the IP address 192.168.0.1.

When Host A tries to communicate with Host B, the following steps resolve Router interface 1's software-assigned address (10.0.0.1) to its hardware-assigned media access control address:

1. Based on the contents of the routing table on Host A, IP determines that the forwarding IP address to be used to reach host B is 10.0.0.1, the IP address of its default gateway. Host A then checks its own local ARP cache for a matching hardware address for 10.0.0.1.

2. If Host A finds no mapping in the cache, it broadcasts an ARP request frame to all hosts on the local network with the question "What is the hardware address for 10.0.0.1?" Both hardware and software addresses for the source, Host A, are included in the ARP request.

   Each host on the local network receives the ARP request and checks for a match to its own IP address. If a host does not find a match, it discards the ARP request.

3. The router determines that the IP address in the ARP request matches its own IP address and adds a hardware/software address mapping for Host A to its local ARP cache.

4. The router then sends an ARP reply message containing its hardware address directly back to Host A.

5. When Host A receives the ARP reply message from the router, it updates its ARP cache with a hardware/software address mapping for 10.0.0.1.

Once the media access control address for Router interface 1 has been determined, Host A can send IP traffic to Router interface 1 by addressing it to the Router interface 1 media access control address. The router then forwards the traffic to Host B through the same ARP process as discussed in this section.

**The ARP cache**
To minimize the number of broadcasts, ARP maintains a cache of IP address-to-media access control address mappings for future use. The ARP cache can contain both dynamic and static entries. Dynamic entries are added and removed automatically

over time. Static entries remain in the cache until the computer is restarted.

Each dynamic ARP cache entry has a potential lifetime of 10 minutes. New entries added to the cache are timestamped. If an entry is not reused within 2 minutes of being added, it expires and is removed from the ARP cache. If an entry is used, it receives two more minutes of lifetime. If an entry keeps getting used, it receives an additional two minutes of lifetime up to a maximum lifetime of 10 minutes.

You can view the ARP cache by using the **arp** command. To view the ARP cache, type **arp -a** at a command prompt. To view **arp** command-line options, type **arp /?** at a command prompt.

**Note**

- There is a separate ARP cache for each network adapter.

# Internet Protocol (IP)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Protocol (IP)**
IP is a required TCP/IP standard defined in RFC 791, "Internet Protocol (IP)." IP is a connectionless, unreliable datagram protocol primarily responsible for addressing and routing packets between hosts.

Connectionless means that a session is not established before exchanging data. Unreliable means that delivery is not guaranteed. IP always makes a best-effort attempt to deliver a packet. An IP packet might be lost, delivered out of sequence, duplicated, or delayed. IP does not attempt to recover from these types of errors. The acknowledgment of packets delivered and the recovery of lost packets is the responsibility of a higher-layer protocol, such as TCP.

An IP packet, also known as an IP datagram, consists of an IP header and an IP payload, as shown in the following illustration.

The IP header contains the following fields for addressing and routing:

| IP header field | Function |
|---|---|
| Source IP address | The IP address of the original source of the IP datagram. |
| Destination IP address | The IP address of the final destination of the IP datagram. |
| Time-to-Live (TTL) | Designates the number of network segments on which the datagram is allowed to travel before being discarded by a router. The TTL is set by the sending host and is used to prevent packets from endlessly circulating on an IP internetwork. When forwarding an IP packet, routers are required to decrease the TTL by at least 1. |

**Note**

- The Windows Server 2003 family includes the latest version of Internet Protocol (IP), known as IP version 6. For more information, see IP Version 6.

# Internet Control Message Protocol (ICMP)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Control Message Protocol (ICMP)**
Internet Control Message Protocol (ICMP) is a required TCP/IP standard defined in RFC 792, "Internet Control Message Protocol (ICMP)." With ICMP, hosts and routers that use IP communication can report errors and exchange limited control and status information.

ICMP messages are usually sent automatically in one of the following situations:

- An IP datagram cannot reach its destination.
- An IP router (gateway) cannot forward datagrams at the current rate of transmission.
- An IP router redirects the sending host to use a better route to the destination.

ICMP messages are encapsulated and sent within IP datagrams, as shown in the following illustration.

Different types of ICMP messages are identified in the ICMP header. Because ICMP messages are carried in IP datagrams, they are unreliable.

The most common ICMP messages are listed and described in the following table.

| ICMP message | Description |
|---|---|
| Echo request | Determines whether an IP node (a host or a router) is available on the network. |
| Echo reply | Replies to an ICMP echo request. |
| Destination unreachable | Informs the host that a datagram cannot be delivered. |
| Source quench | Informs the host to lower the rate at which it sends datagrams because of congestion. |
| Redirect | Informs the host of a preferred route. |
| Time exceeded | Indicates that the Time-to-Live (TTL) of an IP datagram has expired. |

You can use the **ping** command to send ICMP echo request messages and record the receipt of ICMP echo reply messages. With these messages, you can detect network or host communication failures and troubleshoot common TCP/IP connectivity problems.

For more information about ICMP, see RFC 792, "Internet Control Message Protocol (ICMP)." For more information about obtaining RFCs, see TCP/IP RFCs

# Internet Group Management Protocol (IGMP)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Group Management Protocol (IGMP)**
The use of IP multicasting in TCP/IP networks is defined as a TCP/IP standard in RFC 1112, "Internet Group Management Protocol (IGMP)." In addition to defining address and host extensions for how IP hosts support multicasting, this RFC also defines the Internet Group Management Protocol (IGMP) version 1. RFC 2236, "Internet Group Management Protocol (IGMP), version 2" defines IGMP version 2. Both versions of IGMP provide a protocol to exchange and update information about host membership in specific multicast groups. Additionally, the Windows Server 2003 family supports IGMP version 3, described in the Internet draft entitled "Internet Group Management Protocol, version 3." With IGMP version 3, hosts can specify interest in receiving multicast traffic from specified sources or from all but a specific set of sources.

**What is IP multicasting?**
Multicast IP traffic is sent to a single address but is processed by multiple hosts. IP multicasting is similar to a newsletter subscription. When only subscribers receive the newsletter when it is published, only host computers that belong to the multicast group receive and process IP traffic sent to the group's reserved IP address. The set of hosts listening on a specific IP multicast address is called a multicast group.

Other important aspects of IP multicasting include the following:

- Group membership is dynamic, allowing hosts to join and leave the group at any time.
- The ability of hosts to join multicast groups is performed through the sending of IGMP messages.
- Groups are not limited by size and members can be spread out across multiple IP networks (if connecting routers support the propagation of IP multicast traffic and group membership information).
- A host can send IP traffic to the group's IP address without belonging to the corresponding group.

**Multicast addressing**
IP multicast addresses are reserved and assigned from within the Class D address range from 224.0.0.0 through 239.255.255.255. The following table is a partial list of well-known Class D addresses that are reserved for IP multicasting and registered with the Internet Assigned Numbers Authority (IANA).

| IP multicast address | Description |
|---|---|
| 224.0.0.0 | Base address (reserved). |
| 224.0.0.1 | The All Hosts multicast group that contains all systems on the same network segment. |
| 224.0.0.2 | The All Routers multicast group that contains all routers on the same network segment. |
| 224.0.0.5 | The Open Shortest Path First (OSPF) AllSPFRouters address. Used to send OSPF routing information to all OSPF routers on a network segment. |
| 224.0.0.6 | The OSPF AllDRouters address. Used to send OSPF routing information to OSPF designated routers on a network segment. |
| 224.0.0.9 | The RIP Version 2 group address. Used to send RIP routing information to all RIP v2 routers on a network segment. |
| 224.0.1.24 | WINS server group address. Used to support autodiscovery and dynamic configuration of replication for WINS servers. For more information, see WINS replication overview. |

For a full and current listing of additional IP addresses that are reserved for multicasting, see the Internet Assigned Numbers Authority (IANA) Web site.

A single IP address within the Class D reserved range identifies each multicast group. Each group's reserved IP address is

shared by all host members of the group who listen and receive any IP messages sent to the group's IP address.

IP multicast addresses are mapped to a reserved set of media access control multicast addresses.

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

**IGMP messages**

IGMP is used to exchange membership status information between IP routers that support multicasting and members of multicast groups. Host membership in a multicast group is reported by individual member hosts, and membership status is periodically polled by multicast routers.

IGMP message types are described in the following table.

| IGMP message type | Description |
|---|---|
| Host membership report | Sent when a host joins a multicast group to declare membership in a specific host group. IGMP host membership report messages are also sent in response to an IGMP host membership query sent by a router. For an IGMP version 3 host membership report message, the host can specify interest in receiving multicast traffic from specified sources or from all but a specific set of sources. Source-specific reporting prevents multicast-enabled routers from delivering multicast traffic to a subnet where there are no listening hosts. |
| Host membership query | Used by a multicast router to periodically poll a network for group members. For an IGMP version 3 host membership query message, the router can query the host's interest in receiving multicast traffic from a specified list of sources. |
| Leave group | Sent by a host when they leave a host group and are the last member of that group on the network segment. |

IGMP messages are encapsulated and sent within IP datagrams as shown in the following illustration.

# User Datagram Protocol (UDP)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**User Datagram Protocol (UDP)**
User Datagram Protocol (UDP) is a TCP/IP standard defined in RFC 768, "User Datagram Protocol (UDP)." UDP is used by some programs instead of TCP for fast, lightweight, unreliable transportation of data between TCP/IP hosts.

UDP provides a connectionless datagram service that offers best-effort delivery, which means that UDP does not guarantee delivery or verify sequencing for any datagrams. A source host that needs reliable communication must use either TCP or a program that provides its own sequencing and acknowledgment services.

UDP messages are encapsulated and sent within IP datagrams, as shown in the following illustration.

**UDP ports**
UDP ports provide a location for sending and receiving UDP messages. A UDP port functions as a single message queue for receiving all datagrams intended for the program specified by each protocol port number. This means UDP-based programs can receive more than one message at a time.

The server side of each program that uses UDP listens for messages arriving on their well-known port number. All UDP server port numbers less than 1,024 (and some higher numbers) are reserved and registered by the Internet Assigned Numbers Authority (IANA).

Each UDP server port is identified by a reserved or well-known port number. The following table shows a partial list of well-known UDP server port numbers that are used by standard UDP-based programs.

| UDP port number | Description |
|---|---|
| 53 | DNS name queries |
| 69 | Trivial File Transfer Protocol (TFTP) |
| 137 | NetBIOS name service |
| 138 | NetBIOS datagram service |
| 161 | Simple Network Management Protocol (SNMP) |
| 520 | Routing Information Protocol (RIP) |

For an updated, complete list of all currently registered well-known UDP ports, see the Internet Assigned Numbers Authority (IANA) Web site.

**Note**

- Copyright

**UDP and TCP**
In general, differences in how UDP and TCP deliver data are similar to the differences between a telephone call and a postcard. TCP works like a telephone call by verifying that the destination is available and ready to communicate. UDP works like a postcard--messages are small and delivery is likely, but not always assured.

UDP is typically used by programs that transmit small amounts of data at one time or have real-time requirements. In these

situations, the low overhead and multicasting capabilities of UDP (for example, one datagram, many recipients) are better suited than TCP.

UDP contrasts directly with the services and features provided by TCP. The following table compares differences in how TCP/IP communication is handled depending on whether UDP or TCP is used for transporting data.

| **UDP** | **TCP** |
|---|---|
| Connectionless service; no session is established between hosts. | Connection-oriented service; a session is established between hosts. |
| UDP does not guarantee or acknowledge delivery, or sequence data. | TCP guarantees delivery through the use of acknowledgments and sequenced delivery of data. |
| Programs that use UDP are responsible for providing any reliability needed to transport data. | Programs that use TCP are provided assurance of reliable data transport. |
| UDP is fast, has low overhead requirements, and can support point-to-point and point-to-multipoint communication. | TCP is slower, has higher overhead requirements, and only supports point-to-point communication. |

Both UDP and TCP use ports to identify communications for each TCP/IP program.

# Transmission Control Protocol (TCP)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Transmission Control Protocol (TCP)**
Transmission Control Protocol (TCP) is a required TCP/IP standard defined in RFC 793, "Transmission Control Protocol (TCP)," that provides a reliable, connection-oriented packet delivery service. The Transmission Control Protocol:

- Guarantees delivery of IP datagrams.
- Performs segmentation and reassembly of large blocks of data sent by programs.
- Ensures proper sequencing and ordered delivery of segmented data.
- Performs checks on the integrity of transmitted data by using checksum calculations.
- Sends positive messages depending on whether data was received successfully. By using selective acknowledgments, negative acknowledgments for data not received are also sent.
- Offers a preferred method of transport for programs that must use reliable session-based data transmission, such as client/server database and e-mail programs.

**How TCP works**
TCP is based on point-to-point communication between two network hosts. TCP receives data from programs and processes this data as a stream of bytes. Bytes are grouped into segments that TCP then numbers and sequences for delivery.

Before two TCP hosts can exchange data, they must first establish a session with each other. A TCP session is initialized through a process known as a three-way handshake. This process synchronizes sequence numbers and provides control information that is needed to establish a virtual connection between both hosts.

Once the initial three-way handshake completes, segments are sent and acknowledged in a sequential manner between both the sending and receiving hosts. A similar handshake process is used by TCP before closing a connection to verify that both hosts are finished sending and receiving all data.

TCP segments are encapsulated and sent within IP datagrams, as shown in the following illustration.

**TCP ports**
TCP ports use a specific program port for delivery of data sent by using Transmission Control Protocol (TCP). TCP ports are more complex and operate differently from UDP ports.

While a UDP port operates as a single message queue and the network endpoint for UDP-based communication, the final endpoint for all TCP communication is a unique connection. Each TCP connection is uniquely identified by dual endpoints.

Each single TCP server port is capable of offering shared access to multiple connections because all TCP connections are uniquely identified by two pairs of IP address and TCP ports (one address/port pairing for each connected host).

TCP programs use reserved or well-known port numbers, as shown in the following illustration.

The server side of each program that uses TCP ports listens for messages arriving on their well-known port number. All TCP server port numbers less than 1,024 (and some higher numbers) are reserved and registered by the Internet Assigned Numbers Authority (IANA).

The following table is a partial list of some well-known TCP server ports used by standard TCP-based programs.

| TCP port number | Description |
|---|---|
| 20 | FTP server (data channel) |
| 21 | FTP server (control channel) |
| 23 | Telnet server |
| 53 | Domain Name System zone transfers |
| 80 | Web server (HTTP) |
| 139 | NetBIOS session service |

For an updated, complete list of all currently registered well-known TCP ports, see the see the Internet Assigned Numbers Authority (IANA) Web site.

# IP Addressing and Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP addressing and routing**
This section covers:

- IP addressing
- Subnet masks
- IP routing
- The IP routing table

# IP addressing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP addressing**

Each TCP/IP host is identified by a logical IP address. This address is unique for each host that communicates by using TCP/IP. Each 32-bit IP address identifies a location of a host system on the network in the same way that a street address identifies a house on a city street.

Just as a street address has a standard two-part format (a street name and a house number), each IP address is separated internally into two parts--a network ID and a host ID:

- The network ID, also known as a network address, identifies a single network segment within a larger TCP/IP internetwork (a network of networks). All the systems that attach and share access to the same network have a common network ID within their full IP address. This ID is also used to uniquely identify each network within the larger internetwork.

- The host ID, also known as a host address, identifies a TCP/IP node (a workstation, server, router, or other TCP/IP device) within each network. The host ID for each device identifies a single system uniquely within its own network.

Here is an example of a 32-bit IP address:

```
10000011 01101011 00010000 11001000
```

To make IP addressing easier, IP addresses are expressed in dotted decimal notation. The 32-bit IP address is segmented into four 8-bit octets. The octets are converted to decimal (base-10 numbering system) and separated by periods. Therefore, the previous IP address example is 131.107.16.200 when converted to dotted decimal notation.

For more information about dotted decimal notation and the conversion of numbers from binary to decimal, see Converting binary to decimal.

The following illustration shows a sample view of an IP address (131.107.16.200) as it is divided into network and host ID sections. The network ID portion (131.107) is indicated by the first two numbers of the IP address. The host ID portion (16.200) is indicated by the last two numbers of the IP address.

**Notes**

- Because IP addresses identify devices on a network, a unique IP address must be assigned to each device on the network.

- In general, most computers have only a single network adapter installed and therefore require only a single IP address. If a computer has multiple network adapters installed, each adapter needs its own IP address.

**IP address classes**

The Internet community has defined five address classes. Class A, B, and C addresses are used for assignment to TCP/IP nodes.

The class of address defines which bits are used for the network and host ID parts of each address. The address class also defines how many networks and hosts per network can be supported.

The following table uses *w.x.y.z* to designate the four octet values in any given IP address. The table is used to show:

- How the value of the first octet (*w*) of any given IP address effectively indicates the class of address.

- How the octets in an address are divided into network ID and host ID.
- The number of possible networks and hosts per network available for each class.

| **Class** | **Value of *w*** | **Network ID** | **Host ID** | **Number of networks** | **Number of hosts per network** |
|---|---|---|---|---|---|
| A | 1-126 | *w* | *x.y.z* | 126 | 16,777,214 |
| B | 128-191 | *w.x* | *y.z* | 16,384 | 65,534 |
| C | 192-223 | *w.x.y* | *z* | 2,097,152 | 254 |
| D | 224-239 | Reserved for multicast addressing | N/A | N/A | N/A |
| E | 240-254 | Reserved for experimental use | N/A | N/A | N/A |

# Subnet masks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Subnet masks**

Network IDs and host IDs within an IP address are distinguished by using a subnet mask. Each subnet mask is a 32-bit number that uses consecutive bit groups of all ones (1) to identify the network ID and all zeroes (0) to identify the host ID portions of an IP address.

For example, the subnet mask normally used with the IP address 131.107.16.200 is the following 32-bit binary number:

```
11111111 11111111 00000000 00000000
```

This subnet mask number is 16 one-bits followed by 16 zero-bits, indicating that the network ID and host ID sections of this IP address are both 16 bits in length. Normally, this subnet mask is displayed in dotted decimal notation as 255.255.0.0.

The following table displays subnet masks for the Internet address classes.

| Address class | Bits for subnet mask | Subnet mask |
|---|---|---|
| Class A | 11111111 00000000 00000000 00000000 | 255.0.0.0 |
| Class B | 11111111 11111111 00000000 00000000 | 255.255.0.0 |
| Class C | 11111111 11111111 11111111 00000000 | 255.255.255.0 |

Typically, default subnet mask values (as shown in the previous table) are acceptable for most networks with no special requirements and where each IP network segment corresponds to a single physical network.

In some cases, you can use customized subnet masks to implement IP subnetting. With IP subnetting, you can subdivide the default host ID portion of an IP address to specify subnets, which are subdivisions of the original class-based network ID.

By customizing the subnet mask length, you can reduce the number of bits that are used for the actual host ID. For more information about using a custom subnet mask for subnetting your network, see Resource Kit.

**Important**

- To prevent addressing and routing problems, you should make sure all TCP/IP computers on any network segment use the same subnet mask.

# IP routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP routing**

In general terms, routing is the process of forwarding packets between connected networks. For TCP/IP-based networks, routing is part of Internet Protocol (IP) and is used in combination with other network protocol services to provide forwarding capabilities between hosts that are located on separate network segments within a larger TCP/IP-based network.

IP is the mailroom of the TCP/IP protocol, where IP data sorting and delivery take place. Each incoming or outgoing packet is called an IP datagram. An IP datagram contains two IP addresses: the source address of the sending host and the destination address of the receiving host. Unlike hardware addresses, the IP addresses within a datagram remain the same as it travels across a TCP/IP network.

Routing is the primary function of IP. IP datagrams are exchanged and processed on each host by using IP at the Internet layer.

Above the IP layer, transport services on the source host pass data in the form of TCP segments or UDP messages to the IP layer. The IP layer assembles IP datagrams with source and destination address information that is used to route the data through the network. The IP layer then passes datagrams down to the network interface layer. At this layer, data-link services convert IP datagrams into frames for transmission over network-specific media on a physical network. This process happens in reverse order on the destination host.

Each IP datagram contains a source and destination IP address. IP layer services on each host examine the destination address of each datagram, compare this address to a locally maintained routing table, and then decide what further forwarding action to take. IP routers are attached to two or more IP network segments that are enabled to forward packets between them. The following sections discuss IP routers and the use of routing tables in further detail.

**IP routers**

TCP/IP network segments are interconnected by IP routers, which are devices that pass IP datagrams from one network segment to another. This process is known as IP routing and is shown in the following illustration.

IP routers provide the primary means of joining together two or more physically separated IP network segments. All IP routers share two essential characteristics:

- IP routers are multihomed hosts.

  A multihomed host is a network host that uses two or more network connection interfaces to connect to each physically separated network segment.

- IP routers provide packet forwarding for other TCP/IP hosts.

  IP routers are distinct from other hosts that use multihoming in one important way: an IP router must be able to forward IP-based communication between networks for other IP network hosts.

You can implement IP routers by using a variety of possible hardware and software products. Box-based routers--dedicated

hardware devices that run specialized software--are common. In addition, you can use routing solutions that are based on software, such as the Routing and Remote Access service.

For information about IP routing with the Routing and Remote Access service, see Routing.

Regardless of the type of IP routers that you use, all IP routing relies on the use of a routing table to communicate between network segments.

**Routing tables**

TCP/IP hosts use a routing table to maintain knowledge about other IP networks and IP hosts. Networks and hosts are identified by using an IP address and a subnet mask. In addition, routing tables are important because they provide needed information to each local host regarding how to communicate with remote networks and hosts.

For each computer on an IP network, you can maintain a routing table with an entry for every other computer or network that communicates with the local computer. In general, this is not practical, and a default gateway (IP router) is used instead.

When a computer prepares to send an IP datagram, it inserts its own source IP address and the destination IP address of the recipient into the IP header. The computer then examines the destination IP address, compares it to a locally maintained IP routing table, and takes appropriate action based on what it finds. The computer does one of three things:

- It passes the datagram up to a protocol layer above IP on the local host.
- It forwards the datagram through one of its attached network interfaces.
- It discards the datagram.

IP searches the routing table for the route that is the closest match to the destination IP address. The most specific to the least specific route is searched for in the following order:

- A route that matches the destination IP address (host route).
- A route that matches the network ID of the destination IP address (network route).
- The default route.

If a matching route is not found, IP discards the datagram.

For more information, see The IP routing table.

# The IP routing table

Updated: April 13, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The IP routing table**

Every computer that runs TCP/IP makes routing decisions. These decisions are controlled by the IP routing table. To display the IP routing table on computers running Windows Server 2003 operating systems, you can type **route print** at a command prompt.

The following table shows an example of an IP routing table. This example is for a computer running Windows Server 2003, Standard Edition with one 10 megabit/second (Mbit/s) network adapter and the following configuration:

- IP address: 10.0.0.169
- Subnet mask: 255.0.0.0
- Default gateway: 10.0.0.1

| Description | Network destination | Netmask | Gateway | Interface | Metric |
|---|---|---|---|---|---|
| Default route | 0.0.0.0 | 0.0.0.0 | 10.0.0.1 | 10.0.0.169 | 30 |
| Loopback network | 127.0.0.0 | 255.0.0.0 | 127.0.0.1 | 127.0.0.1 | 1 |
| Local network | 10.0.0.0 | 255.0.0.0 | 10.0.0.169 | 10.0.0.169 | 30 |
| Local IP address | 10.0.0.169 | 255.255.255.255 | 127.0.0.1 | 127.0.0.1 | 30 |
| Multicast addresses | 224.0.0.0 | 240.0.0.0 | 10.0.0.169 | 10.0.0.169 | 30 |
| Limited broadcast address | 255.255.255.255 | 255.255.255.255 | 10.0.0.169 | 10.0.0.169 | 1 |

**Note**

- The descriptions in the first column of the preceding table are not actually displayed in the output of the **route print** command.

The routing table is built automatically, based on the current TCP/IP configuration of your computer. Each route occupies a single line in the displayed table. Your computer searches the routing table for an entry that most closely matches the destination IP address.

Your computer uses the default route if no other host or network route matches the destination address included in an IP datagram. The default route typically forwards an IP datagram (for which there is no matching or explicit local route) to a default gateway address for a router on the local subnet. In the previous example, the default route forwards the datagram to a router with a gateway address of 10.0.0.1.

Because the router that corresponds to the default gateway contains information about the network IDs of the other IP subnets within the larger TCP/IP internet, it forwards the datagram to other routers until the datagram is eventually delivered to an IP router that is connected to the specified destination host or subnet within the larger network.

The following sections describe each of the columns displayed in the IP routing table: network destination, netmask, gateway, interface, and metric.

**Network destination**

The network destination is used with the netmask to match the destination IP address. The network destination can range from 0.0.0.0 for the default route through 255.255.255.255 for the limited broadcast, which is a special broadcast address to all hosts on the same network segment.

**Netmask**

The netmask is the subnet mask that is applied to the destination IP address when matching it to the value in the network

destination. When netmask is written in binary, a "1" must match and a "0" need not match. For example, a default route uses a 0.0.0.0 netmask that translates to the binary value 0.0.0.0, so bits need not match. A host route--a route that matches an IP address--uses a 255.255.255.255 netmask that translates to the binary value 11111111.11111111.11111111.11111111, so all of the bits must match.

**Gateway**
The gateway address is the IP address that the local host uses to forward IP datagrams to other IP networks. This is either the IP address of a local network adapter or the IP address of an IP router (such as a default gateway router) on the local network segment.

**Interface**
The interface is the IP address that is configured on the local computer for the local network adapter that is used when an IP datagram is forwarded on the network.

**Metric**
A metric indicates the cost of using a route, which is typically the number of hops to the IP destination. Anything on the local subnet is one hop, and each router crossed after that is an additional hop. If there are multiple routes to the same destination with different metrics, the route with the lowest metric is selected.

For information about adding routes to the IP routing table, see Add a static IP route. For information about deleting routes in the IP routing table, see Remove a static IP route.

**Multihomed hosts**
The following shows the default routing table for a multihomed Windows Server 2003, Standard Edition host with this configuration:

- Network adapter 1 (10 MB)
    - IP address: 10.0.0.169
    - Subnet mask: 255.0.0.0
    - Default gateway: 10.0.0.1
- Network adapter 2 (100 MB)
    - IP address: 192.168.0.200
    - Subnet mask: 255.255.0.0
    - Default gateway: 192.168.0.1

| Adapter | Description | Network destination | Netmask | Gateway | Interface | Metric |
|---|---|---|---|---|---|---|
| 1 | Default route | 0.0.0.0 | 0.0.0.0 | 10.0.0.1 | 10.0.0.169 | 20 |
| 2 | Default route | 0.0.0.0 | 0.0.0.0 | 192.168.0.1 | 192.168.0.200 | 30 |
| 1 | Loopback network | 127.0.0.0 | 255.0.0.0 | 127.0.0.1 | 127.0.0.1 | 1 |
| 1 | Local network | 10.0.0.0 | 255.0.0.0 | 10.0.0.169 | 10.0.0.169 | 20 |
| 1 | Local IP address | 10.0.0.169 | 255.255.255.255 | 127.0.0.1 | 127.0.0.1 | 20 |
| 2 | Local network | 192.168.0.0 | 255.255.0.0 | 192.168.0.200 | 192.168.0.200 | 30 |
| 2 | Local IP address | 192.168.0.200 | 255.255.255.255 | 127.0.0.1 | 127.0.0.1 | 30 |
| 2 | Subnet broadcast | 192.168.0.255 | 255.255.255.255 | 192.168.0.200 | 192.168.0.200 | 30 |
| 1 | Multicast address | 224.0.0.0 | 240.0.0.0 | 10.0.0.169 | 10.0.0.169 | 20 |

| | | | | | | |
|---|---|---|---|---|---|---|
| 2 | Multicast address | 224.0.0.0 | 240.0.0.0 | 192.168.0.200 | 192.168.0.200 | 30 |
| 1 | Limited broadcast | 255.255.255.255 | 255.255.255.255 | 10.0.0.169 | 10.0.0.169 | 1 |
| 2 | Limited broadcast | 255.255.255.255 | 255.255.255.255 | 192.168.0.200 | 192.168.0.200 | 1 |

**Note**

- The descriptions in the first and second columns of the preceding table are not actually displayed in the output of the **route print** command.

For information about enabling IP forwarding on a multihomed computer running a Windows Server 2003 operating system, see Enable the Routing and Remote Access service.

**Notes**

- When you configure a default gateway on each network adapter, you create a 0.0.0.0 route for each network adapter. However, only one default route is actually used. In the previous example, the 10.0.0.169 IP address is the first network adapter in the TCP/IP bindings, and therefore the default route for Network adapter 1 is used. Because only one default gateway is used, you only need to configure one network adapter with a default gateway. This reduces confusion and assures the results you intended.

- If the IP router is a server running Windows Server 2003 and does not have an interface on a given network, it needs a route to get to that network. You can add static routes or use routing protocols that are provided by the Routing and Remote Access service. For information about IP routing with the Routing and Remote Access service, see Routing.

# Name Resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Name resolution**
By default, Windows Server 2003 operating systems use name resolution to translate numerical IP addresses, which are necessary for TCP/IP communications, to computer names, which are easier for users to remember and use than 32-bit IP addresses. With name resolution, you can assign computer names to the IP addresses of the source and destination hosts, and then use the computer name to contact the hosts, rather than using the 32-bit IP addresses. If you use a computer name as an IP alias, ensure that the name is unique and that it resolves to the correct IP address.

There are two types of names to resolve:

- **Host names**

  Host names are used by programs that use the Windows Sockets programming interface, such as Web browsers. For more information, see Host name resolution.

- **NetBIOS names**

  NetBIOS names are used by network programs or services that use the NetBIOS programming interface, such as Client for Microsoft Networks and File and Printer Sharing for Microsoft Networks. For more information, see NetBIOS name resolution.

# Host name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Host name resolution**

Host name resolution means successfully mapping a host name to an IP address. A host name is an alias that is assigned to an IP node to identify it as a TCP/IP host. The host name can be up to 255 characters long and can contain alphabetic and numeric characters, hyphens, and periods. You can assign multiple host names to the same host.

Windows Sockets (Winsock) programs, such as Internet Explorer and the FTP utility, can use one of two values for the destination to which you want to connect: the IP address or a host name. When the IP address is specified, name resolution is not needed. When a host name is specified, the host name must be resolved to an IP address before IP-based communication with the desired resource can begin.

Host names can take various forms. The two most common forms are a nickname and a domain name. A nickname is an alias to an IP address that individual people can assign and use. A domain name is a structured name in a hierarchical namespace called the Domain Name System (DNS). An example of a domain name is www.microsoft.com.

Nicknames are resolved through entries in the Hosts file, which is stored in the *systemroot*\System32\Drivers\Etc folder. For more information, see TCP/IP database files.

Domain names are resolved by sending DNS name queries to a configured DNS server. The DNS server is a computer that stores domain name-to-IP address mapping records or has knowledge of other DNS servers. The DNS server resolves the queried domain name to an IP address and sends the result back.

You are required to configure your computers with the IP address of your DNS server in order to resolve domain names. You must configure Active Directory-based computers running Windows XP Professional or Windows Server 2003 operating systems with the IP address of a DNS server.

For more information, see DNS defined.

# NetBIOS name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**NetBIOS name resolution**

NetBIOS name resolution means successfully mapping a NetBIOS name to an IP address. A NetBIOS name is a 16-byte address that is used to identify a NetBIOS resource on the network. A NetBIOS name is either a unique (exclusive) or group (nonexclusive) name. When a NetBIOS process is communicating with a specific process on a specific computer, a unique name is used. When a NetBIOS process is communicating with multiple processes on multiple computers, a group name is used.

An example of a process that uses a NetBIOS name is the File and Printer Sharing for Microsoft Networks service on a computer running Windows XP Professional. When your computer starts up, this service registers a unique NetBIOS name based on the name of your computer. The exact name used by the service is the 15-character computer name plus a 16th character of 0x20. If the computer name is not 15 characters long, it is padded with spaces up to 15 characters.

When you attempt to make a file-sharing connection to a computer by using its computer name, the File and Printer Sharing for Microsoft Networks service on the file server you specify corresponds to a specific NetBIOS name. For example, when you attempt to connect to a computer called CORPSERVER, the NetBIOS name corresponding to the File and Printer Sharing for Microsoft Networks service on that computer is:

```
CORPSERVER      [20]
```

Note the use of spaces to pad the computer name. Before you can establish a file and print sharing connection, a TCP connection must be created. In order for a TCP connection to be established, the NetBIOS name "CORPSERVER [20]" must be resolved to an IP address.

The exact mechanism by which NetBIOS names are resolved to IP addresses depends on the NetBIOS node type that is configured for the node. RFC 1001, "protocol Standard for a NetBIOS Service on a TCP/UDP Transport: Concepts and Methods," defines the NetBIOS node types, as listed in the following table.

| Node type | Description |
|---|---|
| B-node(broadcast) | B-node uses broadcast NetBIOS name queries for name registration and resolution. B-node has two major problems: (1) Broadcasts disturb every node on the network, and (2) Routers typically do not forward broadcasts, so only NetBIOS names on the local network can be resolved. |
| P-node (peer-peer) | P-node uses a NetBIOS name server (NBNS), such as a WINS server, to resolve NetBIOS names. P-node does not use broadcasts; instead, it queries the name server directly. |
| M-node (mixed) | M-node is a combination of B-node and P-node. By default, an M-node functions as a B-node. If an M-node is unable to resolve a name by broadcast, it queries a NBNS using P-node. |
| H-node(hybrid) | H-node is a combination of P-node and B-node. By default, an H-node functions as a P-node. If an H-node is unable to resolve a name through the NBNS, it uses a broadcast to resolve the name. |

Computers running Windows Server 2003 operating systems are B-node by default and become H-node when they are configured with a WINS server. Those computers can also use a local database file called Lmhosts to resolve remote NetBIOS names. The Lmhosts file is stored in the *systemroot*\System32\Drivers\Etc folder. For more information, see TCP/IP database files.

It is highly recommended that you configure Windows-based computers with the IP address of your WINS server in order for remote NetBIOS names to be resolved. You must configure Active Directory-based computers, such as Windows XP Professionaland Windows Server 2003 operating systems, with the IP address of a WINS server if they are to communicate with computers running Windows NT, Windows 95, Windows 98, Windows 2000, or Windows Millennium Edition that are not Active Directory-based.

For more information about WINS, see WINS defined.

# Using TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using TCP/IP**

This section covers:

- TCP/IP configuration items
- TCP/IP configuration methods
- Configuring TCP/IP
- Numbering your network
- Default gateways
- Advanced configuration
- Managing TCP/IP from the command line

# TCP/IP configuration items

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP configuration items**
For TCP/IP to function properly, you need to configure the following:

- IP address
- Subnet mask
- Default gateway
- DNS server
- WINS server

**IP address**
You must configure each interface on each TCP/IP node (host or router) with a unique IP address that is correct for the attached network segment. The IP address is a required configuration item.

For more information, see IP addressing.

**Subnet mask**
You must configure each interface on each TCP/IP node (host or router) with a subnet mask that, when combined with the IP address, yields the network ID. All IP interfaces on the same network segment must use the same network ID. Therefore, all IP interfaces on the same network segment must use the same subnet mask. The subnet mask is a required configuration item.

For more information, see Subnet masks.

**Default gateway**
To communicate with TCP/IP nodes on other network segments, you must configure at least one interface with the IP address of a default gateway (a local router that forwards remote TCP/IP traffic to its destination).

You do not need to configure a default gateway for a network that consists of a single network segment.

For more information, see IP routing.

**DNS server**
A DNS server can resolve domain names to IP addresses. When a TCP/IP host is configured with the IP address of a DNS server, the TCP/IP host sends DNS name queries to the DNS server for resolution. A DNS server is required for computers operating in an Active Directory-based network environment.

You do not need to configure a DNS server for a network that consists of a single network segment.

For more information, see Host name resolution.

A server running Windows Server 2003 can be a DNS server. For more information, see DNS.

**WINS server**
A WINS server can store and resolve NetBIOS names to IP addresses. When a TCP/IP host is configured with the IP address of a WINS server, the TCP/IP host registers its own NetBIOS names with the WINS server and sends NetBIOS name queries to the WINS server for resolution. A WINS server is highly recommended when there is more than one network segment in your network and when you have computers that are not based on Active Directory (for example, computers running Windows NT 4.0, Windows 95, Windows 98, and Windows Millennium Edition).

You do not need to configure a WINS server for a network that consists of a single network segment.

For more information, see NetBIOS name resolution.

A server running Windows Server 2003 can be a WINS server. For more information, see WINS.

**IPSec**

To provide security for TCP/IP, you need to configure Internet Protocol security (IPSec). IPSec is a framework of open standards for ensuring private, secure communications over Internet Protocol (IP) networks, through the use of cryptographic security services. It provides aggressive protection against private network and Internet attacks through end-to-end security. In Windows XP and the Windows Server 2003 family, IPSec provides the ability to protect communication between workgroups, local area network computers, domain clients and servers, branch offices (which might be physically remote), extranets, and roving clients.

For more information, see Internet Protocol Security (IPSec).

# TCP/IP configuration methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP configuration methods**
You can configure TCP/IP on servers running Windows Server 2003 by using the following methods:

- Automatic configuration
- Dynamic configuration
- Alternate configuration
- Manual configuration

If you are using either a dynamic or manual configuration, find out more about developing an effective TCP/IP network numbering plan in Numbering your network.

**Automatic configuration**
TCP/IP uses Automatic Private IP Addressing (APIPA) by default to provide automatic configuration, using the IP address range 169.254.0.1 to 169.254.255.254 and the subnet mask 255.255.0.0. There is no automatic configuration of a default gateway, DNS server, or WINS server since APIPA is designed for networks that consist of a single network segment and that are not connected to the Internet.

For more information, see Configure TCP/IP for automatic addressing.

**Dynamic configuration**
By using DHCP, TCP/IP configuration is done dynamically and automatically when the computer is started. Dynamic configuration requires the configuration of a DHCP server. By default, computers running Windows Server 2003 operating systems are DHCP clients. By properly configuring the DHCP server, TCP/IP hosts can obtain IP address, subnet mask, default gateway, DNS server, NetBIOS node type, and WINS server configuration information. Dynamic configuration (using DHCP) is recommended for medium-to-large TCP/IP networks.

For more information, see Configure TCP/IP for dynamic addressing.

**Alternate configuration**
Alternate configuration enables a computer to use an alternate, manually configured IP address configuration in the absence of a DHCP server. You can use an alternate configuration when a computer is used on more than one network, at least one of the networks does not have a DHCP server, and automatic configuration is not wanted.

For example, if you have a laptop computer that you use both at the office and at home, it is useful to configure TCP/IP for an alternate configuration. At the office, the laptop uses a DHCP-allocated TCP/IP configuration. At home, where there is no DHCP server present, the laptop automatically uses the alternate configuration, which provides easy access to home network devices and the Internet and allow seamless operation on both networks, without the manual reconfiguration of TCP/IP settings.

Without an alternate configuration, TCP/IP uses APIPA by default.

For more information, see Configure TCP/IP for an alternate configuration.

**Manual configuration**
By manually configuring the properties of the TCP/IP protocol through the properties of a network connection (in Network Connections), you can assign an IP address, subnet mask, default gateway, DNS server, and WINS server. Manual configuration is required in a network with multiple network segments when no DHCP server is present.

For more information, see Configure TCP/IP for static addressing.

# Configuring TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring TCP/IP**

TCP/IP is installed by default. Before you configure TCP/IP you need to know:

- Whether your network supports a *dynamic*TCP/IP configuration, which uses the Dynamic Host Configuration Protocol (DHCP).

  A dynamic configuration is the simplest to complete and can be used if there is a DHCP server on your network. The DHCP server provides IP address, subnet mask, default gateway (IP router), DNS domain name, DNS server, and WINS server configuration information. TCP/IP is configured to use a dynamic configuration by default.

- Whether your network requires a *manual*TCP/IP configuration.

  Some existing networks either do not use DHCP or require that TCP/IP configuration is performed manually for each computer.

- Whether your computer uses an *alternate*TCP/IP configuration.

  For example, laptop computers are sometimes connected to a corporate network that provides dynamic addressing. At other times, laptops require an alternate, manual configuration for home networks.

For more information about configuration methods, see TCP/IP configuration methods.

If you do not use DHCP to configure TCP/IP dynamically, obtain the following information from your network administrator to configure TCP/IP manually:

- The IP address and subnet mask for each network adapter that is installed on the computer.

- The IP address for the local default gateway (IP router).

- The name of your DNS domain and the IP addresses of the DNS servers on the network.

  For Active Directory deployment, the primary DNS suffix (also known as the primary domain name) of a computer is, by default, the name of the Active Directory domain that the computer has joined. If you want your computer's primary DNS suffix to be different from the name of the Active Directory domain that the computer has joined, see Change the DNS suffix of your computer.

- The IP addresses for the WINS servers, if WINS services are available on your network.

For more information about configuration items, see TCP/IP configuration items.

For instructions about configuring TCP/IP, see Configure TCP/IP.

For information and instructions about securing TCP/IP, see Internet Protocol Security (IPSec)

# Numbering your network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Numbering your network**

For private TCP/IP networks that are not directly or indirectly connected to the Internet, you can use any range of valid IP addresses from Class A, B, or C.

For private TCP/IP networks that are indirectly connected to the Internet by using a network address translator (NAT) or an application layer gateway such as a proxy server, the Internet Assigned Numbers Authority (IANA) recommends that you use the private IP addresses shown in the following table.

| Private network ID | Subnet mask | Range of IP addresses |
|---|---|---|
| 10.0.0.0 | 255.0.0.0 | 10.0.0.1 - 10.255.255.254 |
| 172.16.0.0 | 255.240.0.0 | 172.16.0.1 - 172.31.255.254 |
| 192.168.0.0 | 255.255.0.0 | 192.168.0.1 - 192.168.255.254 |

Numbers in these ranges are reserved by IANA for private use on TCP/IP networks and are not used on the Internet.

Usually, for security reasons, you should not connect more than a few TCP/IP systems within your network directly to the Internet. For any host systems on your network that connect to the Internet, you must obtain the use of registered IP addresses from your Internet service provider (ISP).

**Notes**

- If your ISP cannot provide sufficient public addresses to accommodate your needs and you are located in the United States, you can apply directly to the American Registry for Internet Numbers (ARIN) to obtain an IANA-assigned IP network address. For more information about registering a public address, see the American Registry for Internet Numbers Web site.
- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.
- For more information about private IP address numbering for private networks, see RFC 1918, "Address Allocation for Private Internets."

# Default gateways

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Default gateways**

Default gateways serve an important role in TCP/IP networking. They provide a default route for TCP/IP hosts to use when communicating with other hosts on remote networks.

The following illustration shows the role played by two default gateways (IP routers) for two networks: Network 1 and Network 2.

In order for Host A on Network 1 to communicate with Host B on Network 2, Host A first checks its routing table to see if a specific route to Host B exists. If there is no specific route to Host B, Host A forwards its TCP/IP traffic for Host B to its own default gateway, IP Router 1.

The same principle applies if Host B is sending to Host A. Without a specific route to Host A, Host B forwards any TCP/IP traffic destined for Host A to its own default gateway, IP Router 2.

**Why gateways work**

Default gateways are important to make IP routing work efficiently. In most cases, the router that acts as the default gateway for TCP/IP hosts--either a dedicated router or a computer that connects two or more network segments--maintains knowledge of other networks in the larger network and how to reach them.

TCP/IP hosts rely on default gateways for most of their communication needs with hosts on remote network segments. In this way, individual hosts are freed of the burden of having to maintain extensive and continuously updated knowledge about individual remote IP network segments. Only the router that acts as the default gateway needs to maintain this level of routing knowledge to reach other remote network segments in the larger internetwork.

If the default gateway fails, communication beyond the local network segment may be impaired. To prevent this, you can use the **Advanced TCP/IP Settings** dialog box (in Network Connections) for each connection to specify multiple default gateways. You can also use the **route** command to manually add routes to the routing table for heavily used hosts or networks.

**Using multiple gateways**

If you have multiple interfaces and you configure a default gateway for each interface, TCP/IP by default automatically calculates an interface metric that is based on the speed of the interface. The interface metric becomes the metric of the default route in the routing table for the configured default gateway. The interface with the highest speed has the lowest metric for its default route. The result is that whenever multiple default gateways are configured on multiple interfaces, the fastest interface will be used to forward traffic to its default gateway.

If multiple interfaces of the same speed have the same lowest interface metric, then, based upon the binding order, the default gateway of the first network adapter is used. The default gateway for the second network adapter is used when the first is unavailable.

In previous versions of TCP/IP, multiple default gateways all had a default route metric set to 1, and the default gateway used depended on the order of the interfaces. This sometimes caused difficulty in determining which default gateway the TCP/IP protocol was using.

The automatic determination of the interface metric is enabled by default through the **Automatic metric** check box on the **IP Settings** tab on the advanced properties of the **Internet Protocol (TCP/IP)** protocol.

You can disable the automatic determination of the interface metric and type a new value for the interface metric.

# Advanced configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Advanced configuration**
Beyond the configuration of an IP address, subnet mask, default gateway, DNS server, and WINS server, you can configure TCP/IP for:

- Advanced IP settings
- Advanced DNS settings
- Advanced WINS settings
- Advanced options

**Advanced IP settings**
Advanced IP settings include:

- **Multiple IP addresses**

  You can use multiple IP addresses per network connection for multiple IP numbering schemes, such as public addresses used for the Internet and private addresses, and for multiple logical IP networks on the same physical network segment.

- **Multiple default gateways**

  You can use TCP/IP to detect downed routers by using a feature called dead gateway detection. If multiple default gateways are configured, a failing TCP connection updates the IP routing table with the next default gateway in the list.

For more information about configuring advanced IP settings, see Configure TCP/IP for static addressing.

**Advanced DNS settings**
Advanced DNS settings include:

- **Multiple DNS servers**

  If multiple DNS servers are configured, and TCP/IP fails to receive any response from the current DNS server, TCP/IP switches to the next DNS server.

- **Unqualified name resolution**

  For unqualified names, you can configure TCP/IP to either:

  - Append the primary and connection-specific DNS suffixes to the unqualified name for DNS queries.
  - Append a series of configured DNS suffixes to the unqualified name for DNS queries.

- **Connection-specific DNS suffixes**

  You can configure each connection in Network Connections to have its own DNS suffix, in addition to the primary DNS suffix that is configured for the computer on the **Computer Name** tab (available in System in Control Panel).

- **DNS dynamic update behavior**

  If you have DNS servers that support DNS dynamic update (such as the Windows 2000 DNS service or the Windows

Server 2003 DNS service), you can enable the DNS dynamic update of the domain name and IP addresses for the computer. If you configure a connection-specific DNS suffix, you can also enable the DNS dynamic update of the domain name and IP addresses for the connection.

For more information about configuring advanced DNS settings, see Configure TCP/IP to use DNS.

**Advanced WINS settings**
Advanced WINS settings include:

- **Multiple WINS servers**

  If multiple WINS servers are configured, and TCP/IP fails to receive any response from the current WINS server, TCP/IP switches to the next WINS server.

- **Enabling and disabling the use of the Lmhosts file**

  If the Lmhosts file is enabled, TCP/IP parses the Lmhosts file found in the *systemroot*\System32\Drivers\Etc folder during NetBIOS name resolution. By default, the use of the Lmhosts file is enabled. For more information, see TCP/IP database files.

- **Enabling and disabling the use of NetBIOS over TCP/IP**

  You can enable or disable the use of NetBIOS over TCP/IP. If the use of NetBIOS over TCP/IP is disabled, NetBIOS programs cannot run over TCP/IP. Therefore, you may not be able to connect to computers that are running an operating system other than Windows 2000, Windows XP, or Windows Server 2003 operating systems. By default, the use of NetBIOS over TCP/IP is specified by the settings obtained from a DHCP server.

For more information about configuring advanced WINS settings, see Configure TCP/IP to use WINS.

**Note**

- You can no longer configure the NetBIOS scope ID on the **WINS** tab. To configure the NetBIOS scope ID, set the following registry value to the name of the scope ID that you want to use:

  **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT\Parameters\ScopeID**

  **Caution**

  - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Advanced options**
Advanced options include:

- **Enabling TCP/IP filtering and specifying TCP/IP traffic**

  If TCP/IP filtering is enabled, you can specify what types of TCP/IP traffic are processed. For more information, see Security features and Configure TCP/IP to use TCP/IP filtering.

# Managing TCP/IP from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing TCP/IP from the command line**

In addition to using the properties of **Internet Protocol (TCP/IP)** in Network Connections to manage TCP/IP configuration, you can manage TCP/IP configuration by using the Netsh commands for Interface IP.

For information about other command-line utilities, see Command-line reference A-Z. For more information about manageability, see Management Strategies and Tools.

# TCP/IP Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

This section covers:

- TCP/IP RFCs
- TCP/IP references
- Resource Kit
- Converting binary to decimal
- Resource: TCP/IP Utilities
- TCP/IP database files
- Using Performance Logs and Alerts

# TCP/IP RFCs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP RFCs**

The standards for TCP/IP are published in a series of documents called Requests for Comments (RFCs). RFCs are an evolving series of reports, proposals for protocols, and protocol standards that describe the internal workings of TCP/IP and the Internet.

Although TCP/IP standards are always published as RFCs, not all RFCs specify standards. RFCs are authored by individuals who voluntarily write and submit a draft proposal for a new protocol or specification to the Internet Engineering Task Force (IETF) and other working groups. Submitted drafts are first reviewed by a technical expert, a task force, or an RFC editor, and then assigned a status.

If a draft passes this initial review stage, it is circulated to the larger Internet community for a period of further comment and review and assigned an RFC number. This RFC number remains constant.

If changes are made to the proposed specification, drafts that are revised or updated are circulated by using a new RFC (a number higher than the original RFC number) to identify more recent documents.

There are five status assignments for RFCs in the standards process, as shown in the following table.

| Status | Description |
|---|---|
| Standard protocol | An official standard protocol of the Internet. |
| Draft standard protocol | Under active consideration and review to become a standard protocol. |
| Proposed standard protocol | A protocol that in the future might become a standard protocol. |
| Experimental protocol | A protocol designed for experimental purposes. An experimental protocol is not intended for operational use. |
| Informational protocol | A protocol developed by another standards organization that is included for the convenience of the Internet community. |
| Historic protocol | Protocols that have been superceded or obsoleted by other protocols. |

**Related RFCs for TCP/IP**

The following table shows the RFCs supported by the TCP/IP protocol and supporting services.

| RFC number | Title |
|---|---|
| 768 | User Datagram Protocol (UDP) |
| 783 | Trivial File Transfer Protocol (TFTP) |
| 791 | Internet Protocol (IP) |
| 792 | Internet Control Message Protocol (ICMP) |
| 793 | Transmission Control Protocol (TCP) |
| 816 | Fault Isolation and Recovery |
| 826 | Address Resolution Protocol (ARP) |
| 854 | Telnet Protocol (TELNET) |
| 862 | Echo Protocol (ECHO) |

| | |
|---|---|

# Resource Kit

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource Kit**

The Windows Server 2003 Resource Kit contains extensive technical information on TCP/IP. See the following chapters:

- "Introduction to TCP/IP" at the Microsoft Resource Kits Web site.
- "Windows Server 2003 TCP/IP" at the Microsoft Windows Resource Kits Web site.
- "TCP/IP Troubleshooting" at the Microsoft Resource Kits Web site.

For more information, see Using the Windows Deployment and Resource Kits.

# Converting binary to decimal

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Converting binary to decimal**

Because all IP addresses and subnet mask values are composed of a standard-length 32-bit data field, they are viewed and interpreted by computers as a single binary numeric string, such as:

10000011 01101011 00000111 00011011

To communicate IP addresses simply and enter them in configurations quickly, you can use *dotted decimal notation* to convert IP address numbers from binary format.

With dotted decimal notation, each 32-bit address number is viewed as four distinct groupings of 8 bits. Each of the four groupings of 8 consecutive bits is referred to as an *octet*.

The first octet uses the first 8 bits (bit places 1-8), the second octet uses the next 8 bits (bit places 9-16), followed by the third octet (bit places 17-24) and fourth octet (bit places 25-32). Periods are used to separate the four octets that are described as separate decimal number values in the IP address.

The following table shows the scientific notation for each bit place in an individual octet and the equivalent decimal value.

**Equivalent decimal values for bit places in a single IP address octet**

| **Octet** | **1st bit** | **2nd bit** | **3rd bit** | **4th bit** | **5th bit** | **6th bit** | **7th bit** | **8th bit** |
|---|---|---|---|---|---|---|---|---|
| Scientific notation | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 |
| Decimal notation | 128 | 64 | 32 | 16 | 8 | 4 | 2 | 1 |

For example, if the first bit place is filled with a bit value of 1, the equivalent decimal value is 128. Where the bit value is 0, the equivalent decimal value is 0 as well.

If all the bit places in an octet are filled with ones (1), the highest equivalent decimal value is 255. If all the bit places are filled with zeroes (0), the lowest equivalent decimal value is 0.

To see how each octet in an IP address is converted from an 8-digit binary number to an equivalent decimal number from 0 through 255, a brief example follows.

The following binary string shows the first octet in an IP address:

10000011

In this 8-digit binary number the first, seventh, and eighth bit places are filled with ones. All other bit places are filled with zeroes. By using the previous table as a reference, you can perform simple addition of each bit place's decimal equivalent value to find the decimal sum for this octet string, as follows:

1st bit (128) + 7th bit (2) + 8th bit (1) = octet total (131)

Because the sum is 131, the first octet of the example IP address is 131. After using this method on the other octets, the final result of the conversion is the dotted decimal equivalent: 131.107.7.27.

# Resource: TCP/IP Utilities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP utilities**

This section covers:

- Diagnostic utilities
- Command-line utilities

# Diagnostic utilities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Diagnostic utilities**

The following table lists TCP/IP diagnostic utilities. You can use these utilities to help identify or resolve TCP/IP networking problems.

| Utility | Description |
|---|---|
| Arp | Allows viewing and editing of the Address Resolution Protocol (ARP) cache. The ARP cache contains software-to-hardware address mappings that are used for sending data on the local network. For more information, see Arp. |
| Hostname | Displays the host name of the computer as used for authentication by the Rcp, Rsh, and Rexec utilities. For more information, see Hostname. |
| Ipconfig | Displays current TCP/IP configuration values. Also used to manually release and renew a TCP/IP configuration lease assigned by a DHCP server and to reset DNS name registrations. For more information, see Ipconfig and Command-line utilities. |
| Lpq | Displays print queue status information on computers running Line Printer Daemon (LPD) print server software. For more information, see Lpq. |
| Nbtstat | Checks the state of current NetBIOS over TCP/IP connections, updates the Lmhosts cache, and determines the registered names and scope ID. For more information, see Nbtstat. |
| Netsh | Displays and administers TCP/IP protocol settings on either the local computer or a remote computer. For more information, see Netsh commands for Interface IP. |
| Netstat | Displays protocol statistics and information on current TCP/IP connections. For more information, see Netstat. |
| Nslookup | Checks records, domain host aliases, domain host services, and operating system information by querying DNS server. For more information, see Nslookup and Verify DNS registration for domain controllers using the nslookup command. |
| Ping | Verifies whether TCP/IP is configured correctly and tests connectivity to other host systems. For more information, see Ping and Test a TCP/IP configuration by using the ping command. |
| Route | Allows viewing and editing of the local IP routing table. For more information, see Route. |
| Tracert | Traces the network route taken by an IP datagram to its destination. For more information, see Tracert and Trace a path by using the tracert command. |
| Pathping | Traces the route a packet takes to a destination and displays information on packet losses for each router in the path. Pathping can also be used to troubleshoot Quality of Service (QoS) connectivity. For more information, see Using the pathping command. |

The following table lists additional administrative utilities you can use for TCP/IP troubleshooting:

| Administrative tool | Description |
|---|---|
| SNMP service | Provides statistical information to SNMP management systems. |
| Event Viewer | Tracks errors and events. |
| Performance Logs and Alerts | Analyzes TCP/IP core protocol performance when the SNMP service is installed. |
| Network Monitor | Captures and analyzes TCP/IP to and from computers running Windows Server 2003 operating systems. |

| | |
|---|---|
| Registry Editor | Allows viewing and editing of registry settings. |

# Command-line utilities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Command-line utilities**
This section covers:

- Viewing configuration by using ipconfig /all
- Viewing configuration by using the Status feature
- Refreshing configuration by using ipconfig /renew
- Managing DNS and DHCP class IDs by using ipconfig
- Testing connections by using ping
- Troubleshooting hardware addresses by using arp
- Troubleshooting NetBIOS names by using nbstat
- Displaying connection statistics by using netstat
- Tracing network connections by using tracert
- Testing routers by using pathping

**Viewing configuration by using ipconfig /all**
When you troubleshoot a TCP/IP networking problem, begin by checking the TCP/IP configuration on the computer that is experiencing the problem. You can use the **ipconfig** command to get host computer configuration information, including the IP address, subnet mask, and default gateway.

**Note**

- For clients running Windows 95, Windows 98, and Windows Millennium Edition, use the **winipcfg** command instead of **ipconfig**.

When you use the **ipconfig** command with the **/all** option, a detailed configuration report is produced for all interfaces, including any configured serial ports. With **ipconfig /all**, you can redirect command output to a file and paste the output into other documents. You can also use this output to confirm the TCP/IP configuration of each computer on the network or to further investigate TCP/IP network problems.

For example, if a computer is configured with an IP address that is a duplicate of an existing IP address, the subnet mask appears as 0.0.0.0.

The following example shows the output of the **ipconfig /all** command on a computer that running Windows XP Professional and is configured to use the DHCP server for automatic TCP/IP configuration, and WINS and DNS servers for name resolution.

```
 IP Configuration

        Node Type . . . . . . . . . . : Hybrid
        IP Routing Enabled. . . . . . : No
        WINS proxy Enabled. . . . . . : No

Ethernet adapter Local Area Connection:

        Host Name . . . . . . . . . . : client1.microsoft.com
        DNS Servers . . . . . . . . . : 10.1.0.200
```

```
Description . . . . . : 3Com 3C90x Ethernet Adapter
Physical Address. . . . . : 00-60-08-3E-46-07
DHCP Enabled. . . . . : Yes
Autoconfiguration Enabled . : Yes
IP Address. . . . . : 192.168.0.112
Subnet Mask . . . . . : 255.255.0.0
Default Gateway . . . . . : 192.168.0.1
DHCP Server . . . . . : 10.1.0.50
Primary WINS Server . . . . : 10.1.0.101
Secondary WINS Server . . . : 10.1.0.102
Lease Obtained. . . . . : Wednesday, September 02, 1998 10:32:13 AM
Lease Expires . . . . . : Friday, September 18, 1998 10:32:13 AM
```

If no problems appear in the TCP/IP configuration, the next step is testing the ability to connect to other host computers on the TCP/IP network.

**Viewing configuration by using the Status feature**
An alternate method of viewing configuration is available through the Status feature of a network connection. For more information, see View the status of a local area connection.

**Refreshing configuration by using ipconfig /renew**
When you troubleshoot a TCP/IP networking problem, begin by checking the TCP/IP configuration on the computer that is experiencing the problem. If the computer is DHCP-enabled and is using a DHCP server to obtain configuration, you can initiate a refresh of the lease by using the **ipconfig /renew** command.

When you use **ipconfig /renew**, all network adapters on the computer that uses DHCP (except those that are manually configured) try to contact a DHCP server and renew their existing configuration or obtain a new configuration.

You can also use the **ipconfig** command with the **/release** option to immediately release the current DHCP configuration for a host.

### Note

- For Windows 95, Windows 98, and Windows Millennium Edition DHCP-enabled clients, use the **release** and **renew** options of the **winipcfg** command instead of **ipconfig /release** and **ipconfig /renew** to perform manual release or renewal of the IP configuration lease for a client.

**Repair feature**
As an alternative to **ipconfig** you can use **Repair** to renew LAN or high-speed Internet connection IP settings. **Repair** performs a series of commands that repair a connection. The commands that are invoked by **Repair** are listed below with their command-line equivalents:

| Repair | Command-line equivalent |
|---|---|
| Checks whether DHCP is enabled and, if enabled, issues a broadcast renew to refresh the IP address | No command line equivalent available |
| Flushes the ARP cache | **arp -d *** |
| Flush the NetBIOS cache | **nbtstat -R** |
| Flushes the DNS cache | **ipconfig /flushdns** |
| Re-registers with WINS | **nbtstat -RR** |
| Re-registers with DNS | **ipconfig /registerdns** |

**Important**

- **Repair** uses a broadcast renew and will cause a computer to accept any lease from any DHCP server that is on the network. In contrast, a unicast renew (**ipconfig /renew**) will only renew the existing lease from the last DHCP server from which the client got a lease.

For more information, see Repair a LAN or high-speed Internet connection.

**Managing DNS and DHCP class IDs by using ipconfig**
You can also use the **ipconfig** command to:

- Display or reset the DNS cache.

  For more information, see Flush and reset a client resolver cache using the ipconfig command.

- Refresh registered DNS names.

  For more information, see Renew DNS client registration using the ipconfig command.

- Display the DHCP class IDs for an adapter.

  For more information, see Show DHCP class ID information at a client computer.

- Set the DHCP class IDs for an adapter.

  For more information, see Set DHCP class ID information at a client computer.

**Testing connections by using ping**
The **ping** command helps to verify IP-level connectivity. When troubleshooting, you can use **ping** to send an ICMP echo request to a target host name or IP address. Use **ping** whenever you need to verify that a host computer can connect to the TCP/IP network and network resources. You can also use **ping** to isolate network hardware problems and incompatible configurations.

It is usually best to verify that a route exists between the local computer and a network host by first using the **ping** command and the IP address of the network host to which you want to connect. Try pinging the IP address of the target host to see if it responds, as follows:

**ping** *IP_address*

You should perform the following steps when using **ping**:

1. Ping the loopback address to verify that TCP/IP is configured correctly on the local computer.

   **ping** 127.0.0.1

2. Ping the IP address of the local computer to verify that it was added to the network correctly.

   **ping***IP_address_of_local_host*

3. Ping the IP address of the default gateway to verify that the default gateway is functioning and that you can communicate with a local host on the local network.

   **ping***IP_address_of_default_gateway*

4. Ping the IP address of a remote host to verify that you can communicate through a router.

   **ping***IP_address_of_remote_host*

The **ping** command uses Windows Sockets-style name resolution to resolve a computer name to an IP address, so if pinging by address succeeds, but pinging by name fails, then the problem lies in address or name resolution, not network connectivity. For more information, see Troubleshooting hardware addresses by using arp.

If you cannot use **ping** successfully at any point, confirm that:

- The computer was restarted after TCP/IP was configured.

- The IP address of the local computer is valid and appears correctly on the **General** tab of the **Internet protocol (TCP/IP) properties** dialog box.

- IP routing is enabled and the link between routers is operational.

You can use different options with the **ping** command to specify the size of packets to use, how many packets to send, whether to record the route used, what Time-to-Live (TTL) value to use, and whether to set the "don't fragment" flag. You can type **ping -?** to see these options.

The following example illustrates how to send two pings, each 1,450 bytes in size, to IP address 131.107.8.1:

```
C:\>ping -n 2 -l 1450 131.107.8.1
Pinging 131.107.8.1 with 1450 bytes of data:

Reply from 131.107.8.1: bytes=1450 time<10ms TTL=32
Reply from 131.107.8.1: bytes=1450 time<10ms TTL=32

Ping statistics for 131.107.8.1:
    Packets: Sent = 2, Received = 2, Lost = 0 (0% loss),
Approximate roundtrip times in milliseconds:
    Minimum = 0ms, Maximum =  10ms, Average =  2ms
```

By default, **ping** waits 4,000 milliseconds (4 seconds) for each response to be returned before displaying the "Request Timed Out" message. If the remote system being pinged is across a high-delay link, such as a satellite link, responses may take longer to be returned. You can use the **-w** (wait) option to specify a longer time-out.

**Troubleshooting hardware addresses by using arp**

The Address Resolution protocol (ARP) allows a host to find the media access control address of a host on the same physical network, given the IP address of the host. To make ARP efficient, each computer caches IP-to-media access control address mappings to eliminate repetitive ARP broadcast requests.

You can use the **arp** command to view and modify the ARP table entries on the local computer. The **arp** command is useful for viewing the ARP cache and resolving address resolution problems.

For more information, see View the Address Resolution Protocol (ARP) cache and Add a static ARP cache entry.

**Troubleshooting NetBIOS names by using nbtstat**

NetBIOS over TCP/IP (NetBT) resolves NetBIOS names to IP addresses. TCP/IP provides many options for NetBIOS name resolution, including local cache lookup, WINS server query, broadcast, DNS server query, and Lmhosts and Hosts file lookup.

Nbtstat is a useful tool for troubleshooting NetBIOS name resolution problems. You can use the **nbtstat** command to remove or correct preloaded entries:

- **nbtstat -n** displays the names that were registered locally on the system by programs such as the server and redirector.

- **nbtstat -c** shows the NetBIOS name cache, which contains name-to-address mappings for other computers.

- **nbtstat -R** purges the name cache and reloads it from the Lmhosts file.

- **nbtstat -RR** releases NetBIOS names registered with a WINS server and then renews their registration.

- **nbtstat -a** *name* performs a NetBIOS adapter status command against the computer specified by *name*. The adapter status command returns the local NetBIOS name table for that computer plus the media access control address of the adapter.

- **nbtstat -S** lists the current NetBIOS sessions and their status, including statistics, as shown in the following example:

```
NetBIOS connection table

Local name State     In/out Remote Host    Input   Output
---------------------------------------------------------------
CORP1 <00> Connected Out    CORPSUP1<20>   6MB     5MB
```

```
    CORP1 <00> Connected Out    CORPPRINT<20>  108KB   116KB
    CORP1 <00> Connected Out    CORPSRC1<20>   299KB   19KB
    CORP1 <00> Connected Out    CORPEMAIL1<20> 324KB   19KB
    CORP1 <03> Listening
```

**Displaying connection statistics by using netstat**

You can use the **netstat** command to display protocol statistics and current TCP/IP connections. The **netstat -a** command displays all connections, and **netstat -r** displays the route table plus active connections. The **netstat -o** command displays process IDs so you can view the owner of the port for each connection. The **netstat -e** command displays Ethernet statistics, and **netstat -s** displays per-protocol statistics. If you use **netstat -n**, addresses and port numbers are not converted to names. The following shows sample output for **netstat**:

```
C:\>netstat -e
Interface Statistics

                       Received      Sent
Bytes                  3995837940    47224622
Unicast packets        120099        131015
Non-unicast packets    7579544       3823
Discards               0             0

**Tracing network connections by using tracert**

Tracert (Trace Route) is a route-tracing utility that is used to determine the path that an IP datagram takes to reach a destination. The **tracert** command uses the IP Time-to-Live (TTL) field and ICMP error messages to determine the route from one host to another through a network.

**How tracert works**

The Tracert diagnostic utility determines the route taken to a destination by sending Internet Control Message protocol (ICMP) echo packets with varying IP Time-to-Live (TTL) values to the destination. Each router along the path is required to decrement the TTL on a packet by at least 1 before forwarding it. When the TTL on a packet reaches 0, the router should send an "ICMP Time Exceeded" message back to the source computer.

Tracert determines the route by sending the first echo packet with a TTL of 1 and incrementing the TTL by 1 on each subsequent transmission until the target responds or the maximum TTL is reached. The route is determined by examining the "ICMP Time Exceeded" messages sent back by intermediate routers. Some routers silently drop packets with expired TTLs and are invisible to the Tracert utility.

The **tracert** command prints out an ordered list of the near-side interface of the routers in the path that returned the "ICMP Time Exceeded" message. If the **-d** option is used, the Tracert utility does not perform a DNS lookup on each IP address.

In the following example, the packet must travel through two routers (10.0.0.1 and 192.168.0.1) to get to host 172.16.0.99. The

default gateway of the host is 10.0.0.1 and the IP address of the router on the 192.168.0.0 network is 192.168.0.1.

```
C:\>tracert 172.16.0.99 -d
Tracing route to 172.16.0.99 over a maximum of 30 hops
1     2 ms     3 ms     2 ms  10.0.0.1
2    75 ms    83 ms    88 ms  192.168.0.1
3    73 ms    79 ms    93 ms  172.16.0.99
Trace complete.
```

**Troubleshooting with tracert**

You can use the **tracert** command to determine where a packet stopped on the network. In the following example, the default gateway has determined that there is not a valid path for the host on 192.168.10.99. There is probably a router configuration problem or the 192.168.10.0 network does not exist (a bad IP address).

```
C:\>tracert 192.168.10.99
Tracing route to 192.168.10.99 over a maximum of 30 hops
1  10.0.0.1  reports: Destination net unreachable.
Trace complete.
```

The Tracert utility is useful for troubleshooting large networks where several paths can be taken to arrive at the same point.

**Tracert command-line options**

The **tracert** command supports several options, as shown in the following table.

**tracert** [**-d**] [**-h** *maximum_hops*] [**-j** *host-list*] [**-w** *timeout*] *target_name*

| Option | Description |
|---|---|
| **-d** | Specifies that IP addresses are not resolved to host names. |
| **-h** *maximum_hops* | Specifies the number of hops to allow in tracing a route to the host named in *target_name*. |
| **-j** *host-list* | Specifies the list of router interfaces in the path taken by the Tracert utility packets. |
| **-w** *timeout* | Waits the number of milliseconds specified by *timeout* for each reply. |
| *target_name* | Name or IP address of the target host. |

For more information, see Trace a path by using the tracert command.

**Testing routers by using pathping**

The **pathping** command is a route tracing tool that combines features of the **ping** and **tracert** commands with additional information that neither of those tools provides. The **pathping** command sends packets to each router on the way to a final destination over a period of time, and then computes results based on the packets returned from each hop. Since the command shows the degree of packet loss at any given router or link, it is easy to determine which routers or links might be causing network problems. A number of options are available, as shown in the following table.

| Option | Name | Function |
|---|---|---|
| **-n** | Hostnames | Does not resolve addresses to host names. |
| **-h** | Maximum hops | Maximum number of hops to search for target. |
| **-g** | Host-list | Loose source route along host list. |
| **-p** | Period | Number of milliseconds to wait between pings. |
| **-q** | Num_queries | Number of queries per hop. |
| **-w** | Time-out | Waits this many milliseconds for each reply. |
| **-i** | address | Use the specified source address. |
| **-4** | IPv4 | Force pathping to use IPv4. |
| **-6** | IPv6 | Force pathping to use IPv6. |

The default number of hops is 30, and the default wait time before a time-out is 3 seconds. The default period is 250 milliseconds, and the default number of queries to each router along the path is 100.

The following is a typical **pathping** report. The compiled statistics that follow the hop list indicate packet loss at each individual router.

```
D:\>pathping -n server1

Tracing route to server1 [10.54.1.196]
over a maximum of 30 hops:
  0  172.16.87.35
  1  172.16.87.218
  2  192.168.52.1
  3  192.168.80.1
  4  10.54.247.14
  5  10.54.1.196

Computing statistics for 125 seconds...
            Source to Here   This Node/Link
Hop  RTT    Lost/Sent = Pct  Lost/Sent = Pct  Address
  0                                           172.16.87.35
                                 0/ 100 =  0%   |

  5   24ms    13/ 100 = 13%      0/ 100 =  0%  10.54.1.196

Trace complete.
```

When **pathping** is run, you first see the results for the route as it is tested for problems. This is the same path that is shown by the **tracert** command. The **pathping** command then displays a busy message for the next 125 seconds (this time varies by the hop count). During this time, **pathping** gathers information from all the routers previously listed and from the links between them. At the end of this period, it displays the test results.

The two rightmost columns--**This Node/Link Lost/Sent=Pct** and **Address**--contain the most useful information. The link between 172.16.87.218 (hop 1), and 192.168.52.1 (hop 2) is dropping 13 percent of the packets. All other links are working normally. The routers at hops 2 and 4 also drop packets addressed to them (as shown in the **This Node/Link** column), but this loss does not affect their forwarding path.

The loss rates displayed for the links (marked as a **|** in the rightmost column) indicate losses of packets being forwarded along the path. This loss indicates link congestion. The loss rates displayed for routers (indicated by their IP addresses in the rightmost column) indicate that those routers' CPUs might be overloaded. These congested routers might also be a factor in end-to-end problems, especially if packets are forwarded by software routers.

# TCP/IP database files

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP database files**

The following table lists the UNIX-style database files that are stored in the *systemroot*\System32\Drivers\Etc folder corresponding to TCP/IP for computers running Windows Server 2003 operating systems.

| File name | Use |
|---|---|
| Hosts | Provides host name-to-IP address resolution for Windows Sockets programs. |
| Lmhosts | Provides NetBIOS name-to-IP address resolution for Windows-based networking. |
| Networks | Provides network name-to-network ID resolution for Windows Sockets programs. |
| Protocols | Provides protocol name-to-protocol ID resolution for Windows Sockets programs. |
| Services | Provides service name-to-port ID resolution for Windows Sockets programs. |

To troubleshoot any of these files on a local computer, do the following:

1. Make sure the format of entries in each file matches the format defined in the sample file originally provided with TCP/IP.
2. Check for spelling errors.
3. Check for invalid IP addresses and identifiers.

**Note**

- By default, the Lmhosts file does not exist. There is an Lmhosts.sam sample file that you can use as a basis for creating an Lmhosts file.

# Using Performance Logs and Alerts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Performance Logs and Alerts**

You can use the Performance Logs and Alerts to view many different TCP/IP-related counters. Because the Performance Logs and Alerts access statistics that are gathered by the SNMP service, the SNMP service must be installed on Windows-based computers where TCP/IP statistics are to be monitored. Counters for Performance Logs and Alerts are available for network adapters, IP, ICMP, UDP, and TCP.

With Performance Logs and Alerts, you can monitor counters from various systems from a single management window. You can also set alert levels for the counters being monitored.

# Troubleshooting TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**
What problem are you having?

- Getting 169.254.y.z address.
- Host name resolution is failing.
- Unable to add a default gateway.
- System error 53 occurred.
- Cannot connect to a specific server.
- Long connect times when using Lmhosts for name resolution.
- TCP/IP connection to a host appears to have stopped.
- Cannot ping across a local router when using a dial-up connection.
- A "The registry subkey already exists" message is displayed.

**Getting 169.254.y.z address.**
**Cause:** Through Automatic Private IP Addressing (APIPA), an IP address in the range 169.254.0.1 to 169.254.255.254 with a subnet mask of 255.255.0.0 is automatically assigned when TCP/IP is configured to obtain an IP address automatically, a Dynamic Host Configuration Protocol (DHCP) server is not available, and an alternate configuration is not specified. APIPA is designed to provide automatic IP addressing on single segment networks.

**Solution:** Disable automatic address configuration, determine and fix the cause of the computer's inability to contact the DHCP server, or specify an alternate configuration.

**See also:** New features for TCP/IP; Configure TCP/IP for an alternate configuration; Disable automatic address configuration

**Host name resolution is failing.**
**Cause:** Host name resolution techniques are failing to resolve a host name to its IP address.

**Solution:** The Windows Server 2003 family includes several basic TCP/IP tools that you can use to troubleshoot address and name resolution problems, including the **ping** command. If you receive the correct response when you use the **ping** command with an IP address but an incorrect response when you use **ping** with the host name or NetBIOS name, there is a name resolution problem.

When you use TCP/IP tools such as the **ping** command, the Hosts file or a DNS server is used for name resolution. You can find the Hosts file in the *systemroot*\System32\Drivers\Etc folder. This file is *not* dynamic; you must manually add entries. The format of the file is as follows:

**IP address  Friendly name**

```
172.16.48.10   server1   # Remarks are denoted with a #.
```

When you use a Hosts file for name resolution, the following steps occur:

1. A user at Computer A enters a command by using the host name of Computer B.
2. The Hosts file on Computer A (in the *systemroot*\System32\Drivers\Etc folder) is parsed. When the host name of Computer B is found, it is resolved to an IP address.

The following problems can occur because of errors related to the Hosts file:

- The Hosts file or the DNS server does not contain the particular host name.
- The host name in the Hosts file or in the command is misspelled.
- An invalid IP address is entered for the host name in the Hosts file.
- The Hosts file contains multiple entries for the same host on separate lines; if so, the first entry from the top of the file is used.
- A mapping for a computer name-to-IP address was mistakenly added to the Hosts file, rather than the Lmhosts file.

For DNS server host name resolution, verify that the correct DNS servers are configured and in the proper order. You can use the **ipconfig /all** command to check the current TCP/IP configuration and the **ping** command to check connectivity with your DNS servers. You can use the **nslookup** command to send DNS name queries to your primary DNS server.

If you use a DNS server for host name resolution, the name resolution steps are similar. Computer A sends a DNS name query to its configured DNS server. The DNS server resolves the host name of Computer B to an IP address and sends the results back to Computer A.

**See also:** Host name resolution; Ipconfig; Ping; Nslookup; Verify DNS registration for domain controllers using the nslookup command; TCP/IP database files

**Unable to add a default gateway.**
**Cause:** The IP address of the default gateway is not on the same IP network ID as your IP address.

**Solution:** Find out whether the default gateway is located on the same logical network as the network adapter of the computer by comparing the IP address of the default gateway with the network IDs of any of the network adapters of the computer.

For example, a computer with a single network adapter that is configured with an IP address of 192.168.0.33 and a subnet mask of 255.255.0.0 requires that the default gateway be of the form 192.168.*y.z* because the network ID portion of the IP interface is 192.168.0.0.

**See also:** IP addressing; Subnet masks; Default gateways

**System error 53 occurred.**
**Cause:** System error 53 is returned if name resolution fails for a particular computer name when the **net use** command is used.

**Solution:** If the computer is on the local subnet, confirm that the name is spelled correctly and that the target computer is running TCP/IP as well. If the computer is not on the local subnet, be sure that its name and IP address mapping are available in the Lmhosts file or the WINS database. If all TCP/IP elements appear to be installed properly, use the **ping** command with the remote computer to verify that its TCP/IP software is working.

**See also:** Test a TCP/IP configuration by using the ping command; Test TCP/IP connections by using the ping and net view commands; Net use; Ping

**Cannot connect to a specific server.**
**Cause:** Either NetBIOS name resolution is failing to resolve the name or the wrong IP address is being resolved.

**Solution:** Use the **nbtstat -n** command on the server to determine what names the server registered on the network. The computer name of the computer you are trying to connect to should be on the displayed list. If the name is not listed, try one of the other unique computer names displayed by **nbtstat**.

If the name being used by a remote computer is the same as the name displayed by the **nbtstat -n** command, then make sure that the remote computer has an entry for the server name on the WINS server or in its Lmhosts file.

**See also:** NetBIOS name resolution; Test TCP/IP connections by using the ping and net view commands; Net use; TCP/IP database files; Nbtstat

**Long connect times when using Lmhosts for name resolution.**
**Cause:** The Lmhosts file is parsed sequentially to locate entries without the #PRE option.

**Solution:** Place frequently used entries near the top of the file and place the #PRE entries near the bottom. If an entry is added to the end of a large Lmhosts file, mark the entry in Lmhosts as a preloaded entry by using the #PRE option. Then use the **nbtstat -R** command to update the local name cache immediately.

**See also:** TCP/IP database files; Nbtstat; View the NetBIOS name table by using the nbtstat command; Release and refresh NetBIOS names by using the nbtstat command

**TCP/IP connection to a host appears to have stopped.**
**Cause:** Either data is blocked in TCP and UDP queues or there are network or user-level software delay problems.

**Solution:** Use the **netstat -a** command to show the status of all activity on TCP and UDP ports on the local computer.

The state of a good TCP connection is usually established with 0 bytes in the send and receive queues. If data is blocked in either queue, or if the state is irregular, there is probably a problem with the connection. If not, you are probably experiencing a network or user-level software delay.

**See also:** Netstat; View current TCP/IP protocol and connection statistics

**Cannot ping across a local router when using a dial-up connection.**
**Cause:** This problem occurs if the **Use default gateway on remote network** check box is selected on the **General** tab in the **Advanced TCP/IP Settings** dialog box (in the **Internet Protocol (TCP/IP)** dialog box on the **General** or **Networking** tab for the properties of the dial-up connection).

This feature adds a default route to the IP routing table that is used instead of the current default route for the duration of the connection. The new default route causes network traffic for IP addresses that are not resolved by other entries in the routing table to be sent across the dial-up connection. This new default route is needed when you dial an Internet service provider (ISP) and use Internet utilities, such as a Web browser or FTP, to access Internet resources.

**Solution:** If you want to ping or otherwise connect to computers in a remote network segment across a local router while you are connected as a dial-up client to an ISP, then use the **route add** command to add the route of the network segment you are attempting to reach by specifying the destination network and subnet mask of the remote network segment and the IP address of the local router.

**See also:** Route

**A "The registry subkey already exists" message is displayed.**
**Cause:** The registry keys for a component being installed already exist.

**Solution:** Ensure that all the components of a given TCP/IP service are properly removed, and then remove the appropriate registry subkeys by using the Registry Editor.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**TCP/IP registry keys**

If you removed TCP/IP and its related service components, you must also remove the following registry subkeys:

- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NetBT**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dhcp**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\LmHosts**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\AdapterName\Parameters\Tcpip**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\NetBT**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Tcpip**

- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\TcpipCU**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WinSock**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WinSock2**

**SNMP service registry keys**

If you removed the SNMP service components, you must also remove the following registry subkeys:

- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\RFC1156Agent**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Snmp**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Snmp**

**TCP/IP Printing service registry keys**

If you removed the TCP/IP Printing service components, you must also remove the following registry subkeys:

- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Lpdsvc**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\TcpPrint**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\LPDSVC**

**Simple TCP/IP Services registry keys**

If you removed the Simple TCP/IP Services components, you must also remove the following registry subkeys:

- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\SimpTcp**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\SimpTcp**

**DHCP service registry keys**

If you removed the DHCP service components, you must also remove the following registry subkeys:

- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\DhcpMibAgent**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\DhcpServer**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DhcpServer**

**WINS service registry keys**

If you removed the WINS service components, you must also remove the following registry subkeys:

- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Wins**
- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WinsMibAgent**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Wins**

**DNS service registry keys**

If you removed the DNS service components, you must also remove the following registry subkeys:

- **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Dns**
- **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Dns**

For more advanced TCP/IP troubleshooting information, see Resource Kit.

# IP Version 6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP version 6**

IP version 6 (IPv6) is a suite of standard protocols that is the next generation of network layer protocols for the Internet.

- Before you begin using IPv6 with this computer, see Checklist: Installing and configuring IPv6.
- For help with specific tasks, see IPv6 How To....
- For general background information, see IPv6 Concepts.
- For problem-solving instructions, see Troubleshooting IPv6.

# Checklist: Installing and configuring IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing and configuring IPv6**

| Step | Reference |
|---|---|
| Review IPv6 concepts, such as core protocols, addressing, and routing. | Understanding IPv6 |
| Review IPv6 name resolution concepts for resolving DNS names to IP addresses. | Name Resolution |
| Verify that network adapter hardware is installed, or install hardware if needed. | Installing devices overview |
| Install IPv6 on this computer. | Install IPv6 |
| (Manual configuration only) Configure IPv6 address and prefix settings. | Configure IPv6 with manual addresses |
| Use the **ping** command to verify that you have IPv6 installed and running. | Test an IPv6 configuration by using the ping command |
| Use the **ping** command to verify that you can communicate with another IPv6 node. | Test IPv6 connectivity by using the ping command |

# IPv6 How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**
This section provides instructions for installing and configuring the IPv6 protocol.

- Install and Configure IPv6
- Managing Routes with IPv6
- Diagnose IPv6 Connections

# Install and Configure IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Install and configure IPv6**

- Install IPv6
- Remove IPv6
- Configure IPv6

# Install IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install IPv6**

1. Open Network Connections.
2. Right-click any local area connection, and then click **Properties**.
3. Click **Install**.
4. In the **Select Network Component Type** dialog box, click **Protocol**, and then click **Add**.
5. In the **Select Network Protocol** dialog box, click **Microsoft TCP/IP version 6**, and then click **OK**.
6. Click **Close** to save changes to your network connection.

### Note

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove IPv6**

1. Open Network Connections.
2. Right-click any local area connection, and then click **Properties**.
3. Click **Microsoft TCP/IP version 6** in the list of installed components, and then click **Uninstall**.
4. In the **Uninstall Microsoft TCP/IP version 6** dialog box, click **Yes**.
5. Click **Close** to save changes to your network connection.

### Note

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure IPv6 with manual addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure IPv6 with manual addresses**

1. Open Command Prompt.
2. At the command prompt, type **netsh**, and then press ENTER.
3. Type **interface ipv6**, and then press ENTER.
4. Type **add address** [**interface=**]*String* [**address=**]*IPv6Address*

Where:

**[ interface=] *String***
Specifies the name for the interface.

**[ address=] *IPv6Address***
Specifies the IPv6 address.

**Notes**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- Additional parameters are available for this command. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure interface attributes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure interface attributes**

1. Open Command Prompt.
2. At the command prompt, type **netsh**, and then press ENTER.
3. Type **interface ipv6**, and then press ENTER.
4. Type **set interface** [**interface=**]*String* [[**forwarding=**]{**enabled** | **disabled**}] [[**advertise=**]{**enabled** | **disabled**}] [[**mtu=**]*Integer*] [[**siteid=**]*Integer*] [[**metric=**]*Integer*] [[**firewall=**]{**enabled** | **disabled**}] [[**siteprefixlength=**]*Integer*] [[**store=**]{**active** | **persistent**}]

Where:

**[ interface=] *String***
Specifies the interface name.

**[[ forwarding=]{ enabled| disabled}]**
Specifies whether packets arriving on this interface can be forwarded to other interfaces. The default is disabled.

**[[ advertise=]{ enabled| disabled}]**
Specifies whether Router Advertisements are sent on this interface. The default is disabled.

**[[ mtu=] *Integer*]**
Specifies the maximum transmission unit (MTU) of this interface. If **mtu** is not specified, the default MTU of the link is used.

**[[ siteid=] *Integer*]**
Specifies the site scope zone identifier. The site identifier is used to distinguish among interfaces belonging to different administrative regions that use site-local addressing.

**[[ metric=] *Integer*]**
Specifies the interface metric, which is added to route metrics for all routes over the interface.

**[[ firewall=]{ enabled| disabled}]**
Specifies whether to operate in firewall mode.

**[[ siteprefixlength=] *Integer*]**
Specifies the default length of the global prefix for the entire site.

**[[ store=]{ active| persistent}]**
If **active** is specified, the change only lasts until the computer is restarted. If **persistent** is specified, the change is permanent. The default is **Persistent**.

**Note**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add an IPv6 route

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an IPv6 route**

1. Open Command Prompt.
2. At the command prompt, type **netsh**, and then press ENTER.
3. Type **interface ipv6**, and then press ENTER.
4. Type **add route** [**prefix=**]*IPv6Address***/***Integer* [[**interface=**]*String*] [[**nexthop=**]*IPv6Address*] [[**siteprefixlength=**]*Integer*] [[**metric=**]*Integer*] [[**publish=**]{**no** | **yes** | **immortal**}] [[**validlifetime=**]{*Integer* | **infinite**}] [[**preferredlifetime=**]{*Integer* | **infinite**}] [[**store=**]{**active** | **persistent**}]

Where:

**[ prefix=] *IPv6Address/Integer***
Required. Specifies the prefix for which to add a route. *Integer* specifies the prefix length.

**[[ interface=] *String*]**
Specifies an interface name or index.

**[[ nexthop=] *IPv6Address*]**
Specifies the gateway address, if the prefix is not on-link.

**[[ siteprefixlength=] *Integer*]**
Specifies the prefix length for the entire site, if the prefix is not on-link.

**[[ metric=] *Integer*]**
Specifies the route metric.

**[[ publish=]{ no| yes| immortal}]**
Specifies whether routes are advertised (**yes**), advertised with an infinite lifetime (**immortal**), or not advertised (**no**) in Route Advertisements. The default selection is **no**.

**[[ validlifetime=]{ *Integer*| infinite}]**
Specifies the lifetime over which the route is valid. The default value is **infinite**.

**[[ preferredlifetime=]{ *Integer*| infinite}]**
Specifies the lifetime over which the route is preferred. The default value is **infinite**.

**[[ store=]{ active| persistent}]**
Specifies whether the change lasts only until the next boot (**active**) or is persistent (**persistent**). The default selection is **persistent**.

**Note**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove an IPv6 route

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove an IPv6 route**

1. Open Command Prompt.
2. At the command prompt, type **netsh**, and then press ENTER.
3. Type **interface ipv6**, and then press ENTER.
4. Type **show routes**

   to obtain the route prefix and the interface index of the interface over which the addresses for the route prefix are reachable.
5. To delete a route, type**delete route** [**prefix=**]*IPv6Address***/***Integer* [**interface=**]*String*

Where:

**[ prefix=] *IPv6Address/Integer***
Specifies the prefix for which to delete a route. *IPv6Address* is an IPv6 address and *Integer* is the prefix length of the route to delete.

**[ interface=] *String***
Specifies the interface name or index.

**Notes**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- Additional parameters are available for this command. For more information, see Related Topics.

**Information about functional differences**

# Enable IPv6 forwarding

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable IPv6 forwarding**

1. Open Command Prompt.
2. At the command prompt, type **netsh**, and then press ENTER.
3. Type **interface ipv6**, and then press ENTER.
4. Type **set interface** [**interface=**]*String* [**forwarding=**]**enabled**

Where:

**[ interface=] *String***
Specifies the interface name or index.

**[ forwarding=] enabled**
Specifies whether packets arriving on this interface can be forwarded to other interfaces. The default is disabled.

**Notes**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- You can also send Router Advertisement messages by adding the **advertise** parameter to the command, as follows:

  **set interface** [**interface=**]*String* [**forwarding=**]**enabled** [**advertise=**]**enabled**

- Additional parameters are available for this command. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Diagnose IPv6 Connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Diagnose connections**

- Test an IPv6 configuration by using the ping command
- Test IPv6 connectivity by using the ping command
- Trace an IPv6 path by using the tracert command
- View the interface configuration
- View the neighbor cache
- View the destination cache

# Test an IPv6 configuration by using the ping command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test an IPv6 configuration by using the ping command**

1. To obtain the IPv6 configuration for a computer, open Command Prompt, and then type **netsh interface ipv6 show interface**. If IPv6 is not installed, see Related Topics.

2. At the command prompt, ping the loopback address by typing **ping ::1**.

   If the **ping** command fails, verify that the ::1 address is assigned to the interface named Loopback Pseudo-Interface.

3. Use the following command to ping a link-local IPv6 address of the computer:

   **ping***Address***%***ZoneID*

   where *Address* is the link-local address and *ZoneID* is the interface index for the interface to which the link-local address is assigned. A link-local address begins with FE80.

   If the **ping** command fails, verify the address and interface index.

4. Use the following command to ping the link-local address of another host on your link (also known as a subnet):

   **ping***Address***%***ZoneID*

   where *Address* is the link-local address of the other host and *ZoneID* is the interface index for the interface from which you want to send the ping packets.

   If the **ping** command fails, verify the link-local address of the other host and the zone ID.

### Note

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test IPv6 connectivity by using the ping command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test IPv6 connectivity by using the ping command**

1. To obtain the IPv6 configuration for a computer, open Command Prompt, and then type **netsh interface ipv6 show interface***InterfaceName*, where *InterfaceName* is the name of an interface on your computer. For example, if you have an interface named Local Area Connection, type:

   **netsh interface ipv6 show interface "Local Area Connection"**

   If IPv6 is not installed, see Related Topics.

2. Use one of the following commands to ping another IPv6 node:

   - To ping the link-local address of another node on your link (also known as a subnet):

     **ping** *Address***%***ZoneID*

     where *Address* is the link-local address of the other node and *ZoneID* is typically the interface index for the interface from which you want to send ping packets. You can obtain the interface index from the display of the **netsh interface ipv6 show interface** command.

     If the **ping** command fails, verify the link-local address of the other node and the zone ID.

   - To ping the site-local address of another node:

     **ping** *Address***%***ZoneID*

     where *Address* is the site-local address of the other node and *ZoneID* is the site identifier (Zone ID for Site) from the display of the **netsh interface ipv6 show interface level=verbose** command. If you are not using site identifiers or have only a single site, the **%***ZoneID* portion of the command is not required.

     If the **ping** command fails, verify the site-local address of the other node and the zone ID.

   - To ping the global address of another node:

     **ping***Address*

     where *Address* is the global address of the other node.

     If the **ping** command fails, verify the global address of the other node.

   - To ping another node by name:

     **ping -6***Name*

     where *Name* is a name that can be resolved to an IPv6 address through entries in the local hosts file, or through AAAA resource records that are present in your Domain Name System (DNS) infrastructure. When you identify the target host by name rather than IPv6 address, it is necessary to include the **-6** parameter to ensure that IPv6 addresses are used.

     If the **ping** command fails, verify that the name can be resolved to an IPv6 address.

**Note**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Trace an IPv6 path by using the tracert command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To trace a path by using the tracert command**

- Open Command Prompt, and type the following:

  **tracert -d -6***HostName*

  Or, type **tracert***IPv6Address***%***ZoneID*

where:

- *HostName* is the host name of the remote computer.
- *IPv6Address* is the IPv6 address of the remote computer.
- *ZoneID* is the zone identifier (ID) for the destination address. The zone ID for link-local destination addresses is typically the interface index of the interface from which you want to send **tracert** packets. You can obtain the interface index from the display of the **netsh interface ipv6 show interface** command. The zone ID for site-local destination addresses is the Zone ID for Site from the display of the **netsh interface ipv6 show interface level=verbose** command. If you are not using site identifiers or have only a single site, the **%***ZoneID* portion of the command for site-local addresses is not required. The **%***ZoneID* portion of the command is not required for global destination addresses.

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- For IPv6, the **tracert** command traces the path taken by IPv6 packets from this computer to another remote computer. The **tracert** command uses ICMPv6 Echo Request messages (similar to the **ping** command) to produce command-line report information about each router that is crossed and the roundtrip time for each hop.
- If **tracert** is unsuccessful, you can use the command-line report information to determine at which intermediate router forwarding either failed or was slowed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Security information for IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for IPv6**

The use of IPv6 is currently supported only when IPv4 is also installed. TCP/IP internetworks are susceptible to a variety of possible attacks, from passive attacks (such as eavesdropping) to active attacks (such as denial-of-service attacks). For more information, see Security issues with IP.

It is important to follow best practices for security when using IPv6 on your network. For more information, see Best practices for security.

Following is known security information for IPv6:

- **The installation of an unauthorized router can cause reconfiguration of clients and rerouting of IPv6 traffic**

  Configuration of IPv6 addresses is based on the receipt of Router Advertisement messages from IPv6 routers. In addition, to communicate with IPv6 nodes on other network segments, IPv6 must use a default router. A default router is automatically assigned based on the receipt of a router advertisement.

  Malicious users with physical access to the IPv6-enabled network can cause a denial of service attack on IPv6 hosts by installing an unauthorized IPv6 router on the network segment. The unauthorized IPv6 router can reconfigure IPv6 clients, set itself as the default router, reroute link traffic, and disrupt other network services.

  **Recommendations:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.

- **Internet Connection Firewall (ICF) and Basic Firewall cannot filter or block IPv6 traffic**

  ICF, available on the 32-bit editions of Microsoft® Windows Server® 2003, Standard Edition and Windows Server 2003, Enterprise Edition, is used to restrict the traffic that is allowed to enter your network from the Internet. Because ICF can only filter IPv4 traffic, IPv6 traffic might circumvent the firewall and enter your network.

  Basic Firewall is a component of Routing and Remote Access that you can enable for any public interface on a computer running both Routing and Remote Access and a member of the Windows Server 2003 family. Because Basic Firewall can only filter IPv4 traffic, IPv6 traffic circumvent the firewall and enter your network.

  **Recommendations:**

  - Use firewall software that can filter and block IPv6 traffic if you are running IPv6 on your network.

- **On-link computers can take control of another IPv6 address, causing on-link devices to create an incorrect entry in their neighbor cache**

  Nodes on an IPv6 link use address resolution to resolve a neighboring node's IPv6 address to its link-layer address (equivalent to ARP in IPv4). The resolved link-layer address becomes an entry in a node's neighbor cache (equivalent to the ARP cache in IPv4). If an IPv6 node uses another node's address, it can cause other computers on the link to add a false entry to their neighbor cache. All traffic intended for the original computer instead goes to the attacker's computer, and the attacker can appear to send traffic from the original computer.

  **Recommendations:**

  - Ensure that unauthorized persons do not have physical or wireless access to your network.

- **When native IPv6 connectivity is not present, spoofing off-link IPv6 source addresses is easier**

The common defense against IP source address spoofing is source ingress and egress filtering on packets by routers. Because traffic between hosts on the same link does not cross a router, this protective filtering is not used.

While this threat applies to native connectivity (in both IPv4 and IPv6) where on-link hosts can spoof off-link addresses in communication with other hosts on the link, the threat is greater when native connectivity does not exist. When native IPv6 connectivity is not present, encapsulation technologies such as ISATAP and 6to4 are used.

Because the virtual link used for packet encapsulation spans a large logical area of the network (for example, in the case of 6to4, the entire IPv4 Internet), an attacker can be anywhere on the IPv4 Internet and still spoof off-link addresses.

**Recommendations:**

- Ensure that native IPv6 connectivity is present.

## Note

- When the computer running IPv6 is started, IPv6 logs event ID 3100 in the system event log.

### Additional information

- This implementation of IPSec for IPv6 is not recommended for use in a production environment because it relies on static keying and has no provisions for updating keys upon sequence number reuse.
- When you manually configure Security Parameters Indexes (SPIs) for IPSec for IPv6, always use random numbers. Do not use sequential numbers for SPIs, or you will compromise the security of your IPSec for IPv6 policies.
- The IPv6 protocol for the Windows Server 2003 family does not support the use of IPSec Encapsulating Security Payload (ESP) encryption. However, the use of ESP with NULL encryption is supported. Although NULL encryption uses the ESP header, only data origin authentication and data integrity services are provided.
- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.
- Internet Connection Firewall is included only in the original releases of Windows Server 2003, Standard Edition, and Windows Server 2003, Enterprise Edition.

For additional information about IPv6 security, see Security features for IPv6 and Using IPSec between two local link hosts.

# Introduction to IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Introduction to IPv6**

The current version of the Internet Protocol (known as IP version 4 or IPv4) has not been substantially changed since RFC 791 was published in 1981. IPv4 has proven to be robust, easily implemented and interoperable, and has stood the test of scaling an internetwork to a global utility the size of today's Internet. This is a tribute to its initial design.

However, the initial design did not anticipate:

- The recent exponential growth of the Internet and the impending exhaustion of the IPv4 address space.

  IPv4 addresses have become relatively scarce, forcing some organizations to use a network address translator (NAT) to map multiple private addresses to a single public IP address. While NATs promote reuse of the private address space, they do not support standards-based network layer security or the correct mapping of all higher layer protocols and can create problems when connecting two organizations that use the private address space.

  Additionally, the rising prominence of Internet-connected devices and appliances assures that the public IPv4 address space will eventually be depleted.

- The growth of the Internet and the ability of Internet backbone routers to maintain large routing tables.

  Because of the way in which IPv4 network IDs have been and are currently allocated, there are routinely over 70,000 routes in the routing tables of Internet backbone routers. The current IPv4 Internet routing infrastructure is a combination of both flat and hierarchical routing.

- The need for simpler configuration.

  Most current IPv4 implementations must be configured either manually or through a stateful address configuration protocol such as Dynamic Host Configuration Protocol (DHCP). With more computers and devices using IP, there is a need for a simpler and more automatic configuration of addresses and other configuration settings that do not rely on the administration of a DHCP infrastructure.

- The requirement for security at the IP level.

  Private communication over a public medium like the Internet requires encryption services that protect the data sent from being viewed or modified in transit. Although a standard now exists for providing security for IPv4 packets (known as Internet Protocol security or IPSec), this standard is optional and proprietary solutions are prevalent.

- The need for better support for real-time delivery of data (also known as quality of service).

  While standards for quality of service (QoS) exist for IPv4, real-time traffic support relies on the IPv4 Type of Service (TOS) field and the identification of the payload, typically using a UDP or TCP port. Unfortunately, the IPv4 TOS field has limited functionality and has different interpretations. In addition, payload identification using a TCP and UDP port is not possible when the IPv4 packet payload is encrypted.

To address these concerns, the Internet Engineering Task Force (IETF) has developed a suite of protocols and standards known as IP version 6 (IPv6). This new version, previously named IP-The Next Generation (IPng), incorporates the concepts of many proposed methods for updating the IPv4 protocol. IPv6 is intentionally designed for minimal impact on upper and lower layer protocols by avoiding the arbitrary addition of new features.

# IPv6 features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 features**
The following are the features of the IPv6 protocol:

- New header format
- Large address space
- Efficient and hierarchical addressing and routing infrastructure
- Stateless and stateful address configuration
- Built-in security
- Better support for quality of service (QoS)
- New protocol for neighboring node interaction
- Extensibility

The following sections discuss each of these new features in detail.

**New header format**
The IPv6 header has a new format that is designed to minimize header overhead. This is achieved by moving both nonessential fields and option fields to extension headers that are placed after the IPv6 header. The streamlined IPv6 header provides more efficient processing at intermediate routers.

IPv4 headers and IPv6 headers are not interoperable and the IPv6 protocol is not backward compatible with the IPv4 protocol. A host or router must use an implementation of both IPv4 and IPv6 in order to recognize and process both header formats. The new IPv6 header is only twice as large as the IPv4 header, even though IPv6 addresses are four times as large as IPv4 addresses.

For more information, see Internet Protocol version 6 (IPv6).

**Large address space**
IPv6 has 128-bit (16-byte) source and destination addresses. Although 128 bits can provide over 3.4×1038 possible combinations, the large address space of IPv6 has been designed to allow for multiple levels of subnetting and address allocation from the Internet backbone to the individual subnets within an organization.

Although only a small percentage of possible addresses are currently allocated for use by hosts, there are plenty of addresses available for future use. With a much larger number of available addresses, address-conservation techniques, such as the deployment of NATs, are no longer necessary.

For more information, see IPv6 Addressing.

**Efficient and hierarchical addressing and routing infrastructure**
IPv6 global addresses used on the IPv6 portion of the Internet are designed to create an efficient, hierarchical, and summarizable routing infrastructure that addresses the common occurrence of multiple levels of Internet service providers. On the IPv6 Internet, backbone routers have much smaller routing tables.

For more information, see Unicast IPv6 addresses.

**Stateless and stateful address configuration**
To simplify host configuration, IPv6 supports both stateful address configuration, such as address configuration in the presence of a DHCP server, and stateless address configuration (address configuration in the absence of a DHCP server). With stateless address configuration, hosts on a link automatically configure themselves with IPv6 addresses for the link (link-local

addresses) and with addresses that are derived from prefixes advertised by local routers. Even in the absence of a router, hosts on the same link can automatically configure themselves with link-local addresses and communicate without manual configuration.

For more information, see IPv6 address autoconfiguration.

**Built-in security**
Support for IPSec is an IPv6 protocol suite requirement. This requirement provides a standards-based solution for network security needs and promotes interoperability between different IPv6 implementations.

For more information, see Security features for IPv6.

**Better support for quality of service (QoS)**
New fields in the IPv6 header define how traffic is handled and identified. Traffic identification, by using a Flow Label field in the IPv6 header, allows routers to identify and provide special handling for packets that belong to a flow. A flow is a series of packets between a source and destination. Because the traffic is identified in the IPv6 header, support for QoS can be easily achieved even when the packet payload is encrypted with IPSec.

**New protocol for neighboring node interaction**
The Neighbor Discovery protocol for IPv6 is a series of Internet Control Message Protocol for IPv6 (ICMPv6) messages that manage the interaction of neighboring nodes (that is, nodes on the same link). Neighbor Discovery replaces Address Resolution Protocol (ARP), ICMPv4 Router Discovery, and ICMPv4 Redirect messages with efficient multicast and unicast messages and provides additional functionality.

For more information, see Neighbor Discovery (ND).

**Extensibility**
IPv6 can be extended for new features by adding extension headers after the IPv6 header. Unlike the IPv4 header, which can only support 40 bytes of options, the size of IPv6 extension headers is only constrained by the size of the IPv6 packet.

# IPv6 protocol features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 protocol features**

The IPv6 protocol for the Microsoft® Windows Server 2003 family includes the following features:

- 6to4 tunneling
- Intrasite Automatic Tunnel Addressing Protocol
- Temporary addresses
- Site prefixes in router advertisements
- DNS support
- IPSec support
- Application support
- RPC support
- Static router support
- Command-line tool support
- 6over4 tunneling

**6to4 tunneling**

6to4 is a tunneling technique that is described in RFC 3056. 6to4 hosts do not require any manual configuration and create 6to4 addresses by using standard autoconfiguration. 6to4 uses the global address prefix of 2002:*WWXX*:*YYZZ*::/48, where *WWXX*:*YYZZ* is the colon-hexadecimal representation of a public IPv4 address (*w.x.y.z*) that is assigned to a site or host. WWXX:YYZZ is the Next Level Aggregator (NLA) portion of a 6to4 address.

6to4 allows IPv6-enabled sites and hosts to communicate by using unicast IPv6 the Internet. IPv6 sites and hosts can use their 6to4 address prefix and the Internet to communicate without obtaining an IPv6 global address prefix from an Internet service provider and connecting to the IPv6 Internet.

For more information, see IPv6 traffic between nodes in different sites across the Internet (6to4).

**Intrasite Automatic Tunnel Addressing Protocol**

Intrasite Automatic Tunnel Addressing Protocol (ISATAP) is an address assignment and tunneling mechanism for communication between IPv6/IPv4 nodes within an IPv4 site. It is described in the Internet draft titled "Intra-Site Automatic Tunnel Addressing Protocol (ISATAP)" (draft-ietf-ngtrans-isatap-0*x*.txt). For more information, see IPv6 traffic between nodes on different subnets of an IPv4 internetwork.

**Temporary addresses**

To provide a level of anonymity when accessing Internet resources, the 64-bit interface identifier of a global IPv6 address is derived by using random numbers to create a temporary global address.

For more information, see IPv6 interface identifiers.

**Site prefixes in router advertisements**

Published on-link prefixes can be configured with a site prefix length, as described in the Internet draft titled "Site prefixes in Neighbor Discovery" (draft-ietf-ipngwg-site-prefixes-0*x*.txt). You can use the **netsh interface ipv6 add route** command to include a site prefix length with the address prefix. For more information, see Netsh commands for Interface IPv6.

When a prefix information option that specifies a site prefix is received, an entry is created in the site prefix table. You can view this table by using the **netsh interface ipv6 show siteprefixes** command. The site prefix table is used to remove inappropriate site-local addresses from those that are returned by the **getaddrinfo()** Windows sockets function.

**DNS support**
Processing for Domain Name System (DNS) IPv6 host records (known as AAAA or quad-A resource records), as defined in RFC 1886, "DNS Extensions to support IP version 6," is supported by the DNS resolver (client) in Microsoft® Windows® XP and the Windows Server 2003 family, and DNS Server service in the Windows Server 2003 family and Windows 2000. All DNS traffic is sent over IPv4 or IPv6.

For more information, see IPv6 Name resolution.

**IPSec support**
Processing for the Authentication Header (AH) using the Message Digest 5 (MD5) hash, and the Encapsulating Security Payload (ESP) using the NULL ESP header and the MD5 hash, is supported. There is no support for ESP data encryption.

### Caution

- This implementation of IPSec for IPv6 is not recommended for use in a production environment because it relies on static keying and has no provisions for updating keys upon sequence number reuse.

For an example configuration, see Using IPSec between two local link hosts.

**Application support**
Applications and components that are provided with the Windows Server 2003 family and support the use of IPv6 include:

- Distributed Component Object Model (DCOM)
- Distributed File System (DFS)
- Domain Name System (DNS) server and client
- File and print sharing
- File Transfer Protocol (FTP) client
- Internet Explorer
- Microsoft .NET Framework
- Network Monitor
- Telnet Server and Telnet Client
- Windows Media Services
- Windows Sockets

For more information, see IPv6 applications.

**RPC support**
Remote Procedure Call (RPC) functions, which are used to forward application function calls to a remote system across the network, can be used over IPv6. A typical use for RPC is remote administration.

**Static router support**
A computer running a member of the Windows Server 2003 family can act as a static IPv6 router that forwards IPv6 packets between interfaces based on the contents of the IPv6 routing table. You can configure static routes with the **netsh interface ipv6 add route** command. There is currently no support for IPv6 routing protocols.

A computer running a member of the Windows Server 2003 family can send router advertisements. The contents of router advertisements are automatically derived from the published routes in the routing table. Nonpublished routes are used for

routing but are not sent in router advertisements. Router advertisements always contain a source link-layer address option and an MTU option. The value for the MTU option is taken from the sending interface's current link MTU. You can change this value with the following Netsh command:

**netsh interface ipv6 set interface** [**interface=**]*String* [[**mtu=**]*Integer*]

A computer running a member of the Windows Server 2003 family will only advertise itself as a default router (by using a router advertisement with a router lifetime other than zero) if there is a default route that is configured to be published.

For more information and examples, see Netsh commands for Interface IPv6, IPv6 traffic between nodes on different subnets of an IPv6 internetwork, and IPv6 test lab tasks.

**Command-line tool support**

The following command-line tools are provided with the Windows Server 2003 family and support the use and configuration of IPv6:

- Netsh commands for Interface IPv6
- Netsh commands for Interface Portproxy
- Ipconfig
- Pathping
- Ping
- Route
- Tracert
- Netstat

The Netstat command-line tool provided with the Windows Server 2003 family and Windows XP includes support for IPv6-related statistics. There are four categories of statistics:

1. IPv6 statistics
2. ICMPv6 statistics
3. TCP connections over IPv6 statistics
4. UDP traffic over IPv6 statistics

**6over4 tunneling**

6over4, also known as IPv4 multicast tunneling, is a tunneling technique that is described in RFC 2529. 6over4 allows IPv6 and IPv4 nodes to communicate by using IPv6 over an IPv4 infrastructure. 6over4 uses the IPv4 infrastructure as a multicast-capable link. In order for 6over4 to work correctly, the IPv4 infrastructure must be IPv4 multicast-enabled.

For more information about configuring a 6over4 interface, see the command **add 6over4tunnel** in Netsh commands for Interface IPv6.

# Security features for IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security features for IPv6**

The IPv6 protocol for Microsoft® Windows Server 2003 family incorporates Internet Protocol security (IPSec), which provides protection of IPv6 data as it is sent over the network. IPSec is a set of Internet standards that uses cryptographic security services to provide the following:

- Confidentiality

  IPSec traffic is encrypted. Captured IPSec traffic cannot be deciphered without the encryption key.

- Authentication

  IPSec traffic is digitally signed with the shared encryption key so that the receiver can verify that it was sent by the IPSec peer.

- Data integrity

  IPSec traffic contains a cryptographic checksum that incorporates the encryption key. The receiver can verify that the packet was not modified in transit.

For an example of configuring IPSec for IPv6, see Using IPSec between two local link hosts.

The IPv6 protocol for Windows Server 2003 family also provides support for temporary addresses. Temporary addresses provide a level of anonymity when accessing Internet resources. For more information about temporary addresses, see the section "Temporary address interface identifiers" in IPv6 interface identifiers.

**Caution**

- This implementation of IPSec for IPv6 is not recommended for use in a production environment because it relies on static keying and has no provisions for updating keys upon sequence number reuse.

**Notes**

- IPSec in IPv6 is separate from and not interoperable with IPSec for the TCP/IP protocol. IPSec policies that are configured with the IP Security Policies or Group Policy snap-ins have no effect on IPv6 traffic. For more information about IPSec for the TCP/IP protocol, see Internet Protocol Security (IPSec).

- IPSec in the IPv6 protocol for Windows Server 2003 family does not support the use of data encryption for data confidentiality.

- IPSec in the IPv6 protocol for Windows Server 2003 family does not support the use of Internet Key Exchange (IKE) to negotiate security associations (SAs). IPSec policies, SAs, and keys must be manually configured.

# Understanding IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding IPv6**
This section covers:

- IPv6 Name resolution
- Core Protocols of IPv6
- IPv6 Addressing and Routing
- IPv6 and Network Applications

# IPv6 Name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Name resolution**

While IPv6 is designed to work with the 128-bit IPv6 addresses of the source and the destination hosts, computer users are likely to experience difficulty in using and remembering the IPv6 addresses of the computers with which they want to communicate. Unique names, which are easier to remember, can be used instead.

If a name is used as an alias for an IPv6 address, you need to ensure that the name is unique and that it resolves to the correct IPv6 address. The IPv6 protocol for the Windows Server 2003 family can use host names to resolve a name to an IPv6 address. Host names are used by programs that use Windows Sockets.

Host name resolution is successfully mapping a host name to an IPv6 address. A host name is an alias that is assigned to an IPv6 node, identifying it as an IPv6 host. The host name can be up to 255 characters long and can contain alphabetic and numeric characters, hyphens, and periods. You can assign multiple host names to the same host.

Windows Sockets (Winsock) programs can use one of two values for the destination to which you want to connect: the IPv6 address or a host name. When the IPv6 address is specified, name resolution is not required. When a host name is specified, the host name must be resolved to an IPv6 address before IPv6-based communication with a resource can begin.

Host names can take various forms. The two most common forms are a nickname and a domain name. A nickname is an alias for an IPv6 address that individuals can assign and use. A domain name is a structured name in a hierarchical namespace named Domain Name System (DNS). An example of a domain name is www.microsoft.com.

Nicknames or domain names are resolved through entries in the Hosts file, which is stored in the *systemroot*\System32\Drivers\Etc folder. For IPv6 name-to-address entries, the IPv6 address is written by using standard colon-hexadecimal format. For more information, see Expressing IPv6 addresses and TCP/IP database files.

Domain names are resolved by sending DNS name queries to a configured DNS server, which is a computer that either stores domain name-to-IPv6 address mapping records or has records of other DNS servers. The DNS server resolves the queried domain name to an IPv6 address and returns the results. The DNS client in Windows XP and the Windows Server 2003 family supports the processing of AAAA (quad-A) resource records. All DNS queries and responses are sent by using IPv6 and IPv4. DNS name devolution for fully qualified domain names is also supported. For more information, see DNS defined.

# Core Protocols of IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Core protocols of IPv6**
This section covers:

- Internet Protocol version 6 (IPv6)
- Internet Control Message Protocol for IPv6 (ICMPv6)
- Multicast Listener Discovery (MLD)
- Neighbor Discovery (ND)

# Internet Protocol version 6 (IPv6)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Protocol version 6 (IPv6)**
IPv6 is defined in RFC 2460, "Internet Protocol, Version 6 (IPv6) Specification." IPv6 is a connectionless, unreliable datagram protocol used primarily for addressing and routing packets between hosts.

Connectionless means that a session is not established before exchanging data. Unreliable means that delivery is not guaranteed. IPv6 always makes a best-effort attempt to deliver a packet. An IPv6 packet might be lost, delivered out of sequence, duplicated, or delayed. IPv6 does not attempt to recover from these types of errors. The acknowledgment of packets delivered and the recovery of lost packets are done by a higher-layer protocol, such as TCP.

An IPv6 packet, also known as an IPv6 datagram, consists of an IPv6 header and an IPv6 payload, as shown in the following illustration.

The IPv6 header contains the following fields for addressing and routing.

| IPv6 header field | Function |
|---|---|
| Source Address | The IPv6 address of the original source of the IPv6 packet. |
| Destination Address | The IPv6 address of the intermediate or final destination of the IPv6 packet. |
| Hop Limit | The number of network segments on which the packet is allowed to travel before being discarded by a router. The Hop Limit is set by the sending host and is used to prevent packets from endlessly circulating on an IPv6 internetwork. When forwarding an IPv6 packet, IPv6 routers are required to decrease the Hop Limit by 1 and to discard the IPv6 packet when the Hop Limit is 0. |

**Note**

- IPv6 is a rapidly evolving standard. The RFCs referenced might have been made obsolete by newer RFCs.

# Internet Control Message Protocol for IPv6 (ICMPv6)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Control Message Protocol for IPv6 (ICMPv6)**
Internet Control Message Protocol for IPv6 (ICMPv6) is a required IPv6 standard defined in RFC 2463, "Internet Control Message Protocol (ICMPv6) for the Internet Protocol Version 6 (IPv6) Specification." With ICMPv6, hosts and routers that use IPv6 communication can report errors and send simple echo messages.

The ICMPv6 protocol also provides a framework for the following:

- Multicast Listener Discovery (MLD)

  MLD is a series of three ICMPv6 messages that replace version 2 of the Internet Group Management Protocol (IGMP) for IPv4 to manage subnet multicast membership. For more information, see Multicast Listener Discovery (MLD).

- Neighbor Discovery (ND)

  Neighbor Discovery is a series of five ICMPv6 messages that manage node-to-node communication on a link. Neighbor Discovery replaces Address Resolution Protocol (ARP), ICMPv4 Router Discovery, and the ICMPv4 Redirect message and provides additional functions. For more information, see Neighbor Discovery (ND).

ICMPv6 messages are usually sent automatically when an IPv6 packet cannot reach its destination.

ICMPv6 messages are encapsulated and sent as the payload of IPv6 packets, as shown in the following illustration.

Different types of ICMPv6 messages are identified in the ICMPv6 header. Because ICMPv6 messages are carried in IPv6 packets, they are unreliable.

ICMPv6 messages that are not related to MLD or ND are listed and described in the following table.

| ICMPv6 message | Description |
|---|---|
| Destination Unreachable | An error message that informs the sending host that a packet cannot be delivered. |
| Packet Too Big | An error message that informs the sending host that the packet is too large to forward. |
| Time Exceeded | An error message that informs the sending host that the Hop Limit of an IPv6 packet has expired. |
| Parameter Problem | An error message that informs the sending host that an error was encountered in processing the IPv6 header or an IPv6 extension header. |
| Echo Request | An informational message that is used to determine whether an IPv6 node is available on the network. |
| Echo Reply | An informational message that is used to reply to the ICMPv6 Echo Request message. |

You can use the **ping** command to send ICMPv6 Echo Request messages and record the receipt of ICMPv6 Echo Reply messages. With ping, you can detect network or host communication failures and troubleshoot common IPv6 connectivity problems. For more information, see Test IPv6 connectivity by using the ping command.

You can use the **tracert** command to send ICMPv6 Echo Request messages with incrementally increasing values in the Hop Limit field. Tracert will trace and display the path taken by IPv6 packets between a source and destination, allowing you to

troubleshoot common IPv6 routing problems. For more information, see Trace an IPv6 path by using the tracert command.

**Note**

- IPv6 is a rapidly evolving standard. The RFCs referenced might have been made obsolete by newer RFCs.

# Multicast Listener Discovery (MLD)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast Listener Discovery (MLD)**
The use of multicasting in IP networks is defined as a TCP/IP standard in RFC 1112, "Internet Group Management Protocol (IGMP)." This RFC defines address and host extensions for the way in which IP hosts support multicasting. The same concepts originally developed for the current version of IP, known as IP version 4 (IPv4), also apply to IPv6.

**What is multicasting?**
Multicast traffic is sent to a single address but is processed by multiple hosts. Multicasting is similar to a newsletter subscription. As only subscribers receive the newsletter when it is published, only host computers that belong to the multicast group receive and process traffic sent to the group's reserved address. The set of hosts listening on a specific multicast address is called a multicast group.

Other important aspects of multicasting include the following:

- Group membership is dynamic, allowing hosts to join and leave the group at any time.
- The joining of multicast groups is performed through the sending of group membership messages. In IPv6, Multicast Listener Discovery (MLD) messages are used to determine group membership on a network segment, also known as a link or subnet.
- Groups are not limited by size and members can be spread out across multiple network segments (if connecting routers support the forwarding of multicast traffic and group membership information).
- A host can send traffic to the group's address without belonging to the corresponding group.

**IPv6 multicast addressing**
IPv6 multicast addresses are reserved and assigned from the Format Prefix 1111 1111 (0xFF). The following table is a partial list of IPv6 multicast addresses that are reserved for IPv6 multicasting and registered with the Internet Assigned Numbers Authority (IANA).

| IPv6 multicast address | Description |
|---|---|
| FF02::1 | The all-nodes address used to reach all nodes on the same link. |
| FF02::2 | The all-routers address used to reach all routers on the same link. |
| FF02::4 | The all-Distance Vector Multicast Routing Protocol (DVMRP) routers address used to reach all DVMRP multicast routers on the same link. |
| FF02::5 | The all-Open Shortest Path First (OSPF) routers address used to reach all OSPF routers on the same link. |
| FF02::6 | The all-OSPF designated routers address used to reach all OSPF designated routers on the same link. |
| FF02::1:FF*XX:XXXX* | The solicited-node address used in the address resolution process to resolve the IPv6 address of a link-local node to its link-layer address. The last 24 bits (*XX:XXXX*) of the solicited-node address are the last 24 bits of an IPv6 unicast address. |

For a full and current listing of additional IPv6 addresses that are reserved for multicasting, see the Information Sciences Institute Web site document: Internet Protocol Version 6 Multicast Addresses.

A single IPv6 multicast address identifies each multicast group. Each group's reserved IPv6 address is shared by all host members of the group who listen and receive any IPv6 messages sent to the group's address.

IPv6 multicast addresses are mapped to a reserved set of media access control (MAC) multicast addresses. For information about the mapping of IPv6 multicast addresses to Ethernet MAC addresses, see RFC 2464, "Transmission of IPv6 Packets over Ethernet Networks."

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

**MLD messages**

MLD is used to exchange membership status information between IPv6 routers that support multicasting and members of multicast groups on a network segment. Host membership in a multicast group is reported by individual member hosts, and membership status is periodically polled by multicast routers. MLD is defined in RFC 2710, "Multicast Listener Discovery (MLD) for IPv6."

MLD message types are described in the following table.

| MLD message type | Description |
|---|---|
| Multicast Listener Query | Sent by a multicast router to poll a network segment for group members. Queries can be general (requesting group membership for all groups), or specific (requesting group membership for a specific group). |
| Multicast Listener Report | Sent by a host when it joins a multicast group, or in response to an MLD Multicast Listener Query sent by a router. |
| Multicast Listener Done | Sent by a host when it leaves a host group and might be the last member of that group on the network segment. |

MLD messages are sent as ICMPv6 messages.

**Note**

- IPv6 is a rapidly evolving standard. The RFCs referenced might have been made obsolete by newer RFCs.

# Neighbor Discovery (ND)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Neighbor Discovery (ND)**
IPv6 Neighbor Discovery (ND) is a set of messages and processes that determine relationships between neighboring nodes. ND replaces Address Resolution Protocol (ARP), Internet Control Message Protocol (ICMP) Router Discovery, and ICMP Redirect, which are used in IPv4, and provides additional functionality. ND is described in RFC 2461, "Neighbor Discovery for IP Version 6 (IPv6)."

ND is used by hosts to:

- Discover neighboring routers.
- Discover addresses, address prefixes, and other configuration parameters.

ND is used by routers to:

- Advertise their presence, host configuration parameters, and on-link prefixes.
- Inform hosts of a better next-hop address to forward packets for a specific destination.

ND is used by nodes to:

- Both resolve the link-layer address of a neighboring node to which an IPv6 packet is being forwarded and determine when the link-layer address of a neighboring node has changed.
- Determine whether IPv6 packets can be sent to and received from a neighbor.

The following table lists and describes ND processes.

| Process | Description |
|---|---|
| Router discovery | The process by which a host discovers the local routers on an attached link (equivalent to ICMPv4 Router Discovery) and automatically configures a default router (equivalent to a default gateway in IPv4). |
| Prefix discovery | The process by which a host discovers the network prefixes for local destinations. |
| Parameter discovery | The process by which a host discovers additional operating parameters, including the link maximum transmission unit (MTU) and the default hop limit for outbound packets. |
| Address autoconfiguration | The process for configuring IP addresses for interfaces in either the presence or absence of a stateful address configuration server such as Dynamic Host Configuration Protocol version 6 (DHCPv6). For more information, see IPv6 address autoconfiguration. |
| Address resolution | The process by which a node resolves a neighboring node's IPv6 address to its link-layer address (equivalent to ARP in IPv4). The resolved link-layer address becomes an entry in a node's neighbor cache (equivalent to the ARP cache in IPv4). You can use the **netsh interface ipv6 show neighbors** command to view the contents of the neighbor cache on a computer running the Windows Server 2003 family and Windows XP. The neighbor cache displays the interface identifier for the neighbor cache entry, the neighboring node's IPv6 address, the corresponding link-layer address, and the state of the neighbor cache entry. For more information, see View the neighbor cache and Netsh commands for Interface IPv6. |

| | |
|---|---|
| Next-hop determination | The process by which a node determines the IPv6 address of the neighbor to which a packet is being forwarded based on the destination address. The forwarding or next-hop address is either the destination address of the packet being sent or the address of a neighboring router. The resolved next hop address for a destination becomes an entry in a node's destination cache (also known as a route cache). You can use the **netsh interface ipv6 show destinationcache** command to view the contents of the destination cache on a computer running the Windows Server 2003 family and Windows XP. The destination cache displays the destination address, the interface identifier and next-hop address, the interface identifier and address used as a source address when sending to the destination, and the path MTU for the destination. For more information, see View the destination cache and Netsh commands for Interface IPv6. |
| Neighbor unreachability detection | The process by which a node determines that IPv6 packets cannot be sent to and received from a neighboring node. After the link-layer address for a neighbor has been determined, the state of the entry in the neighbor cache is tracked. If the neighbor is no longer receiving and sending back packets, the neighbor cache entry is eventually removed. Neighbor unreachability detection provides a mechanism for IPv6 to determine that neighboring hosts or routers are no longer available on the local network segment. |
| Duplicate address detection | The process by which a node determines that an address considered for use is not already in use by a neighboring node (equivalent to the use of gratuitous ARP frames in IPv4). |
| Redirect function | The process by which a router informs a host of a better first-hop IPv6 address to reach a destination (equivalent to the function of the IPv4 ICMP Redirect message). |

**Note**

- IPv6 is a rapidly evolving standard. The RFCs referenced might have been made obsolete by newer RFCs.

# IPv6 Addressing and Routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 addressing and routing**
This section covers:

- IPv6 address autoconfiguration
- IPv6 routing
- The IPv6 routing table
- IPv6 Addressing

# IPv6 address autoconfiguration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 address autoconfiguration**
A highly useful aspect of IPv6 is its ability to automatically configure itself without the use of a stateful configuration protocol, such as Dynamic Host Configuration Protocol for IPv6 (DHCPv6). By default, an IPv6 host can configure a link-local address for each interface. By using router discovery, a host can also determine the addresses of routers, additional addresses, and other configuration parameters. Included in the Router Advertisement message is an indication of whether a stateful address configuration protocol should be used.

Address autoconfiguration can only be performed on multicast-capable interfaces. Address autoconfiguration is described in RFC 2462, "IPv6 Stateless Address Autoconfiguration."

**Autoconfigured address states**
Autoconfigured addresses are in one or more of the following states:

- Tentative

  The address is in the process of being verified as unique. Verification occurs through duplicate address detection.

- Preferred

  An address for which uniqueness has been verified. A node can send and receive unicast traffic to and from a preferred address. The period of time that an address can remain in the tentative and preferred states is included in the Router Advertisement message.

- Deprecated

  An address that is still valid, but its use is discouraged for new communication. Existing communication sessions can continue to use a deprecated address. A node can send and receive unicast traffic to and from a deprecated address.

- Valid

  An address from which unicast traffic can be sent and received. The valid state covers both the preferred and deprecated states. The amount of time that an address remains in the tentative and valid states is included in the Router Advertisement message. The valid lifetime must be greater than or equal to the preferred lifetime.

- Invalid

  An address for which a node can no longer send or receive unicast traffic. An address enters the invalid state after the valid lifetime expires.

The relationship between the states of an autoconfigured address and the preferred and valid lifetimes is shown in the following illustration.

**Note**

- With the exception of link-local addresses, address autoconfiguration is only specified for hosts. Routers must obtain address and configuration parameters through another means (for example, manual configuration).

**Types of autoconfiguration**
There are three types of autoconfiguration:

1. Stateless

   Configuration of addresses is based on the receipt of Router Advertisement messages. These messages include stateless address prefixes and require that hosts not use a stateful address configuration protocol.

2. Stateful

   Configuration is based on the use of a stateful address configuration protocol, such as DHCPv6, to obtain addresses and other configuration options. A host uses stateful address configuration when it receives Router Advertisement messages that do not include address prefixes and require that the host use a stateful address configuration protocol. A host will also use a stateful address configuration protocol when there are no routers present on the local link.

3. Both

   Configuration is based on receipt of Router Advertisement messages. These messages include stateless address prefixes and require that hosts use a stateful address configuration protocol.

For all autoconfiguration types, a link-local address is always configured.

**Autoconfiguration process**
The address autoconfiguration process for an IPv6 node occurs as follows:

1. A tentative link-local address is derived, based on the link-local prefix of FE80::/64 and the 64-bit interface identifier.

2. Duplicate address detection is performed to verify the uniqueness of the tentative link-local address.

3. If duplicate address detection fails, manual configuration must be performed on the node.

4. If duplicate address detection succeeds, the tentative link-local address is assumed to be unique and valid. The link-local address is initialized for the interface. The corresponding solicited-node multicast link-layer address is registered with the network adapter.

For an IPv6 host, address autoconfiguration continues as follows:

1. The host sends a Router Solicitation message.

2. If no Router Advertisement messages are received, then the host uses a stateful address configuration protocol to obtain addresses and other configuration parameters. The IPv6 protocol for the Windows Server 2003 family and Windows XP does not support the use of a stateful address configuration protocol.

3. If a Router Advertisement message is received, the configuration information that is included in the message is set on the host.

4. For each stateless autoconfiguration address prefix that is included:

   - The address prefix and the appropriate 64-bit interface identifier are used to derive a tentative address.

   - Duplicate address detection is used to verify the uniqueness of the tentative address.

If the tentative address is in use, the address is not initialized for the interface.

If the tentative address is not in use, the address is initialized. This includes setting the valid and preferred lifetimes based on

information included in the Router Advertisement message.

1. If it is specified in the Router Advertisement message, the host uses a stateful address configuration protocol to obtain additional addresses or configuration parameters.

**Notes**

- IPv6 is a rapidly evolving standard. The RFCs referenced might have been made obsolete by newer RFCs.

- Standards for stateful address configuration for IPv6 are in development. The IPv6 protocol for the Windows Server 2003 family and Windows XP does not support stateful address configuration or the DHCPv6 protocol.

# IPv6 routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 routing**

Routing is the process of forwarding packets between connected network segments. For IPv6-based networks, routing is the part of IPv6 that provides forwarding capabilities between hosts that are located on separate segments within a larger IPv6-based network.

IPv6 is the mailroom in which IPv6 data sorting and delivery occur. Each incoming or outgoing packet is called an IPv6 packet. An IPv6 packet contains both the source address of the sending host and the destination address of the receiving host. Unlike link-layer addresses, IPv6 addresses in the IPv6 header typically remain the same as the packet travels across an IPv6 network.

Routing is the primary function of IPv6. IPv6 packets are exchanged and processed on each host by using IPv6 at the Internet layer.

Above the IPv6 layer, transport services on the source host pass data in the form of TCP segments or UDP messages down to the IPv6 layer. The IPv6 layer creates IPv6 packets with source and destination address information that is used to route the data through the network. The IPv6 layer then passes packets down to the link layer, where IPv6 packets are converted into frames for transmission over network-specific media on a physical network. This process occurs in reverse order on the destination host.

IPv6 layer services on each sending host examine the destination address of each packet, compare this address to a locally maintained routing table, and then determine what additional forwarding is required. IPv6 routers are attached to two or more IPv6 network segments that are enabled to forward packets between them.

**IPv6 routers**

IPv6 network segments, also known as links or subnets, are connected by IPv6 routers, which are devices that pass IPv6 packets from one network segment to another. This process is known as IPv6 routing and is shown in the following illustration.

IPv6 routers provide the primary means for joining together two or more physically separated IPv6 network segments. All IPv6 routers have the following characteristics:

- IPv6 routers are physically multihomed hosts.

  A physically multihomed host is a network host that uses two or more network connection interfaces to connect to each physically separated network segment.

- IPv6 routers provide packet forwarding for other IPv6 hosts.

  IPv6 routers are distinct from other hosts that use multihoming. An IPv6 router must be able to forward IPv6-based communication between networks for other IPv6 network hosts.

You can implement IPv6 routers by using a variety of hardware and software products, including a computer running a member of the Windows Server 2003 family with the IPv6 protocol. Routers that are dedicated hardware devices running specialized software are common. Regardless of the type of IPv6 routers that you use, all IPv6 routing relies on a routing table to communicate between network segments.

**Routing tables**

IPv6 hosts use a routing table to maintain information about other IPv6 networks and IPv6 hosts. Network segments are identified by using an IPv6 network prefix and prefix length. In addition, routing tables provide important information for each

local host regarding how to communicate with remote networks and hosts.

For each computer on an IPv6 network, you can maintain a routing table with an entry for every other computer or network that communicates with that local computer. In general, this is not practical, and a default router is used instead.

Before a computer sends an IPv6 packet, it inserts its source IPv6 address and the destination IPv6 address (for the recipient) into the IPv6 header. The computer then examines the destination IPv6 address, compares it to a locally maintained IPv6 routing table, and takes appropriate action. The computer does one of three things:

- It passes the packet to a protocol layer above IPv6 on the local host.
- It forwards the packet through one of its attached network interfaces.
- It discards the packet.

IPv6 searches the routing table for the route that is the closest match to the destination IPv6 address. The most specific to the least specific route is determined in the following order:

1. A route that matches the destination IPv6 address (a host route with a 128-bit prefix length).
2. A route that matches the destination with the longest prefix length.
3. The default route (the network prefix ::/0).

If a matching route is not found, the destination is determined to be an on-link destination.

For more information, see The IPv6 routing table.

# The IPv6 routing table

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The IPv6 routing table**

Every computer that runs IPv6 determines how to forward packets based on the contents of the IPv6 routing table. To display the IPv6 routing table on a computer that is running a member of the Windows Server 2003 family or Windows XP, type **netsh interface ipv6 show routes** at the Command Prompt.

Entries in the IPv6 routing table consist of:

- An address prefix
- The interface over which packets matching the address prefix are sent
- A forwarding or next-hop address
- A preference value used to select between multiple routes with the same prefix
- The lifetime of the route
- The specification of whether the route is published (advertised in a Routing Advertisement)
- The specification of how the route is aged
- The route type

The IPv6 routing table is built automatically, based on the current IPv6 configuration of your computer. When forwarding IPv6 packets, the routing table is searched by your computer for an entry that is the most specific match to the destination IPv6 address. A route for the link-local prefix (FE80::/64) is not displayed.

The default route (a route with a prefix of ::/0) is typically used to forward an IPv6 packet to a default router on the local link. Because the router that corresponds to the default router contains information about the network prefixes of the other IPv6 subnets within the larger IPv6 internetwork, it forwards the packet to other routers until it is eventually delivered to the destination.

For information about managing IPv6 routes, see Managing Routes with IPv6.

# IPv6 Addressing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 addressing**
This section covers:

- IPv6 address space
- Expressing IPv6 addresses
- Unicast IPv6 addresses
- Multicast IPv6 addresses
- Anycast IPv6 addresses
- Addresses for hosts and routers
- IPv6 interface identifiers

# IPv6 address space

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 address space**

The most obvious distinguishing feature of IPv6 is its use of much larger addresses. The size of an address in IPv6 is 128 bits, which is four times larger than an address in IPv4. A 32-bit address space allows for 232 or 4,294,967,296 possible addresses. A 128-bit address space allows for 2128 or 340,282,366,920,938,463,463,374,607,431,768,211,456 (3.4 × 1038) possible addresses.

In the late 1970s when the IPv4 address space was designed, it was unimaginable that it could be exhausted. However, due to changes in technology and an allocation practice that did not anticipate the recent explosion of hosts on the Internet, the IPv4 address space was consumed to the point that by 1992, it was clear a replacement would be necessary.

With IPv6, it is even harder to conceive that the IPv6 address space will be consumed. To help put this number in perspective, a 128-bit address space provides 655,570,793,348,866,943,898,599 (6.5 × 1023) addresses for every square meter of the Earth's surface.

It is important to note that the decision to make the IPv6 address 128 bits in length was not so that every square meter of the Earth could have 6.5 x 1023 addresses. Rather, the relatively large size of the IPv6 address is designed to be subdivided into hierarchical routing domains that reflect the topology of the modern-day Internet. The use of 128 bits provides multiple levels of hierarchy and flexibility in designing hierarchical addressing and routing that is currently lacking on the IPv4-based Internet.

The architecture of IPv6 addressing is described in RFC 2373, "IP Version 6 Addressing Architecture."

**Current allocation**

Similar to the way in which the IPv4 address space is divided, the IPv6 address space is divided based on the value of high order bits in the address. The high order bits and their fixed values are known as a Format Prefix (FP).

The following table shows the allocation of the IPv6 address space by FPs.

| Allocation | Format Prefix (FP) | Fraction of the address space |
|---|---|---|
| Reserved | 0000 0000 | 1/256 |
| Reserved for NSAP allocation | 0000 001 | 1/128 |
| Aggregatable global unicast addresses | 001 | 1/8 |
| Link-local unicast addresses | 1111 1110 10 | 1/1024 |
| Site-local unicast addresses | 1111 1110 11 | 1/1024 |
| Multicast addresses | 1111 1111 | 1/256 |

The remainder of the IPv6 address space is unassigned.

The current set of unicast addresses that can be used with IPv6 nodes consists of aggregatable global unicast addresses, link-local unicast addresses, and site-local unicast addresses. These represent only 15 percent of the entire IPv6 address space. For more information, see Unicast IPv6 addresses.

**Note**

- IPv6 is a rapidly evolving standard. The RFCs referenced might have been made obsolete by newer RFCs.

# Expressing IPv6 addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Expressing IPv6 addresses**

IPv4 addresses are represented in dotted-decimal format. This 32-bit address is divided along 8-bit boundaries. Each set of 8 bits is converted to its decimal equivalent and separated by periods. For IPv6, the 128-bit address is divided along 16-bit boundaries, and each 16-bit block is converted to a 4-digit hexadecimal number and separated by colons. The resulting representation is called colon-hexadecimal.

The following is an IPv6 address in binary form:

```
0010000111011010000000011010011000000000000000000010111100111011
0000001010101010000000001111111111111110001010001001110001011010
```

The 128-bit address is divided along 16-bit boundaries, as follows:

```
0010000111011010   0000000011010011   0000000000000000   0010111100111011
0000001010101010   0000000011111111   1111111000101000   1001110001011010
```

Each 16-bit block is converted to hexadecimal and delimited with colons. The result is:

```
21DA:00D3:0000:2F3B:02AA:00FF:FE28:9C5A
```

IPv6 representation can be further simplified by removing the leading zeros within each 16-bit block. However, each block must have at least a single digit. With leading zero suppression, the address representation becomes:

```
21DA:D3:0:2F3B:2AA:FF:FE28:9C5A
```

**Compressing zeros**

Some types of addresses contain long sequences of zeros. To further simplify the representation of IPv6 addresses, a contiguous sequence of 16-bit blocks set to 0 in the colon-hexadecimal format can be compressed to :: (known as double-colon).

For example, the link-local address of FE80:0:0:0:2AA:FF:FE9A:4CA2 can be compressed to FE80::2AA:FF:FE9A:4CA2. The multicast address of FF02:0:0:0:0:0:0:2 can be compressed to FF02::2. Zero compression can only be used to compress a single contiguous series of 16-bit blocks expressed in colon-hexadecimal notation. You cannot use zero compression to include part of a 16-bit block. For example, you cannot express FF02:30:0:0:0:0:0:5 as FF02:3::5.

To determine how many 0 bits are represented by the ::, you can count the number of blocks in the compressed address, subtract this number from 8, and then multiply the result by 16. For example, in the address FF02::2, there are two blocks (the FF02 block and the 2 block). The number of bits expressed by the :: is 96 (96 = (8 - 2) × 16).

Zero compression can only be used once in a given address. Otherwise, you could not determine the number of 0 bits represented by each instance of a double-colon (::).

**IPv6 prefixes**

The prefix is the part of the address that indicates the bits that have fixed values or are the bits of the network identifier. Prefixes for IPv6 routes and subnet identifiers are expressed in the same way as Classless Inter-Domain Routing (CIDR) notation for IPv4. An IPv6 prefix is written in *address/prefix-length* notation. For example, 21DA:D3::/48 is a route prefix and 21DA:D3:0:2F3B::/64 is a subnet prefix.

### Note

- IPv4 implementations commonly use a dotted decimal representation of the network prefix known as the subnet mask. A subnet mask is not used in IPv6. Only prefix-length notation is supported.

# Unicast IPv6 addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unicast IPv6 addresses**
A unicast address identifies a single interface within the scope of the type of unicast address. With the appropriate unicast routing topology, packets addressed to a unicast address are delivered to a single interface. The following types of addresses are unicast IPv6 addresses:

- Aggregatable global unicast addresses
- Link-local addresses
- Site-local addresses
- Special addresses
- Compatibility addresses
- NSAP addresses

**Aggregatable global unicast addresses**
Aggregatable global unicast addresses, identified by the Format Prefix (FP) of 001, are equivalent to public IPv4 addresses. They are globally routable and reachable on the IPv6 Internet. Aggregatable global unicast addresses are also known as global addresses.

As the name implies, aggregatable global unicast addresses are designed to be aggregated or summarized to produce an efficient routing infrastructure. Unlike the current IPv4-based Internet, which has a mixture of both flat and hierarchical routing, the IPv6-based Internet has been designed from its foundation to support efficient, hierarchical addressing and routing. The scope, the region of the IPv6 internetwork over which the address is unique, of an aggregatable global unicast address is the entire IPv6 Internet.

The fields in the aggregatable global unicast address are described as follows:

- TLA ID

  The TLA ID field indicates the Top Level Aggregation Identifier (TLA ID) for the address. The size of this field is 13 bits. The TLA identifies the highest level in the routing hierarchy. TLAs are administered by IANA and allocated to local Internet registries that, in turn, allocate individual TLA IDs to large, global Internet service providers (ISPs). A 13-bit field allows up to 8,192 different TLA IDs. Routers in the highest level of the IPv6 Internet routing hierarchy (called default-free routers) do not have a default route--only routes with 16-bit prefixes that correspond to the allocated TLAs.

- Res

  The Res field is reserved for future use in expanding the size of either the TLA ID or the NLA ID. The size of this field is 8 bits.

- NLA ID

  The NLA ID field indicates the Next Level Aggregation Identifier (NLA ) for the address. The NLA ID is used to identify a specific customer site. The size of this field is 24 bits. The NLA ID allows an ISP to create multiple levels of addressing hierarchy to organize addressing and routing and to identify sites. The structure of the ISP's network is not visible to the default-free routers.

- SLA ID

  The SLA ID field indicates the Site Level Aggregation Identifier (SLA ID) for the address. The SLA ID is used by an individual organization to identify subnets within its site. The size of this field is 16 bits. The organization can use these 16 bits within its site to create 65,536 subnets or multiple levels of addressing hierarchy and an efficient routing infrastructure. With 16 bits of subnetting flexibility, an aggregatable global unicast prefix assigned to an organization is equivalent to that organization being allocated an IPv4 Class A network ID (assuming that the last octet is used for identifying nodes on subnets). The structure of the customer's network is not visible to the ISP.

- Interface ID

  The Interface ID field indicates the interface of a node on a specific subnet. The size of this field is 64 bits.

The following illustration shows how the fields within the aggregatable global unicast address create a three-level topological structure.

The public topology is the collection of larger and smaller ISPs that provide access to the IPv6 Internet. The site topology is the collection of subnets within an organization's site. The interface identifier identifies a specific interface on a subnet within an organization's site. For more information about aggregatable global unicast addresses, see RFC 2374, "An IPv6 Aggregatable Global Unicast Address Format."

**Local-use unicast addresses**

There are two types of local-use unicast addresses:

1. Link-local addresses, which are used between on-link neighbors and for Neighbor Discovery processes.

2. Site-local addresses, which are used between nodes that communicate with other nodes in the same site.

**Link-local addresses**

Link-local addresses, identified by the FP of 1111 1110 10, are used by nodes when communicating with neighboring nodes on the same link. For example, on a single link IPv6 network with no router, link-local addresses are used to communicate between hosts on the link. Link-local addresses are equivalent to Automatic Private IP Addressing (APIPA) IPv4 addresses (using the 169.254.0.0/16 prefix). The scope of a link-local address is the local link. A link-local address is required for Neighbor Discovery processes and is always automatically configured, even in the absence of all other unicast addresses. For more information about the address autoconfiguration process for link-local addresses, see IPv6 address autoconfiguration.

Link-local addresses always begin with FE80. With the 64-bit interface identifier, the prefix for link-local addresses is always FE80::/64. An IPv6 router never forwards link-local traffic beyond the link.

For information about how to use link-local addresses, see Single subnet with link-local addresses.

**Site-local addresses**

Site-local addresses, identified by the FP of 1111 1110 11, are equivalent to the IPv4 private address space (10.0.0.0/8, 172.16.0.0/12, and 192.168.0.0/16). For example, private intranets that do not have a direct, routed connection to the IPv6 Internet can use site-local addresses without conflicting with aggregatable global unicast addresses. Site-local addresses are not reachable from other sites, and routers must not forward site-local traffic outside of the site. Site-local addresses can be used in addition to aggregatable global unicast addresses. The scope of a site-local address is the site (the organization internetwork).

Unlike link-local addresses, site-local addresses are not automatically configured and must be assigned either through stateless or stateful address configuration processes. For more information, see IPv6 address autoconfiguration.

The first 48-bits are always fixed for site-local addresses, beginning with FEC0::/48. After the 48 fixed bits is a 16-bit subnet identifier (Subnet ID field) that provides 16 bits with which you can create subnets within your organization. With 16 bits, you can have up to 65,536 subnets in a flat subnet structure, or you can subdivide the high-order bits of the Subnet ID field to create a hierarchical and aggregatable routing infrastructure. After the Subnet ID field is a 64-bit Interface ID field that identifies a specific interface on a subnet.

The aggregatable global unicast address and site-local address share the same structure beyond the first 48 bits of the address. In aggregatable global unicast addresses, the SLA ID identifies the subnet within an organization. For site-local addresses, the Subnet ID performs the same function. Because of this, you can assign a specific subnet number to identify a subnet that is used for both site-local and aggregatable global unicast addresses.

**Special addresses**
The following are special IPv6 addresses:

- Unspecified address

  The unspecified address (0:0:0:0:0:0:0:0 or ::) is used only to indicate the absence of an address. It is equivalent to the IPv4 unspecified address of 0.0.0.0. The unspecified address is typically used as a source address for packets that are attempting to verify the uniqueness of a tentative address. The unspecified address is never assigned to an interface or used as a destination address.

- Loopback address

  The loopback address (0:0:0:0:0:0:0:1 or ::1) is used to identify a loopback interface, enabling a node to send packets to itself. It is equivalent to the IPv4 loopback address of 127.0.0.1. Packets addressed to the loopback address are never sent on a link or forwarded by an IPv6 router.

**Compatibility addresses**
To aid in the migration from IPv4 to IPv6 and facilitate the coexistence of both types of hosts, the following addresses are defined:

- IPv4-compatible address

  The IPv4-compatible address, 0:0:0:0:0:0:*w.x.y.z* or ::*w.x.y.z* (where *w.x.y.z* is the dotted decimal representation of a public IPv4 address), is used by dual-stack nodes that are communicating with IPv6 over an IPv4 infrastructure. Dual-stack nodes are nodes with both IPv4 and IPv6 protocols. When the IPv4-compatible address is used as an IPv6 destination, IPv6 traffic is automatically encapsulated with an IPv4 header and sent to the destination by using the IPv4 infrastructure.

- IPv4-mapped address

  The IPv4-mapped address, 0:0:0:0:0:FFFF:*w.x.y.z* or ::FFFF:*w.x.y.z*, is used to represent an IPv4-only node to an IPv6 node. It is used only for internal representation. The IPv4-mapped address is never used as a source or destination address for an IPv6 packet. The IPv6 protocol does not support the use of IPv4-mapped addresses.

- 6to4 address

  The 6to4 address is used for communicating between two nodes running both IPv4 and IPv6 over the Internet. The 6to4 address is formed by combining the prefix 2002::/16 with the 32 bits of the public IPv4 address of the node, forming a 48-bit prefix. For example, for the IPv4 address of 131.107.0.1, the 6to4 address prefix is 2002:836B:1::/48. For more information about 6to4, see IPv6 traffic between nodes in different sites across the Internet (6to4).

**NSAP addresses**
To provide a means for mapping Network Service Access Point (NSAP) addresses to IPv6 addresses, NSAP addresses use the FP of 0000001 and map the last 121 bits of the IPv6 address to an NSAP address. For more information about the four types of NSAP address mappings, see RFC 1888, "OSI NSAPs and IPv6."

### Note

- IPv6 is a rapidly evolving standard. The RFCs referenced might have been made obsolete by newer RFCs.

# Multicast IPv6 addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multicast IPv6 addresses**

A multicast address identifies multiple interfaces. With the appropriate multicast routing topology, packets addressed to a multicast address are delivered to all interfaces that are identified by the address.

IPv6 multicast addresses have the Format Prefix (FP) of 1111 1111. An IPv6 address is simple to classify as multicast because it always begins with FF. Multicast addresses cannot be used as source addresses.

Beyond the FP, multicast addresses include additional structure to identify their flags, scope, and multicast group, as shown in the following illustration.

The fields in the multicast address are as follows:

- Flags

  The Flags field indicates flags that are set on the multicast address. The size of this field is 4 bits. As of RFC 2373, the only flag defined is the Transient (T) flag. The T flag uses the low-order bit of the Flags field. When set to 0, the T flag indicates that the multicast address is a permanently-assigned (well-known) multicast address allocated by the Internet Assigned Numbers Authority (IANA). When set to 1, the T flag indicates that the multicast address is a transient (not permanently assigned) multicast address.

- Scope

  The Scope field indicates the scope of the IPv6 internetwork for which the multicast traffic is intended. The size of this field is 4 bits. In addition to information provided by multicast routing protocols, routers use the multicast scope to determine whether multicast traffic can be forwarded.

- The following scopes are defined in RFC 2373:

| Scope field value | Scope |
|---|---|
| 1 | Node-local |
| 2 | Link-local |
| 5 | Site-local |
| 8 | Organization-local |
| E | Global |

  For example, traffic with the multicast address of FF02::2 has a link-local scope. An IPv6 router never forwards this traffic beyond the local link.

- Group ID

  The Group ID field identifies the multicast group and is unique within the scope. The size of this field is 112 bits. Permanently assigned group IDs are independent of the scope. Transient group IDs are only relevant to a specific scope. Multicast addresses from FF01:: through FF0F:: are reserved, well-known addresses.

To identify all nodes for the node-local and link-local scopes, the following multicast addresses are defined:

- FF01::1 (node-local scope all-nodes address)

- FF02::1 (link-local scope all-nodes address)

To identify all routers for the node-local, link-local, and site-local scopes, the following multicast addresses are defined:

- FF01::2 (node-local scope all-routers address)
- FF02::2 (link-local scope all-routers address)
- FF05::2 (site-local scope all-routers address)

With 112 bits in the Group ID, it is possible to have 2112 group IDs. However, because of the way in which IPv6 multicast addresses are mapped to Ethernet multicast MAC addresses, RFC 2373 recommends assigning the Group ID from the low order 32 bits of the IPv6 multicast address and setting the remaining original group ID bits to 0. By using only the low-order 32 bits in the group ID, each group ID maps to a unique Ethernet multicast MAC address.

**Solicited-node address**
The solicited-node address facilitates efficient querying of network nodes during address resolution. In IPv4, the ARP Request frame is sent to the MAC-level broadcast, disturbing all nodes on the network segment, including those that are not running IPv4. IPv6 uses the Neighbor Solicitation message to perform address resolution. However, instead of using the local-link scope all-nodes address as the Neighbor Solicitation message destination, which would disturb all IPv6 nodes on the local link, the solicited-node multicast address is used. The solicited-node multicast address consists of the prefix FF02::1:FF00:0/104 and the last 24-bits of the IPv6 address that is being resolved.

For example, for the node with the link-local IPv6 address of FE80::2AA:FF:FE28:9C5A, the corresponding solicited-node address is FF02::1:FF28:9C5A. To resolve the FE80::2AA:FF:FE28:9C5A address to its link layer address, a node sends a Neighbor Solicitation message to the solicited-node address of FF02::1:FF28:9C5A. The node that is using the address of FE80::2AA:FF:FE28:9C5A is listening for multicast traffic at the solicited-node address and, for interfaces that correspond to a physical network adapter, has registered the corresponding multicast address with the network adapter.

The result of using the solicited-node multicast address is that address resolution, which commonly occurs on a link, is not required to use a mechanism that disturbs all network nodes. In fact, very few nodes are disturbed during address resolution. In practice, because of the relationship between the Ethernet MAC address, the IPv6 interface ID, and the solicited-node address, the solicited-node address acts as a pseudo-unicast address for very efficient address resolution.

# Anycast IPv6 addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Anycast IPv6 addresses**

An anycast address identifies multiple interfaces. With the appropriate routing topology, packets addressed to an anycast address are delivered to a single interface (the nearest interface that is identified by the address). The nearest interface is defined as being closest in terms of routing distance. A multicast address is used for one-to-many communication, with delivery to multiple interfaces. An anycast address is used for one-to-one-of-many communication, with delivery to a single interface.

In order to facilitate delivery to the nearest anycast group member, the routing infrastructure must be aware of the interfaces that are assigned anycast addresses and their distances in terms of routing metrics. At present, anycast addresses are used only as destination addresses and are assigned only to routers. Anycast addresses are assigned from the unicast address space. The scope of an anycast address is the scope of the type of unicast address from which the anycast address is assigned.

**Subnet-router anycast address**

The subnet-router anycast address is both predefined and required. It is created from the subnet prefix for a given interface. To construct the subnet-router anycast address, the bits in the subnet prefix are fixed at their appropriate values and the remaining bits are set to 0. All router interfaces attached to a subnet are assigned the subnet-router anycast address for that subnet. The subnet-router anycast address is used for communication with one of multiple routers attached to a remote subnet.

# Addresses for hosts and routers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Addresses for hosts and routers**

An IPv4 host with a single network adapter typically has a single IPv4 address assigned to that adapter. An IPv6 host, however, usually has multiple IPv6 addresses, even with a single interface.

An IPv6 host is assigned the following unicast addresses:

- A link-local address for each interface
- Unicast addresses for each interface (which could be a site-local address and one or multiple global addresses)
- The loopback address (::1) for the loopback interface

Typical IPv6 hosts are logically multihomed because they have at least two addresses with which they can receive packets. Each host has a link-local address for local link traffic and a routable site-local or global address.

Additionally, each host is listening for traffic on the following multicast addresses:

- The node-local scope all-nodes address (FF01::1)
- The link-local scope all-nodes address (FF02::1)
- The solicited-node address for each unicast address on each interface
- The multicast addresses of joined groups on each interface

An IPv6 router is assigned the following unicast addresses:

- A link-local address for each interface
- Unicast addresses for each interface (which might be a site-local address and one or multiple aggregatable global unicast addresses)
- The loopback address (::1) for the loopback interface

An IPv6 router is assigned the following anycast addresses:

- A subnet-router anycast address for each subnet
- Additional anycast addresses (optional)

Additionally, each router is listening for traffic on the following multicast addresses:

- The node-local scope all-nodes address (FF01::1)
- The node-local scope all-routers address (FF01::2)
- The link-local scope all-nodes address (FF02::1)
- The link-local scope all-routers address (FF02::2)
- The site-local scope all-routers address (FF05::2)

- The solicited-node address for each unicast address on each interface
- The addresses of joined groups on each interface

# IPv6 interface identifiers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 interface identifiers**

The last 64 bits of an IPv6 address are the interface identifier that is unique to the 64-bit prefix of the IPv6 address. The ways in which an interface identifier is determined are as follows:

- RFC 2373 states that all unicast addresses that use the prefixes 001 through 111 must also use a 64-bit interface identifier that is derived from the Extended Unique Identifier (EUI)-64 address.
- RFC 3041 describes a randomly-generated interface identifier that changes over time to provide a level of anonymity.
- An interface identifier that is assigned during stateful address autoconfiguration (for example, through DHCPv6). DHCPv6 standards are currently being defined. The IPv6 protocol for the Windows Server 2003 family and Windows XP does not support stateful address configuration or DHCPv6.
- An interface identifier that is manually configured.

**EUI-64 address-based interface identifiers**

The 64-bit EUI-64 address is defined by the Institute of Electrical and Electronic Engineers (IEEE). EUI-64 addresses are either assigned to a network adapter or derived from IEEE 802 addresses.

**IEEE 802 addresses**

Traditional interface identifiers for network adapters use a 48-bit address called an IEEE 802 address. This address consists of a 24-bit company ID (also called the manufacturer ID), and a 24-bit extension ID (also called the board ID). The combination of the company ID, which is uniquely assigned to each manufacturer of network adapters, and the board ID, which is uniquely assigned to each network adapter at the time of assembly, produces a globally unique 48-bit address. This 48-bit address is also called the physical, hardware, or media access control (MAC) address.

Defined bits within the IEEE 802 address are the following:

- Universal/Local (U/L)

  The U/L bit is the seventh bit of the first byte and is used to determine whether the address is universally or locally administered. If the U/L bit is set to 0, the IEEE, through the designation of a unique company ID, has administered the address. If the U/L bit is set to 1, the address is locally administered. The network administrator has overridden the manufactured address and specified a different address.

- Individual/Group (I/G)

  The I/G bit is the low order bit of the first byte and is used to determine whether the address is an individual address (unicast) or a group address (multicast). When set to 0, the address is a unicast address. When set to 1, the address is a multicast address.

For a typical 802.x network adapter address, both the U/L and I/G bits are set to 0, corresponding to a universally administered, unicast MAC address.

**IEEE EUI-64 addresses**

The IEEE EUI-64 address represents a new standard for network interface addressing. The company ID is still 24-bits in length, but the extension ID is 40 bits, creating a much larger address space for a network adapter manufacturer. The EUI-64 address uses the U/L and I/G bits in the same way as the IEEE 802 address.

**Mapping IEEE 802 addresses to EUI-64 addresses**

To create an EUI-64 address from an IEEE 802 address, the 16 bits of 11111111 11111110 (0xFFFE) are inserted into the IEEE 802 address between the company ID and the extension ID. The following illustration shows the conversion of an IEEE 802 address to an EUI-64 address.

**Mapping EUI-64 addresses to IPv6 interface identifiers**

To obtain the 64-bit interface identifier for IPv6 unicast addresses, the U/L bit in the EUI-64 address is complemented (if it is a 1, it is set to 0; and if it is a 0, it is set to 1). The following illustration shows the conversion for a universally administered, unicast EUI-64 address.

To obtain an IPv6 interface identifier from an IEEE 802 address, you must first map the IEEE 802 address to an EUI-64 address, and then complement the U/L bit. The following illustration shows the conversion process for a universally administered, unicast IEEE 802 address.

**IEEE 802 address conversion example**

Host A has the Ethernet MAC address of 00-AA-00-3F-2A-1C. First, it is converted to EUI-64 format by inserting FF-FE between the third and fourth bytes, yielding 00-AA-00-FF-FE-3F-2A-1C. Next, the U/L bit, which is the seventh bit in the first byte, is complemented. The first byte in binary form is 00000000. When the seventh bit is complemented, it becomes 00000010 (0x02). The final result is 02-AA-00-FF-FE-3F-2A-1C which, when converted to colon-hexadecimal notation, becomes the interface identifier 2AA:FF:FE3F:2A1C. As the result, the link-local address that corresponds to the network adapter with the MAC address of 00-AA-00-3F-2A-1C is FE80::2AA:FF:FE3F:2A1C.

### Note

- When complementing the U/L bit, add 0x2 to the first byte if the EUI-64 address is universally administered, and subtract 0x2 from the first byte if the EUI-64 address is locally administered.

**Temporary address interface identifiers**

In today's IPv4-based Internet, a typical Internet user connects to an Internet service provider (ISP) and obtains an IPv4 address by using the Point-to-Point Protocol (PPP) and the Internet Protocol Control Protocol (IPCP). Each time the user connects, a different IPv4 address might be obtained. Because of this, it is difficult to track a user's traffic on the Internet on the basis of IP address.

For IPv6-based dial-up connections, the user is assigned a 64-bit prefix after the connection is made through router discovery and stateless address autoconfiguration. If the interface identifier is always based on the EUI-64 address (as derived from the static IEEE 802 address), it is possible to identify the traffic of a specific node regardless of the prefix, making it easy to track a specific user and their use of the Internet. To address this concern and provide a level of anonymity, an alternative IPv6 interface identifier that is randomly generated and changes over time is described in RFC 3041.

The initial interface identifier is generated by using random numbers. For IPv6 systems that cannot store any historical information for generating future interface identifier values, a new random interface identifier is generated each time the IPv6 protocol is initialized. For IPv6 systems that have storage capabilities, a history value is stored and, when the IPv6 protocol is initialized, a new interface identifier is created through the following process:

1. Retrieve the history value from storage and append the interface identifier based on the EUI-64 address of the adapter.

2. Compute the Message Digest-5 (MD5) one-way encryption hash over the quantity in step 1.

3. Save the last 64 bits of the MD5 hash computed in step 2 as the history value for the next interface identifier computation.

4. Take the first 64 bits of the MD5 hash computed in Step 2 and set the seventh bit to zero. The seventh bit corresponds to the U/L bit which, when set to 0, indicates a locally administered interface identifier. The result is the interface identifier.

The resulting IPv6 address, based on this random interface identifier, is known as a temporary address. Temporary addresses are generated for public address prefixes that use stateless address autoconfiguration. Temporary addresses are used for the lower of the following values of the valid and preferred lifetimes:

- The lifetimes included in the Prefix Information option in the received Router Advertisement message.

- Local default values of 1 week for valid lifetime and 1 day for preferred lifetime.

After the valid lifetime of a temporary address expires, a new interface identifier and temporary address are generated.

The IPv6 protocol for the Windows Server 2003 family does not create temporary addresses for global address prefixes by default. You can modify this default setting with the **netsh interface ipv6 set privacy state=enabled** command. For more information, see Netsh commands for Interface IPv6.

# IPv6 and Network Applications

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 and network applications**
This section covers:

- Support for Windows Sockets
- IPv6 applications

# Support for Windows Sockets

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Support for Windows Sockets**

Changes to existing Windows Sockets functions for IPv6 are documented in RFC 2553, "Basic Socket Interface Extensions for IPv6." The IPv6 protocol for the Windows Server 2003 family supports RFC 2553 with the following exceptions:

- The header files listed in the RFC do not apply to the Windows Server 2003 family. The Windows Server 2003 family header files are Winsock2.h and Ws2tcpip.h.
- The Windows Server 2003 family socket structure does not include the **sa_len** member. Therefore, section 3.3 applies, but section 3.4 does not.
- IPv4-mapped addresses, as described in section 3.7, are not supported.
- The interface identification functions described in Section 4 are not supported.
- Sections 6.1 through 6.3 and 6.6 are not supported because they are in the process of being made obsolete by the Internet Engineering Task Force (IETF).

**Tools for IPv6 application development**

For Winsock IPv6 application development, the following are required:

- Microsoft Platform SDK (January 2000 or later)
- Microsoft Visual C++ 6.0 or later
- IPv6 protocol for the Windows Server 2003 family

# IPv6 applications

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 applications**

The Windows Server 2003 family includes the following IPv6-enabled applications and components:

- FTP client

  The File Transfer Protocol (FTP) client, Ftp.exe, can be used to establish FTP sessions with IPv4 and IPv6 FTP servers.

- Telnet client

  The Telnet client, Telnet.exe, can be used to establish Telnet sessions with IPv4 and IPv6 Telnet servers.

- Internet Explorer

  The new Internet extensions dynamic link library, Wininet.dll, enables Web browsers to access IPv6-enabled Web servers. For example, Wininet.dll is used by Microsoft Internet Explorer to make connections with a Web server to view Web pages. Internet Explorer uses IPv6 to download Web pages when the Domain Name System (DNS) query for the name of the Web server in the URL returns an IPv6 address.

  URLs that use the format for literal IPv6 addresses described in RFC 2732, "Format for Literal IPv6 Addresses in URLs," are not supported by the version of Internet Explorer provided with Windows 2000.

  For a list of IPv6-only Web sites, see the IPv6 Web site. Accessing IPv6-only Web sites assumes that you can connect to the IPv6 Internet. For more information about connecting to the IPv6 Internet, see Connecting to the IPv6 Internet.

Additionally, the Remote Procedure Call (RPC) components of Windows Server 2003 family are IPv6-enabled and the versions of Network Monitor provided with the Windows Server 2003 family, Windows 2000, and Systems Management Server 2.0 support the parsing of IPv6 headers.

**Notes**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

- Internet Explorer cannot browse IPv6 Web sites if it is configured to use a proxy server. When Internet Explorer is configured to use a proxy server, all name resolution requests for Web sites are forwarded to the proxy server. Until the proxy server is IPv6-enabled, proxy-based requests for local or remote IPv6 Web pages are unsuccessful. For information about how to configure Internet Explorer to operate without the use of a proxy server, see Internet Explorer Help.

# Administering IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering IPv6**
This section covers:

- IPv6 configuration items
- IPv6 configuration methods
- IPv6 Configurations
- Setting up an IPv6 Test Lab

# IPv6 configuration items

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 configuration items**
You can configure the following for the IPv6 protocol:

- IPv6 address
- Default router
- DNS server

**IPv6 address**
By default, link-local addresses are automatically configured for each interface on each IPv6 node (host or router) with a unique link-local IPv6 address. If you want to communicate with IPv6 nodes that are not on attached links, the host must have additional site-local or global unicast addresses. Additional addresses for hosts are either obtained from router advertisements sent by a router or assigned manually. Additional addresses for routers must be assigned manually.

For more information, see Unicast IPv6 addresses, Configure IPv6 with manual addresses, and IPv6 address autoconfiguration.

**Default router**
To communicate with IPv6 nodes on other network segments, IPv6 must use a default router. A default router is automatically assigned based on the receipt of a router advertisement. Alternately, you can add a default route to the IPv6 routing table. You do not need to configure a default router for a network that consists of a single network segment.

For more information, see IPv6 address autoconfiguration and Add an IPv6 route.

**DNS server**
You can use a Domain Name System (DNS) server to resolve host names to IPv6 addresses. When an IPv6 host is configured with the address of a DNS server, the host sends DNS name queries to the server for resolution. AAAA (quad-A) resource records, which are stored on your DNS servers, enable mapping from a host name to its IPv6 address.

To enable DNS name resolution, configure an IPv6 router with forwarding enabled and a global prefix that is advertised to clients. You can do this by using the **netsh interface ipv6 add route** and **netsh interface ipv6 set interface** commands. For more information, see Add an IPv6 route and Enable IPv6 forwarding.

By default, DNS is configured to allow DNS dynamic updates. You can either leave dynamic update enabled when you use IPv6 with DNS, or you can manually add DNS records for IPv6 clients.

**Configuring clients with the DNS server address**
To provide communication between DNS clients and servers, you can configure the clients with the IPv6 address of the DNS server, or you can configure your DNS server with one of the three default DNS server IPv6 addresses that are automatically configured on all IPv6 clients.

You can configure clients with the IPv6 address of the DNS server by using the **netsh interface ipv6 add dns** command at each client computer or in a logon script that is run each time a client logs on to the network.

To configure the DNS server with one of the three IPv6 addresses that are available on IPv6 client computers by default, use the **netsh interface ipv6 add address** command. The three default DNS server addresses are:

- FEC0:0:0: FFFF::1
- FEC0:0:0: FFFF::2
- FEC0:0:0:FFFF::3

If your DNS server is on a different subnet than your IPv6 clients, configure a static route to the DNS server on any IPv6 router that is available on the DNS server's subnet.

**Configuring the DNS server to listen on IPv6**

You can configure the DNS server to listen for DNS name registration and resolution requests over IPv6. When your DNS server is configured to listen on both IPv4 and IPv6:

- Devices that function over IPv6 but not IPv4 will function properly with your DNS server.
- Computers and other devices that are configured with both IPv4 and IPv6 use IPv6 by default.

To configure your DNS server to listen over IPv6, do the following:

1. Install Windows Support Tools.

   For more information, see Install Windows Support Tools

2. Open Command Prompt.

3. Type the following command:

   **dnscmd /config /EnableIPv6 1**

4. Restart the DNS Server service.

   For more information, see Start or stop a DNS server.

For more information, see IPv6 Name resolution, DNS, and Netsh commands for Interface IPv6.

# IPv6 configuration methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 configuration methods**

The IPv6 protocol can use the following configuration methods:

- Automatic configuration using stateless addresses
- Manual configuration

**Automatic configuration**

The IPv6 protocol supports address autoconfiguration for stateless addresses as defined in RFC 2462, "IPv6 Stateless Address Autoconfiguration." IPv6 nodes (hosts and routers) automatically create unique link-local addresses for all LAN interfaces that appear to be Ethernet or FDDI interfaces. IPv6 hosts use received Router Advertisement messages to automatically configure:

- A default router.
- The default setting for the Hop Limit field in the IPv6 header.
- The determination of whether the node should use a stateful address configuration protocol, such as Dynamic Host Configuration Protocol for IPv6 (DHCPv6), for addresses and other configuration requirements. The IPv6 protocol for the Windows Server 2003 family does not currently support DHCPv6 or any other stateful address configuration protocol.
- The timers used in Neighbor Discovery processes.
- The maximum transmission unit (MTU) of the local link.
- The list of network prefixes that are defined for the link. Each network prefix contains both the IPv6 network prefix and its valid and preferred lifetimes. If indicated, a network prefix is combined with the interface identifier to create a stateless IPv6 address configuration for the receiving interface. A network prefix also defines the range of addresses for nodes on the local link.

For more information, see IPv6 address autoconfiguration.

Additionally, the IPv6 protocol for the Windows Server 2003 family automatically configures:

- 6to4 addresses on a 6to4 tunneling interface for all public IPv4 addresses that are assigned to the computer (if a Router Advertisement is not received and the computer is configured with a public IPv4 address).
- Intrasite Automatic Tunnel Addressing Protocol (ISATAP) addresses on the Automatic Tunneling Pseudo-Interface for all IPv4 addresses that are assigned to the computer.
- Routes to off-link prefixes (if the off-link address prefix is advertised by a router running a member of the Windows Server 2003 family).

**Manual configuration**

You can manually configure IPv6 addresses and routes by using the Netsh commands for Interface IPv6 command-line tool. Manual configuration might be required in a network that has multiple IPv6 network segments within which routers are not configured to send router advertisements.

For more information, see Netsh commands for Interface IPv6, Configure IPv6 with manual addresses, and Add an IPv6 route.

# IPv6 Configurations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 configurations**
This section covers:

- Single subnet with link-local addresses
- Using IPSec between two local link hosts
- IPv6 traffic between nodes on different subnets of an IPv6 internetwork
- IPv6 traffic between nodes on different subnets of an IPv4 internetwork
- IPv6 traffic between nodes in different sites across the Internet (6to4)
- Connecting to the IPv6 Internet
- Using IPv4-compatible addresses

# Single subnet with link-local addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Single subnet with link-local addresses**
This configuration requires only the installation of the IPv6 protocol on at least two nodes on the same network segment (also known as a link or subnet) with no intermediate routers.

The following illustration shows the configuration of two nodes on a single subnet using link-local addresses.

By default, the IPv6 protocol for the Windows Server 2003 family and Windows XP configures link-local addresses for each interface that corresponds to installed Ethernet network adapters. Link-local addresses have the prefix of FE80::/64. The last 64 bits of the IPv6 address is known as the interface identifier. It is derived from the 48-bit MAC address of the network adapter. For more information, see IPv6 interface identifiers.

To create the IPv6 interface identifier from the 48-bit (6-byte) Ethernet MAC address:

- The hexadecimal digits 0xFF-FE are inserted between the third and fourth bytes of the MAC address.
- The Universal/Local bit (the second low-order bit of the first byte of the MAC address) is complemented. If it is a 1, it is set to 0; and if it is a 0, it is set to 1.

For example, for the MAC address of 00-60-08-52-F9-D8:

- The hexadecimal digits 0xFF-FE are inserted between 0x08 (the third byte) and 0x52 (the fourth byte) of the MAC address, forming the 64-bit address of 00-60-08-FF-FE-52-F9-D8.
- The Universal/Local bit, the second low-order bit of 0x00 (the first byte) of the MAC address, is complemented. The second low-order bit of 0x00 is 0 which, when complemented, becomes 1. The result is that for the first byte, 0x00 becomes 0x02.

As a result, the IPv6 interface identifier that corresponds to the Ethernet MAC address of 00-60-08-52-F9-D8 is 02-60-08-FF-FE-52-F9-D8.

The link-local address of a node is the combination of the prefix FE80::/64 and the 64-bit interface identifier expressed in colon-hexadecimal notation. As a result, the link-local address of this example node, with the prefix of FE80::/64 and the interface identifier 02-60-08-FF-FE-52-F9-D8, is FE80::260:8FF:FE52:F9D8.

You can view your link local address by using **netsh interface ipv6 show interface**. When you run this command without any additional parameters, a simple list is provided as output:

```
Idx  Met   MTU    State         Name
---  ----  -----  ------------  -----
  5     0   1500  Connected     Local Area Connection
  4     0   1500  Connected     Local Area Connection 2
  3     1   1280  Connected     6to4 Tunneling Pseudo-Interface
  2     1   1280  Connected     Automatic Tunneling Pseudo-Interface
  1     0   1500  Connected     Loopback Pseudo-Interface
```

For more detailed output, you can designate a connection name as a command parameter (for example, **netsh interface ipv6 show interface "Local Area Connection 2"**). Using the **interface** parameter (with either an interface name or an interface index number) results in the following output, which includes the link local address for the connection:

```
Interface 4: Local Area Connection 2

Addr Type  DAD State  Valid Life   Pref. Life   Address

```

Interface 4 is an interface that corresponds to an installed Ethernet adapter with a link-local address of FE80::2C0:4FFF:FE19:BAD3.

**Testing connectivity between two link-local hosts**

You can perform a simple ping (an exchange of ICMPv6 Echo Request and Echo Reply messages) with IPv6 between two link-local hosts by completing the following steps:

1. Install IPv6 on two computers. For more information, see Install IPv6.

2. Use **netsh interface ipv6 show interface** on Host A to obtain the link-local address and the interface index for the Ethernet interface.

   For example, the link-local address of Host A is FE80::210:5AFF:FEAA:20A2, and the interface index of the Ethernet interface is 4.

3. Use **netsh interface ipv6 show interface** on Host B to obtain the link-local address and the interface index for the Ethernet interface.

   For example, the link-local address of Host B is FE80::260:97FF:FE02:6EA5, and the interface index for the Ethernet interface is 3.

4. From Host A, use Ping.exe to ping Host B.

   For example, **ping FE80::260:97FF:FE02:6EA5%4**

When you specify a link-local or site-local destination address, you can specify the zone ID to make the zone (an area of the network of a specific scope) of the traffic specific.

- For example, on a computer with multiple Ethernet adapters that are connected to separate links, each Ethernet adapter is assigned a link-local address. Destination link-local addresses in this configuration are ambiguous because a specific link-local address can be assigned to multiple nodes located on the links that are reachable from all of the installed

Ethernet adapters. To define the area of the network for which the destination is intended, the zone ID is used to indicate the Ethernet adapter over which traffic is sent and received. In the IPv6 protocol, the zone ID for link-local addresses is typically the interface index from the display of the **netsh interface ipv6 show interface** command. The interface index is defined locally on each IPv6 host. Because of this, the interface index used by Host A to reach Host B might not be the same as the interface index used by Host B to reach Host A.

- When using site-local addresses, it is possible to be connected to multiple sites. In this case, each site is assigned a site identifier. To define the area of the network for which the destination is intended, the zone ID is used to indicate the site identifier. In the IPv6 protocol, the zone ID is the Zone ID for Site from the display of the **netsh interface ipv6 show interface level=verbose** command. If you are connected only to a single site, the default site identifier is 1 and the zone ID does not have to be specified. The site identifier is defined locally on each IPv6 host. Because of this, the site identifier used by Host A to reach Host B might not be the same as the site identifier used by Host B to reach Host A.

The notation that is used to specify the zone ID with an address is *Address***%***ZoneID*.

For additional information about configurations, see IPv6 Configurations.

For information about using IPv6 in a test lab, see Setting up an IPv6 Test Lab.

For more information about the **netsh interface ipv6 show interface** command, see Netsh commands for Interface IPv6.

# Using IPSec between two local link hosts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using IPSec between two local link hosts**

**Caution**

- This implementation of IPSec for IPv6 is not recommended for use in a production environment because it relies on static keying and has no provisions for updating keys upon sequence number reuse.
- When you manually configure Security Parameters Indexes (SPIs), always use random numbers. Do not use sequential numbers for SPIs, or you will compromise the security of your IPSec for IPv6 policies.
- The IPv6 protocol for the Windows Server 2003 family does not support the use of IPSec Encapsulating Security Payload (ESP) encryption. However, the use of ESP with NULL encryption is supported. Although NULL encryption uses the ESP header, only data origin authentication and data integrity services are provided.

This configuration creates an IPSec security association (SA) between two hosts on the same subnet. The SA performs authentication by using the Authentication Header (AH) and the Message Digest 5 (MD5) hashing algorithm. In this example, the configuration secures all traffic between two neighboring hosts. Host 1 has the link-local address of FE80::2AA:FF:FE53:A92C, and Host 2 has the link-local address of FE80::2AA:FF:FE92:D0F1.

1. On Host 1, create blank security association (.sad) and security policy (.spd) files by using the **ipsec6 s** command. In this example, the Ipsec6.exe command is **ipsec6 s test**. This creates two files with blank entries for manually configuring security associations (Test.sad) and security policies (Test.spd).

2. On Host 1, edit the .spd file, adding a security policy that secures all traffic between Host 1 and Host 2.

   The following table shows the security policy entry that is added to Test.spd before the first entry (the first entry in Test.spd is not modified):

| .spd file field name | Example value |
|---|---|
| Policy | 2 |
| RemoteIPAddr | - FE80::2AA:FF:FE92:D0F1 |
| LocalIPAddr | - * |
| Protocol | - * |
| RemotePort | - * |
| LocalPort | - * |
| IPSecProtocol | AH |
| IPSecMode | TRANSPORT |
| RemoteGWIPAddr | * |
| SABundleIndex | NONE |
| Direction | BIDIRECT |
| Action | APPLY |
| InterfaceIndex | 0 |

Type a semicolon at the end of the entry configuring this security policy. Policy entries must be placed in decreasing numerical order.

3. On Host 1, edit the .sad file, adding SA entries to secure all traffic between Host 1 and Host 2. Two security associations must be created, one for traffic to Host 2 and one for traffic from Host 2.

   The following table shows the first SA entry that is added to Test.sad (for traffic to Host 2):

| .sad file field name | Example value |
|---|---|
| SAEntry | 2 |
| SPI | 3001 |
| SADestIPAddr | FE80::2AA:FF:FE92:D0F1 |
| DestIPAddr | POLICY |
| SrcIPAddr | POLICY |
| Protocol | POLICY |
| DestPort | POLICY |
| SrcPort | POLICY |
| AuthAlg | HMAC-MD5 |
| KeyFile | Test.key |
| Direction | OUTBOUND |
| SecPolicyIndex | 2 |

   Type a semicolon at the end of the entry configuring this SA.

   The following table shows the second SA entry that is added to Test.sad (for traffic from Host 2):

| .sad file field name | Example value |
|---|---|
| SAEntry | 1 |
| SPI | 3000 |
| SADestIPAddr | FE80::2AA:FF:FE53:A92C |
| DestIPAddr | POLICY |
| SrcIPAddr | POLICY |
| Protocol | POLICY |
| DestPort | POLICY |
| SrcPort | POLICY |
| AuthAlg | HMAC-MD5 |
| KeyFile | Test.key |
| Direction | INBOUND |
| SecPolicyIndex | 2 |

Type a semicolon at the end of the entry configuring this SA. SA entries must be placed in decreasing numerical order.

4. On Host 1, create a file that contains data used to create and validate the Message Digest 5 (MD5) keyed hash on each IPSec-protected packet that is exchanged with Host 2. In this example, a text file is used. Test.key is created with the contents **This is a test**. There are no extra characters, spaces, or lines.

   The IPv6 protocol supports only manually configured keys for quick mode SAs (also known as IPSec or Phase II SAs), because main mode negotiation through Internet Key Exchange (IKE) is not performed. Manual keys are configured by creating files that contain either the text or binary data of the manual key. In this example, the same key for the SAs is used in both directions. You can use different keys for inbound and outbound SAs by creating different key files and referencing them with the **KeyFile** field in the .sad file.

5. On Host 2, use the **ipsec6 s** command to create blank security association (.sad) and security policy (.spd) files. In this example, the Ipsec6.exe command is **ipsec6 s test**. This creates two files with blank entries for manually configuring security associations (Test.sad) and security policies (Test.spd).

   To simplify the example, the same file names for the .sad and .spd files are used on Host 2. You can choose to use different file names on each host.

6. On Host 2, edit the .spd file, adding a security policy that secures all traffic between Host 2 and Host 1.

   The following table shows the security policy entry that is added to Test.spd before the first entry (the first entry in Test.spd is not modified):

| **.spd file field name** | **Example value** |
|---|---|
| Policy | 2 |
| RemoteIPAddr | - FE80::2AA:FF:FE53:A92C |
| LocalIPAddr | - * |
| Protocol | - * |
| RemotePort | - * |
| LocalPort | - * |
| IPSecProtocol | AH |
| IPSecMode | TRANSPORT |
| RemoteGWIPAddr | * |
| SABundleIndex | NONE |
| Direction | BIDIRECT |
| Action | APPLY |
| InterfaceIndex | 0 |

   Type a semicolon at the end of the entry configuring this security policy. Policy entries must be placed in decreasing numerical order.

7. On Host 2, edit the .sad file, adding SA entries to secure all traffic between Host 2 and Host 1. Two security associations must be created: one for traffic to Host 1 and one for traffic from Host 1.

   The following table shows the first SA entry that is added to Test.sad (for traffic to Host 1):

| .sad file field name | Example value |
|---|---|
| SAEntry | 2 |
| SPI | 3000 |
| SADestIPAddr | FE80::2AA:FF:FE53:A92C |
| DestIPAddr | POLICY |
| SrcIPAddr | POLICY |
| Protocol | POLICY |
| DestPort | POLICY |
| SrcPort | POLICY |
| AuthAlg | HMAC-MD5 |
| KeyFile | Test.key |
| Direction | OUTBOUND |
| SecPolicyIndex | 2 |

Type a semicolon at the end of the entry configuring this SA.

The following table shows the second SA entry that is added to Test.sad (for traffic from Host 1):

| .sad file field name | Example value |
|---|---|
| SAEntry | 1 |
| SPI | 3001 |
| SADestIPAddr | FE80::2AA:FF:FE92:D0F1 |
| DestIPAddr | POLICY |
| SrcIPAddr | POLICY |
| Protocol | POLICY |
| DestPort | POLICY |
| SrcPort | POLICY |
| AuthAlg | HMAC-MD5 |
| KeyFile | Test.key |
| Direction | INBOUND |
| SecPolicyIndex | 2 |

Type a semicolon at the end of the entry configuring this SA. SA entries must be placed in decreasing numerical order.

8. On Host 2, create a text file that contains a text string that is used to authenticate the SAs created with Host 1. In this example, Test.key is created with the contents **This is a test**. There are no extra characters, spaces, or lines.

9. On Host 1, use the **ipsec6 l** command to add the configured security policies and SAs from the .spd and .sad files. In this example, the **ipsec6 l test** command is run on Host 1.

10. On Host 2, use the **ipsec6 l** command to add the configured security policies and SAs from the .spd and .sad files. In this example, the **ipsec6 l test** command is run on Host 2.

11. On Host 2, use the **ping** command to ping Host 1's link-local address.

    If you use Network Monitor to capture the traffic, you should see the exchange of ICMPv6 Echo Request and Echo Reply messages, with an Authentication Header (AH) listed between the IPv6 header and the ICMPv6 header.

For additional information about configurations, see IPv6 Configurations.

For information about using IPv6 in a test lab, see Setting up an IPv6 Test Lab.

# IPv6 traffic between nodes on different subnets of an IPv6 internetwork

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 traffic between nodes on different subnets of an IPv6 internetwork**

This configuration requires three computers (two hosts and one router) and additional router configuration beyond the installation of the IPv6 protocol. There are two separate network segments (also known as links or subnets) and an IPv6-capable router that forwards IPv6 packets between hosts on the segments.

The following illustration shows the configuration of two hosts on separate network segments that are connected by a router.

By default, the IPv6 protocol for the Windows Server 2003 family configures link-local IP addresses for each interface that correspond to installed Ethernet network adapters. Link-local addresses have the prefix of FE80::/64. The last 64 bits of the IPv6 address are the interface identifier, as derived from the 48-bit MAC address of the network adapter. For more information, see IPv6 interface identifiers. With link-local addresses, Host A and Host B can communicate with the router computer, but not with each other.

In this configuration, additional site-local prefixes are advertised by the router. The site-local prefixes are used by Host A and Host B to automatically configure site-local addresses that are derived from the 48-bit MAC address of the network adapter. After Host A and Host B have site-local addresses, they can communicate with each other.

To obtain the interface index numbers of the two Ethernet adapters on the router computer, type the following command for each adapter:

**netsh interface ipv6 show interface** [**interface=**]*String*

Where *String* is the name or index of the interface, (for example, **Local Area Connection**). Subnet 1 is the network segment to which Host A is attached. Subnet 2 is the network segment to which Host B is attached.

After you have obtained the interface index numbers, type the following commands on the router computer:

**netsh interface ipv6 set interface** [**interface=**]*Subnet1InterfaceIndex* [**forwarding=**]**enabled** [**advertise=**]**enabled**

**netsh interface ipv6 set interface** [**interface=**]*Subnet2InterfaceIndex* [**forwarding=**]**enabled** [**advertise=**]**enabled**

**netsh interface ipv6 add route** [**prefix=**]**FEC0:0:0:1::/64** [**interface=**]*Subnet1InterfaceIndex* [**publish=**]**yes**

**netsh interface ipv6 add route** [**prefix=**]**FEC0:0:0:2::/64** [**interface=**]*Subnet2InterfaceIndex* [**publish=**]**yes**

Where:

- *Subnet1InterfaceIndex* is the interface index of the adapter on the router computer that is attached to Subnet 1.
- *Subnet2InterfaceIndex* is the interface index of the adapter on the router computer that is attached to Subnet 2.

For example, if the Subnet 1 and Subnet 2 interface indexes of the router computer are 4 and 3 respectively, the commands are:

**netsh interface ipv6 set interface 4 enabled enabled**

**netsh interface ipv6 set interface 3 enabled enabled**

**netsh interface ipv6 add route FEC0:0:0:1::/64 4 publish=yes**

**netsh interface ipv6 add route FEC0:0:0:2::/64 3 publish=yes**

Wait about 30 seconds for both the router computer to advertise new site-local prefixes on Subnets 1 and 2 and for Hosts A and B to automatically configure site-local addresses based on these prefixes.

On Host A, type the **netsh interface ipv6 show interface** command to check for a new IPv6 address for the Ethernet adapter that is based on the site-local prefix of FEC0:0:0:1::/64. On Host B, type the **netsh interface ipv6 show interface** command to check for a new IPv6 address for the Ethernet adapter that is based on the site-local prefix of FEC0:0:0:2::/64.

On Host A, use the **ping** command and the site-local address of Host B to ping Host B. For example, if the Host B site-local address is FEC0::2:260:97FF:FE02:6EA5, the command is **ping FEC0::2:260:97FF:FE02:6EA5**.

For more information about Netsh commands, see Netsh overview and Netsh commands for Interface IPv6.

For additional information about configurations, see IPv6 Configurations.

For information about using IPv6 in a test lab, see Setting up an IPv6 Test Lab.

# IPv6 traffic between nodes on different subnets of an IPv4 internetwork

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 traffic between nodes on different subnets of an IPv4 internetwork**

The IPv6 protocol for the Windows Server 2003 family and Windows XP provides the following methods for communicating between IPv6 nodes on different subnets of an IPv4 internetwork:

- Intrasite Automatic Tunnel Addressing Protocol addresses
- 6over4

  6over4 requires that the IPv4 internetwork be multicast-capable. Because most IPv4 networks are not multicast-capable, 6over4 is rarely used. For more information about 6over4, see IPv6 protocol features and RFC 2529.

- 6to4

  While 6to4 is primarily designed to allow communication between separate IPv6-enabled 6to4 sites, 6to4 hosts that are using the IPv6 protocol can also use 6to4 addresses and 6to4 tunneling to communicate across the IPv4 Internet. For more information, see IPv6 traffic between nodes in different sites across the Internet (6to4).

- IPv4-compatible addresses

  IPv4-compatible addresses derived from IPv4 public addresses provide a method for connecting IPv6 hosts or sites over the existing IPv4 Internet infrastructure. For more information, see Using IPv4-compatible addresses.

In all of these cases, while IPv6 traffic is being carried as the payload of an IPv4 packet (treating the IPv4 infrastructure as an IPv6 link-layer), it remains IPv6 traffic. Applications that use the addresses associated with these methods are using the same Windows Sockets functions as if global IPv6 addresses and an IPv6 infrastructure were being used.

**Using Intrasite Automatic Tunnel Addressing Protocol addresses**

Another address assignment and tunneling mechanism that can be used for communication between IPv6/IPv4 nodes on an IPv4 network is described in the Internet draft titled "Intra-Site Automatic Tunnel Addressing Protocol (ISATAP)" (draft-ietf-ngtrans-isatap-O*x*.txt). These addresses are called Intrasite Automatic Tunnel Addressing Protocol (ISATAP) addresses. ISATAP addresses use the locally administered interface ID ::0:5EFE:*w.x.y.z* where:

- The 0:5EFE portion is formed from the combination of both the organizational unit identifier that is assigned to the Internet Assigned Numbers Authority (IANA) (00-00-5E) and a type that indicates an embedded IPv4 address (FE).
- The *w.x.y.z* portion is any unicast IPv4 address, which includes both public and private addresses.

The ISATAP interface ID can be combined with any 64-bit prefix that is valid for IPv6 unicast addresses. This includes the link-local address prefix (FE80::/64), site-local prefixes, and global prefixes.

Like IPv4-compatible addresses, 6over4 addresses, and 6to4 addresses, ISATAP addresses contain an embedded IPv4 address that is used to determine either the source or destination IPv4 addresses within the IPv4 header when ISATAP-addressed IPv6 traffic is sent across an IPv4 network.

By default, the IPv6 protocol for the Windows Server 2003 family and Windows XP automatically configures the ISATAP address of FE80::5EFE:*w.x.y.z* on the Automatic Tunneling Pseudo-Interface for each IPv4 address that is assigned to the node. This link-local ISATAP address allows two hosts to communicate over an IPv4 network by using each other's ISATAP addresses.

For example, Host A is configured with the IPv4 address of 10.40.1.29 and Host B is configured with the IPv4 address of 192.168.41.30. When the IPv6 protocol for the Windows Server 2003 family and Windows XP is started, Host A is automatically configured with the ISATAP address of FE80::5EFE:10.40.1.29 and Host B is automatically configured with the

ISATAP address of FE80::5EFE:192.168.41.30. When Host A sends IPv6 traffic to Host B by using Host B's ISATAP address, the source and destination addresses for the IPv4 and IPv6 headers are listed in the following table.

| Field | Value |
|---|---|
| Source address in IPv6 header | FE80::5EFE:10.40.1.29 |
| Destination address in IPv6 header | FE80::5EFE:192.168.41.30 |
| Source address in IPv4 header | 10.40.1.29 |
| Destination address in IPv4 header | 192.168.41.30 |

To test connectivity, you can use the **ping** command. For example, Host A would use the following command to ping Host B by using its link-local ISATAP address:

**ping FE80::5EFE:192.168.41.30%2**

The **%***ZoneID* portion of the command is used to specify the interface index of the interface from which traffic is sent. In this case, **%2** specifies interface 2, which is the interface index assigned to the Automatic Tunneling Pseudo-Interface on Host A.

The use of link-local ISATAP addresses allows IPv6/IPv4 hosts on an IPv4 intranet to communicate with each other, but not with other IPv6 hosts outside of the site. To communicate outside of the site, the following additional configuration is required:

- A host must receive a router advertisement from the site border router that contains a global address prefix. The site border router is placed between the intranet and either the IPv4 Internet or the IPv6 Internet. A site border router is most often a 6to4 router that is connected to the Internet. Upon receiving the router advertisement, additional ISATAP addresses that are based on the global prefix are automatically added.

  For example, if the site is connected to the IPv6 Internet and Host A receives the global prefix of 3FFE:FFF::/64 in a router advertisement, the ISATAP address of 3FFE:FFFF::5EFE:10.40.1.29 is automatically configured. Without a global address prefix and an IPv6 Internet connection, a site can use a 6to4-based global address prefix and connect to other 6to4 sites, 6to4 hosts, and the IPv6 Internet, by using the IPv4 Internet. If the site is using the 6to4 address prefix of 2002:836B:1:5::/64 (based on the public address of 131.107.0.1 and an SLA ID of 5), the ISATAP address of 2002:836B:1:5:0:5EFE:10.40.1.29 is automatically configured.

  ISATAP router addresses are auto-configured in Windows XP when IPv6 queries for "_ISATAP" and receives responses from ISATAP routers. For members of the Windows Server 2003 family and for Windows XP Service Pack 1, IPv6 queries for "ISATAP" (without the underscore character) and auto-configures ISATAP router addresses when responses from ISATAP routers are received.

- A host must have a default route, pointing to an ISATAP address that corresponds to the intranet interface of the site border router.

  For example, if the intranet interface of the site border router is configured with the IPv4 address of 172.16.0.1, Host A must be configured with a default route (::/0), which uses the ISATAP address of FE80::5EFE:172.16.0.1 as the next-hop address. As the result, all IPv6 traffic that matches this default route (as the closest matching route) is encapsulated and forwarded to the site border router. The site border router then forwards the traffic. If the site border router is a 6to4 router, it encapsulates the IPv6 traffic and forwards it on the Internet.

  For more information, see Add an IPv6 route.

For additional information about configurations, see IPv6 Configurations. For information about using IPv6 in a test lab, see Setting up an IPv6 Test Lab.

# IPv6 traffic between nodes in different sites across the Internet (6to4)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 traffic between nodes in different sites across the Internet (6to4)**

6to4 is a tunneling technique that is described in RFC 3056. When 6to4 is used, IPv6 traffic is encapsulated with an IPv4 header before it is sent over the IPv4 Internet.

6to4 uses the global address prefix of 2002:*WWXX*:*YYZZ*::/48, where *WWXX*:*YYZZ* is both the Next Level Aggregation ID (NLA ID) portion of a global address and the colon-hexadecimal representation of a public IPv4 address (*w.x.y.z*) that is assigned to the site or host. The complete 6to4 address of a 6to4 host is 2002:*WWXX*:*YYZZ*:[*SLAID*]:[*InterfaceID*].

RFC 3056 defines the following:

- 6to4 host

  An IPv6 host that is configured with at least one 6to4 address.

- 6to4 router

  An IPv4/IPv6 router that forwards 6to4-addressed traffic both between the 6to4 hosts within a site and to other 6to4 routers or 6to4 relay routers on the IPv6 Internet.

- 6to4 relay router

  An IPv4/IPv6 router that forwards 6to4-addressed traffic between 6to4 routers on the Internet and hosts on the IPv6 Internet.

When you use 6to4 hosts, an IPv6 routing infrastructure within 6to4 sites, a 6to4 router at site boundaries, and a 6to4 relay router, the following types of communication are possible:

1. A 6to4 host can communicate with another 6to4 host within the same site.

   This type of communication is available through the IPv6 routing infrastructure, which provides reachability to all hosts within the site.

2. A 6to4 host can communicate with 6to4 hosts in other sites across the IPv4 Internet.

   This type of communication occurs when a 6to4 host forwards IPv6 traffic, which is destined to a 6to4 host in another site, to the local site 6to4 router. The local site 6to4 router encapsulates the IPv6 traffic with an IPv4 header and sends it to the 6to4 router at the destination site on the Internet. At the destination site, the 6to4 router removes the IPv4 header and forwards the IPv6 packet to the appropriate 6to4 host by using the IPv6 routing infrastructure of the destination site.

3. A 6to4 host can communicate with hosts on the IPv6 Internet.

   This type of communication occurs when a 6to4 host forwards IPv6 traffic, which is destined for an IPv6 Internet host, to the local site 6to4 router. The local site 6to4 router encapsulates the IPv6 traffic with an IPv4 header and sends it to a 6to4 relay router that is connected to both the IPv4 Internet and the IPv6 Internet. The 6to4 relay router removes the IPv4 header and forwards the IPv6 packet to the appropriate IPv6 Internet host by using the IPv6 routing infrastructure of the IPv6 Internet.

All of these types of communication use IPv6 traffic without the requirement of obtaining either a direct connection to the IPv6 Internet or an IPv6 global address prefix from an Internet service provider (ISP).

Support for 6to4 hosts and routers is provided in the IPv6 Helper service that is included with the IPv6 protocol for Windows

Server 2003 family and Windows XP. The IPv6 Helper service:

- Automatically configures 6to4 addresses on the interface (named 6to4 Pseudo-Interface or interface index 3) that is used for all public IPv4 addresses that are assigned to interfaces on the computer. For more information, see Single subnet with link-local addresses.

- Automatically creates a 2002::/16 route that forwards all 6to4 traffic with the 6to4 Pseudo-Interface (interface index 3). All traffic forwarded by this host to 6to4 destinations is encapsulated with an IPv4 header.

- Automatically performs a Domain Name System (DNS) query for the name 6to4.ipv6.microsoft.com to obtain the IPv4 address of the Microsoft 6to4 relay router on the Internet. You can use the **netsh interface ipv6 6to4 set relay** command to specify which DNS name to query. For more information, see IPv6 utilities.

With the IPv6 Helper service configuration, computers are automatically configured as a 6to4 host when:

- The host is running the IPv6 protocol.

- The host is configured with an IPv4 public IP address.

- The host does not receive a Router Advertisement from an IPv6 router.

A 6to4 host can perform its own tunneling to reach either 6to4 hosts in other sites or hosts on the IPv6 Internet.

For more information about connecting to the IPv6 Internet, see Connecting to the IPv6 Internet.

If Internet Connection Sharing (ICS) is enabled on an interface that is assigned a public IPv4 address, the IPv6 Helper service:

- Enables routing on the private interface.

- Sends Router Advertisements that contain 6to4 address prefixes, which are based on the public IPv4 address of the public interface. The SLA ID in the 6to4 address prefix is set to the interface ID of the interface on which the advertisements are sent.

By enabling ICS, you can use a computer running the IPv6 protocol for Windows XP as a 6to4 router, which is capable of both encapsulating and forwarding 6to4 traffic to other 6to4 hosts or sites on the Internet, and forwarding IPv6 Internet traffic to a 6to4 relay router on the Internet.

The following illustration shows how 6to4 is used to communicate between two 6to4 sites.

Each site uses a computer with ICS enabled on the public interface to create a 6to4 router. Host computers on the private network segments receive the Router Advertisement that is sent by their site's 6to4 router and contains a 6to4 address prefix. As the result, two 6to4 hosts can communicate by using 6to4 addresses over the Internet.

For additional information about configurations, see IPv6 Configurations.

For information about using IPv6 in a test lab, see Setting up an IPv6 Test Lab.

**Note**

- Internet Connection Sharing and Network Bridge are not included in Windows Server 2003, Web Edition; Windows Server 2003, Datacenter Edition; and the Itanium-based versions of the original release of the Windows Server 2003 operating systems.

# Connecting to the IPv6 Internet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connecting to the IPv6 Internet**

The simplest way to connect to the IPv6 Internet is to use 6to4, which is included with the IPv6 protocol for the Windows Server 2003 family. You can use 6to4 as either a 6to4 host or as a 6to4 router by enabling Internet Connection Sharing (ICS) on a computer that is connected to the Internet. The IPv6 Helper service automatically configures itself with the appropriate 6to4 addresses and uses a specific 6to4 relay router on the Internet. For more information, see IPv6 traffic between nodes in different sites across the Internet (6to4). The following illustration shows the configuration of a host that is using 6to4 to communicate on the IPv6 Internet through a 6to4 relay router.

With 6to4, you can ping other computers on the IPv6 Internet (for example, **ping -6 ipv6.research.microsoft.com**). The IPv6 Web site provides a list of IPv6-accessible servers that communicate on the IPv6 Internet. Additionally, the registry available at this site contains the names of other IPv6 Internet computers.

Some IPv6 Internet sites might be inaccessible. You might also experience connectivity problems. The **tracert -d***Address* command might be helpful in either case. The **-d** parameter prevents reverse DNS lookup on intermediate router addresses. For more information about the IPv6 Internet, see the 6bone Web site.

For additional information about configurations, see IPv6 Configurations.

For information about using IPv6 in a test lab, see Setting up an IPv6 Test Lab.

**Notes**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.
- Internet Connection Sharing and Network Bridge are not included in Windows Server 2003, Web Edition; Windows Server 2003, Datacenter Edition; and the Itanium-based versions of the original release of the Windows Server 2003 operating systems.

# Using IPv4-compatible addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using IPv4-compatible addresses**

IPv4-compatible addresses, derived from IPv4 public addresses, provide a method for connecting IPv6 hosts or sites over the existing IPv4 Internet infrastructure. IPv6 traffic, when used with IPv4-compatible addresses, does not require the addition of IPv6 routers. Its traffic is encapsulated with an IPv4 header.

The following illustration shows the configuration of two nodes on separate subnets using IPv4-compatible addresses to communicate across an IPv4 router.

When IPv4-compatible IPv6 addresses are enabled, the IPv6 protocol for the Windows Server 2003 family and Windows XP automatically configures IPv4-compatible addresses for IPv4 public addresses on the Automatic Tunneling Pseudo-Interface (interface ID 2). An IPv4-compatible address takes the form ::*w.x.y.z*, where *w.x.y.z* is an IPv4 public address assigned to an interface on the computer. When IPv4-compatible addresses are enabled, the IPv6 protocol also automatically creates a ::/96 route that forwards all IPv4-compatible addressed traffic with the Automatic Tunneling Pseudo-Interface (interface ID 2). All traffic forwarded by this host to IPv4-compatible destinations is encapsulated with an IPv4 header.

IPv4-compatible addresses are disabled by default. To enable IPv4-compatible addresses, open Command Prompt and type:

**netsh interface ipv6 set state v4compat=enabled**

When you send traffic to an IPv4-compatible address, the traffic is sent from an IPv4-compatible address and is encapsulated with an IPv4 header. The Protocol field is set to 41 in the IPv4 header to indicate that the payload is an IPv6 packet. The IPv4 header allows the traffic to travel across an IPv4 infrastructure. The IPv4 addresses that are embedded in the source and destination IPv4-compatible addresses of the IPv6 header become the IPv4 source and destination addresses in the IPv4 header.

For example, when Host A (which is configured with the IPv4 address of 131.107.41.17) uses IPv4-compatible addresses to send IPv6 traffic to Host B (which is configured with the IPv4 address of 157.60.15.93), the source and destination addresses for the IPv4 and IPv6 headers are listed in the following table.

| Field | Value |
|---|---|
| Source address in IPv6 header | ::131.107.41.17 |
| Destination address in IPv6 header | ::157.60.15.93 |
| Source address in IPv4 header | 131.107.41.17 |
| Destination address in IPv4 header | 157.60.15.93 |

The IPv4 routing infrastructure forwards the packet from Host A to Host B, based on the IPv4 destination address of 157.60.15.93. After it is received at Host B, the IPv4 packet payload (the IPv6 packet) is passed to the IPv6 protocol.

To test connectivity, use the **ping** command. For example, Host A would use the following command to ping Host B by using its IPv4-compatible address:

**ping ::157.60.15.93**

For more information, see Add an IPv6 route.

For additional information about configurations, see IPv6 Configurations.

For information about using IPv6 in a test lab, see Setting up an IPv6 Test Lab.

# Setting up an IPv6 Test Lab

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up an IPv6 test lab**

This section provides information about how you can use five computers to create a test lab to configure and test the IPv6 protocol. These instructions are designed to walk you through a set of tasks, exposing you to the IPv6 protocol and its associated functionality. Beyond the set of tasks, these instructions allow you to create a functioning IPv6 configuration. You can use this configuration to learn about and experiment with IPv6 features and functionality, to aid in developing applications for IPv6 or porting existing IPv4 applications.

This section covers:

- Setting up the IPv6 infrastructure
- IPv6 test lab tasks

**Note**

- The following instructions are for configuring a test lab using a minimum number of computers. Individual computers are needed to separate the services provided on the network and to clearly show the desired functionality. This configuration is neither designed to reflect best practices nor is it designed to reflect a desired or recommended configuration for a production network. The configuration, including IP addresses and all other configuration parameters, is designed only to work on a separate test lab network.

# Setting up the IPv6 infrastructure

Updated: April 13, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting up the infrastructure**

The infrastructure for the IPv6 test lab network consists of five computers performing the following services:

- A computer running Windows Server 2003, Standard Edition, that is used as a Domain Name System (DNS) server. This computer is named DNS1.
- A computer running Windows XP Professional that is used as a client. This computer is named CLIENT1.
- A computer running Windows Server 2003, Standard Edition, that is used as a router. This computer is named ROUTER1.
- A computer running Windows Server 2003, Standard Edition, that is used as a router. This computer is named ROUTER2.
- A computer running Windows XP Professional that is used as a client. This computer is named CLIENT2.

**Note**

- You can configure the computers named ROUTER1 and ROUTER2 with Windows XP Professional. The computer named DNS1, however, must be configured with Windows Server 2003, Standard Edition.

The following illustration shows the configuration of the IPv6 test lab.

There are three network segments:

- A network segment known as Subnet 1 that uses the private IP network ID of 10.0.1.0/24 and subnet ID of 2001:DB8:0:1::/64.
- A network segment known as Subnet 2 that uses the private IP network ID of 10.0.2.0/24 and subnet ID of 2001:DB8:0:2::/64.
- A network segment known as Subnet 3 that uses the private IP network ID of 10.0.3.0/24 and subnet ID of 2001:DB8:0:3::/64.

All computers on each subnet are connected to a separate common hub or Layer 2 switch. The two router computers, ROUTER1 and ROUTER2, have two network adapters installed.

For the IPv4 configuration, each computer is manually configured with the appropriate IP address, subnet mask, default gateway, and DNS server IP address. Dynamic Host Configuration protocol (DHCP) and Windows Internet Name Service (WINS) servers are not used. For the IPv6 configuration, link-local addresses are used initially.

The following sections describe how each of the computers in the test lab are configured. To reconstruct this test lab, please configure the computers in the order presented.

**Note**

- The following instructions are for configuring a test lab using a minimum number of computers. Individual computers are needed to separate the services provided on the network and to clearly show the desired functionality. This configuration is neither designed to reflect best practices nor is it designed to reflect a desired or recommended configuration for a production network. The configuration, including IP addresses and all other configuration parameters, is designed only to work on a separate test lab network.

**DNS1**

DNS1 is a computer running Windows Server 2003, Standard Edition. It is providing DNS server services for the testlab.microsoft.com DNS domain. To configure DNS1 for this service, perform the following steps:

1. Install Windows Server 2003, Standard Edition, as a stand-alone server. Set the Administrator password.

2. After restarting, log on as Administrator.

3. Install the IPv6 protocol. For more information, see Install IPv6.

4. Install the Domain Name System (DNS) server service. During installation of DNS, define a forward lookup zone named testlab.microsoft.com that allows dynamic updates. For more information, see Install a DNS server. You can also create a forward lookup zone after DNS installation. For more information, see Add a forward lookup zone

5. Configure the TCP/IP protocol with the IP address of 10.0.1.2, the subnet mask of 255.255.255.0, and the default gateway of 10.0.1.1. For more information, see Configure TCP/IP for static addressing.

**Note**

- When you install DNS using Configure Your server, the Configure Your DNS server Wizard runs after the DNS service is installed. The Configure Your DNS server Wizard prompts you to define either a forward or reverse lookup zone. To complete the test lab tasks, you must define a forward lookup zone that allows dynamic updates. The definition of a reverse lookup zone is optional.

**CLIENT1**

CLIENT1 is a computer running Windows XP Professional that is being used as a client. To configure CLIENT1 as a client computer, perform the following steps:

1. On CLIENT1, install Windows XP as a workgroup computer. Set the Administrator password.

2. After restarting, log on as Administrator.

3. Install the IPv6 protocol. For more information, see Install IPv6.

4. Configure the TCP/IP protocol with the IP address of 10.0.1.3, the subnet mask of 255.255.255.0, a default gateway of 10.0.1.1, and the DNS server IP address of 10.0.1.2. For more information, see Configure TCP/IP for static addressing and Configure TCP/IP to use DNS.

**ROUTER1**

ROUTER1 is a computer running Windows Server 2003, Standard Edition, that is being used as a router between Subnet 1 and Subnet 2. To configure ROUTER1 as a router, perform the following steps:

1. On ROUTER1, install Windows Server 2003, Standard Edition, as a workgroup computer. Set the Administrator password.

2. After restarting, log on as Administrator.

3. Install the IPv6 protocol. For more information, see Install IPv6.

4. For the interface on Subnet 1, configure the TCP/IP protocol with the IP address of 10.0.1.1, the subnet mask of 255.255.255.0, and the DNS server IP address of 10.0.1.2. For more information, see Configure TCP/IP for static addressing and Configure TCP/IP to use DNS.

5. For the interface on Subnet 2, configure the TCP/IP protocol with the IP address of 10.0.2.1, the subnet mask of 255.255.255.0, and a default gateway of 10.0.2.2. For more information, see Configure TCP/IP for static addressing.

6. Enable IP forwarding using Routing and Remote Access. For more information, see Enable the Routing and Remote Access service.

**ROUTER2**

ROUTER2 is a computer running Windows Server 2003, Standard Edition, that is being used as a router between Subnet 2 and Subnet 3. To configure ROUTER2 as a router, perform the following steps:

1. On ROUTER2, install Windows Server 2003, Standard Edition, as a workgroup computer. Set the Administrator password.

2. After restarting, log on as Administrator.

3. Install the IPv6 protocol. For more information, see Install IPv6.

4. For the interface on Subnet 2, configure the TCP/IP protocol with the IP address of 10.0.2.2, the subnet mask of 255.255.255.0, and a default gateway of 10.0.2.1. For more information, see Configure TCP/IP for static addressing.

5. For the interface on Subnet 3, configure the TCP/IP protocol with the IP address of 10.0.3.1, and the subnet mask of 255.255.255.0. For more information, see Configure TCP/IP for static addressing.

6. Enable IP forwarding using Routing and Remote Access. For more information, see Enable the Routing and Remote Access service.

**CLIENT2**

CLIENT2 is a computer running Windows XP that is being used as a client. To configure CLIENT2 as a client computer, perform the following steps:

1. On CLIENT2, install Windows XP as a workgroup computer. Set the Administrator password.

2. After restarting, log on as Administrator.

3. Install the IPv6 protocol. For more information, see Install IPv6.

4. Configure the TCP/IP protocol with the IP address of 10.0.3.2, the subnet mask of 255.255.255.0, and a default gateway of 10.0.3.1. For more information, see Configure TCP/IP for static addressing.

5. Verify the integrity of the IPv4 routing infrastructure by pinging 10.0.1.3 from the CLIENT2 computer.

# IPv6 test lab tasks

Updated: April 13, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 test lab tasks**

The following tasks are designed to take you through the common IPv6 configurations by using the test lab infrastructure configured in Setting up the IPv6 infrastructure.

- Link-local ping
- Creating a static routing infrastructure
- Using name resolution

To complete these tasks, you must use the Netsh commands for Interface IPv6 at the command prompt. For information about how to use Netsh, see Netsh overview. For the complete IPv6 Netsh reference, see Netsh commands for Interface IPv6.

**Note**

- The following instructions are for configuring a test lab using a minimum number of computers. Individual computers are needed to separate the services provided on the network and to clearly show the desired functionality. This configuration is neither designed to reflect best practices nor is it designed to reflect a desired or recommended configuration for a production network. The configuration, including IP addresses and all other configuration parameters, is designed only to work on a separate test lab network.

**Link-local ping**

To ping a host using link-local addresses and view the entries created in the neighbor and route caches, complete the following steps:

1. On DNS1, type the command **netsh interface ipv6 show address** to obtain the link-local address of the interface named **Local Area Connection**.

2. On CLIENT1, type the command **netsh interface ipv6 show address** to obtain the link-local address and interface index of the interface named **Local Area Connection**.

3. On CLIENT1, type the following command to ping the link-local address of DNS1:

   **ping***DNS1LinkLocalAddress***%***InterfaceIndex*

   For example, if the link-local address of DNS1 is FE80::2AA:FF:FE9D:10C5, and the interface index for the **Local Area Connection** interface on CLIENT1 is 3, the command is:

   **ping FE80::2AA:FF:FE9D:10C5%3**

4. On CLIENT1, type the following command:

   **netsh interface ipv6 show neighbors**

   to view the entry in the CLIENT1 neighbor cache for DNS1. For more information, see Neighbor Discovery (ND)

5. On CLIENT1, type the following command:

   **netsh interface ipv6 show destinationcache**

   to view the entry in the CLIENT1 destination cache for DNS1. For more information, see Neighbor Discovery (ND).

6. On CLIENT1, type the following command:

   **netsh interface ipv6 show routes**

   to view the entries in the CLIENT1 routing table. For more information, see The IPv6 routing table

**Creating a static routing infrastructure**

To configure a static IPv6 routing infrastructure so that all test lab nodes are reachable by using IPv6 traffic, complete the following steps:

1. On ROUTER1, type the **netsh interface ipv6 show address** command to obtain the interface indexes of the interfaces connected to Subnet 1 Connection, Subnet 2 Connection, and their link-local addresses.

2. On ROUTER2, type the **netsh interface ipv6 show address** command to obtain the interface indexes of the interfaces connected to Subnet 2 Connection, Subnet 3 Connection, and their link-local addresses.

3. On ROUTER1, type the following commands:

   **netsh interface ipv6 set interface"Subnet 1 Connection"forwarding=enabledadvertise=enabled**

   **netsh interface ipv6 set interface"Subnet 2 Connection"forwarding=enabledadvertise=enabled**

   **netsh interface ipv6 add route2001:DB8:0:1::/64interface="Subnet 1 Connection"publish=yes**

   **netsh interface ipv6 add route2001:DB8:0:2::/64"Subnet 2 Connection"publish=yes**

   **netsh interface ipv6 add route::/0"Subnet 2 Connection"nexthop=***ROUTER2AddressOnSubnet2***publish=yes**

   In the preceding command, *ROUTER2AddressOnSubnet2* represents the link-local address assigned to the Subnet 2 Connection interface on ROUTER2.

   For example, if the Subnet 2 Connection interface on ROUTER2 is FE80::2AA:FF:FE87:4D5C, the last command is typed as follows:

   **netsh interface ipv6 add route ::/0 "Subnet 2 Connection"nexthop=fe80::2aa:ff:fe87:4d5c publish=yes**

4. On ROUTER2, type the following commands:

   **netsh interface ipv6 set interface"Subnet 2 Connection"forwarding=enabledadvertise=enabled**

   **netsh interface ipv6 set interface"Subnet 3 Connection"forwarding=enabledadvertise=enabled**

   **netsh interface ipv6 add route2001:DB8:0:2::/64"Subnet 2 Connection"publish=yes**

   **netsh interface ipv6 add route2001:DB8:0:3::/64"Subnet 3 Connection"publish=yes**

   **netsh interface ipv6 add route::/0"Subnet 2 Connection"nexthop=***ROUTER1AddressOnSubnet2***publish=yes**

   In the preceding command, *ROUTER1AddressOnSubnet2* represents the link-local address assigned to the Subnet 2 Connection interface on ROUTER1.

For example, if the link-local address of the Subnet 2 Connection interface on ROUTER1 is FE80::2AA:FF:FE9A:203F, the last command should be typed as follows:

- **netsh interface ipv6 add route ::/0 "Subnet 2 Connection" nexthop=fe80::2aa:ff:fe9a:203f publish=yes**

On CLIENT1, type the command **netsh interface ipv6 show address** to obtain the address beginning with 2001:DB8

assigned to the interface named **Local Area Connection**.

On CLIENT2, type the following commands:

- **ping** *CLIENT1Address*
- **tracert -d** *CLIENT1Address*

**Using name resolution**

To view DNS AAAA (quad-A) records and test the use of DNS with IPv6, do the following:

1. On DNS1, open the DNS console. Under the server DNS1, click **Forward Lookup Zones**. In the right pane, open **testlab.microsoft.com**. In the right pane, you can view both IPv4 A records and IPv6 AAAA records. To view the quad-A record properties for one of the clients on your network, double-click the quad-A record.

   For example, for the CLIENT2 address of 2001:DB8::3:260:8FF:FE52:F9D8, the contents of the AAAA resource record are:

   Name: client2.testlab.microsoft.com

   Address: 2001:DB8::3:260:8FF:FE52:F9D8

2. On CLIENT1, type the following command:

   **ping -6 client2.testlab.microsoft.com**

   The name client2.testlab.microsoft.com is resolved to its address by sending a DNS query to DNS1.

3. On CLIENT2, create the following entry in the Hosts file (located in the *systemroot*\System32\Drivers\Etc folder):

   **client1***Client1Address*

4. On CLIENT2, type the following command:

   **ping -6 client1**

   The name client1.testlab.microsoft.com is resolved to its address by using the local Hosts file.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

# IPv6 Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

This section covers:

- IPv6 RFCs and Internet drafts
- IPv6 references
- IPv6 utilities

# IPv6 RFCs and Internet drafts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 RFCs and Internet drafts**

The following table displays the RFCs and Internet drafts that are implemented by the IPv6 protocol for the Windows Server 2003 family and Windows XP.

| RFC number or Internet draft | Title |
|---|---|
| 1752 | The Recommendation for the IP Next Generation Protocol |
| 1828 | IP Authentication Using Keyed MD5 |
| 1886 | DNS Extensions to support IP version 6 |
| 1933 | Transition Mechanisms for IPv6 Hosts and Routers |
| 1981 | Path MTU Discovery for IP version 6 |
| 2185 | Routing Aspects of IPv6 Transition |
| 2373 | IP Version 6 Addressing Architecture |
| 2374 | An IPv6 Aggregatable Global Unicast Address Format |
| 2401 | Security Architecture for the Internet Protocol |
| 2402 | IP Authentication Header |
| 2403 | The Use of HMAC-MD5-96 within ESP and AH (implemented for AH only) |
| 2404 | The Use of HMAC-SHA-1-96 within ESP and AH (implemented for AH only) |
| 2406 | IP Encapsulating Security Payload (ESP) |
| 2428 | FTP Extensions for IPv6 and NATs |
| 2460 | Internet Protocol, Version 6 (IPv6) Specification |
| 2461 | Neighbor Discovery for IP Version 6 (IPv6) |
| 2462 | IPv6 Stateless Address Autoconfiguration |
| 2463 | Internet Control Message Protocol (ICMPv6) for the Internet Protocol Version 6 (IPv6) Specification |
| 2464 | Transmission of IPv6 Packets over Ethernet Networks |
| 2467 | Transmission of IPv6 Packets over FDDI Networks |
| 2526 | Reserved IPv6 Subnet Anycast Addresses |
| 2529 | Transmission of IPv6 over IPv4 Domains without Explicit Tunnels |
| 2553 | Basic Socket Interface Extensions for IPv6 |
| 2710 | Multicast Listener Discovery (MLD) for IPv6 (implemented for host only) |

| | |
|---|---|
| 2711 | IPv6 Router Alert Option (implemented for host only) |
| 2732 | Format for Literal IPv6 Addresses in URLs |
| 3041 | Privacy Extensions for Stateless Address Autoconfiguration in IPv6 |
| 3056 | Connection of IPv6 Domains via IPv4 Clouds |
| Internet draft | An Extension of Format for IPv6 Scoped Addresses |
| Internet draft | Intra-Site Automatic Tunnel Addressing Protocol (ISATAP) |
| Internet draft | Default Address Selection for IPv6 |
| Internet draft | IP Version 6 Addressing Architecture |
| Internet draft | IP Version 6 Scoped Address Architecture |
| Internet draft | Mobility Support in IPv6 (host only) |
| Internet draft | Routing of Scoped Addresses in the Internet Protocol Version 6 (IPv6) |
| Internet draft | Site Prefixes in Neighbor Discovery |
| Internet draft | The UDP Lite Protocol |

**Obtaining RFCs and Internet drafts**
You can obtain RFCs and Internet drafts from the Internet Engineering Task Force Web site.

### Note

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# IPv6 references

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 references**

For more information about the IPv6 protocol suite, you can consult the following references:

- Davies, J. *Understanding IPv6*. Redmond, WA: Microsoft Press, 2002.
- Huitema, C. *IPv6: The New Internet Protocol*. Second edition. Upper Saddle River, NJ: Prentice Hall, 1998.
- Miller, M. *Implementing IPv6: Supporting the Next Generation of Protocols*. Second edition. Foster City, CA: M&T Books, 2000.

# IPv6 utilities

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPv6 utilities**
The following IPv6 command-line utilities are available for making configuration changes.

**Netsh commands for Interface IPv6**
You can configure the IPv6 protocol with the interface IPv6 context of Netsh.exe, which is used for both configuring and displaying the configuration of interfaces, addresses, caches, and routes.

Netsh commands for Interface IPv6 is a set of commands, each with its own set of parameters. In addition, you can use commands that are available in the **netsh interface IPv6 6to4** context to both configure or display the configuration of the IPv6 Helper service on either a 6to4 host or a 6to4 router.

For more information about using the IPv6 Helper service, see IPv6 traffic between nodes in different sites across the Internet (6to4).

For more information about Netsh, see Netsh overview.

For the complete Netsh interface IPv6 command reference, see Netsh commands for Interface IPv6.

**Ipsec6.exe**
You can use Ipsec6.exe to configure IPSec policies and security associations.

Ipsec6.exe has multiple commands, each with its own set of parameters.

- **ipsec6 sp** [*Interface*]

  Displays the active security policies. Alternately, displays the active security policies for a specific interface.

- **ipsec6 sa**

  Displays the active security associations.

- **ipsec6 l** *FileNameWithNoExtension*

  Loads the security policies from *FileName*.spd, and the security associations from *FileName*.sad.

- **ipsec6 s** *FileNameWithNoExtension*

  Saves the current security policies to *FileName*.spd, and the current security associations to *FileName*.sad. You can use this command to create files that are used to configure security policy and security associations. When there are no security policies or security associations, this command creates *FileName*.spd for security policies and *FileName*.sad for security associations. You can use these files as templates to configure the desired security policies or security associations by modifying them with a text editor.

- **ipsec6 d** [{**sp** | **sa**}] [*Index*]

  Deletes the security policies (using the **sp** parameter) or security associations (using the **sa** parameter) from the list of active security policies and security associations, as specified by index number. You can use **ipsec6 sp** or **ipsec6 sa** to display the index number.

- **ipsec6 m** [{**on** | **off**}]

  Specifies whether binding updates that are used for mobile IPv6 are protected by IP security. This is enabled by default.

**Caution**

- This implementation of IPSec for IPv6 is not recommended for use in a production environment because it relies on static keying and has no provisions for updating keys upon sequence number reuse.

- When you manually configure Security Policies Identifiers (SPIs), always use random numbers. Do not use sequential numbers for SPIs, or you will compromise the security of your IPSec for IPv6 policies.

- The IPv6 protocol for the Windows Server 2003 family does not support the use of IPSec Encapsulating Security Payload (ESP) encryption. However, the use of ESP with NULL encryption is supported. Although NULL encryption uses the ESP header, only data origin authentication and data integrity services are provided.

# Troubleshooting IPv6

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**
What problem are you having?

- A router is not advertising itself as a default router.
- A default route is not present on the host.
- Address has unexpected interface identifier.
- Internet Explorer is not connecting when literal IPv6 addresses are used in the URL.
- Off-link routes are in the routing table.
- Ping fails Echo Request messages when specifying a link-local destination.
- IPSec traffic is not encrypted.
- IPSec in IPv6 is not operating according to local or domain-based IPSec policies.
- Tunneled traffic is not reaching the destination.
- No IPv4-compatible address is configured on my Automatic Tunneling Pseudo-Interface.
- Unable to reach other 6to4 sites or the IPv6 Internet by using the 6to4 router.

**A router is not advertising itself as a default router.**
**Cause:** A computer running a member of the Windows Server 2003 family that is being used as an IPv6 router will not advertise itself as a default router unless it is configured with a default route (::/0) that is configured to be published.

**Solution:** Add a default route to the router computer and configure it to be published with the **netsh interface ipv6 add route** command.

**See also:** Netsh commands for Interface IPv6; Add an IPv6 route; IPv6 utilities; Setting up an IPv6 Test Lab

**A default route is not present on the host.**
**Cause:** A computer running a member of the Windows Server 2003 family that is being used as an IPv6 router will not advertise itself as a default router unless it is configured with a default route (::/0) that is configured to be published.

**Solution:** Add a default route to the router computer and configure it to be published with the **netsh interface ipv6 add route** command.

**See also:** Netsh commands for Interface IPv6; Add an IPv6 route; IPv6 utilities; Setting up an IPv6 Test Lab

**Address has unexpected interface identifier.**
**Cause:** A local router is configured to advertise a global prefix. By default, a temporary address that is based on the global prefix is automatically configured.

**Solution:** Use the **netsh interface ipv6 set privacy state=disabled** command to disable temporary addresses.

**See also:** Netsh commands for Interface IPv6; IPv6 interface identifiers; IPv6 utilities

**Internet Explorer is not connecting when literal IPv6 addresses are used in the URL.**
**Cause:** The version of the Internet Explorer provided with Windows Server 2003 family does not support the format for literal IPv6 addresses in URLs that is described in RFC 2732, "Format for Literal IPv6 Addresses."

**Solution:** Create DNS AAAA resource records that resolve Web server names to an IPv6 address and then use Web server names in the URL.

**See also:** IPv6 applications; IPv6 Name resolution

**Off-link routes are in the routing table.**
**Cause:** When a router running a member of the Windows Server 2003 family sends a Router Advertisement message, it includes Route Information options for directly attached subnets.

**Solution:** None. This is intended.

**See also:** IPv6 routing

**Ping fails Echo Request messages when specifying a link-local destination.**
**Cause:** The zone ID is not specified.

**Solution:** This is a common problem when a link-local destination address is used. Link-local addresses are often configured automatically for multiple interfaces. To specify the exact interface over which to send Echo Request messages, use the **ping***Address***%***ZoneID* syntax where *ZoneID* is the interface index for the interface over which the **ping** traffic is sent.

**See also:** Single subnet with link-local addresses; IPv6 utilities

**IPSec traffic is not encrypted.**
**Cause:** The IPv6 protocol for Windows Server 2003 family does not support the use of IPSec Encapsulating Security Payload (ESP) encryption. However, the use of ESP with NULL encryption is supported. Although NULL encryption uses the ESP header, only data origin authentication and data integrity services are provided.

**Solution:** None. This is a current limitation of the IPv6 protocol for Windows Server 2003 family and Windows XP.

**See also:** Security features for IPv6; Using IPSec between two local link hosts

**IPSec in IPv6 is not operating according to local or domain-based IPSec policies.**
**Cause:** IPSec support for IPv4 traffic is separate from IPSec support for IPv6 traffic. Local or domain-based IPSec policies configured with the IP Security Policies or Group Policy snap-ins are for IPv4 traffic only. These policies have no effect on IPv6 traffic.

**Solution:** None. This is a current limitation of the IPv6 protocol for Windows Server 2003 family and Windows XP.

**See also:** Security features for IPv6; Using IPSec between two local link hosts

**Tunneled traffic is not reaching the destination.**
**Cause:** Routers or firewalls are dropping IPv4 traffic that has the IP Protocol field value set to 41.

**Solution:** All IPv6 traffic that is encapsulated (tunneled) inside of an IPv4 header has the IPv4 Protocol field in the header set to 41. IPv6 tunneled traffic includes traffic that uses IPv4-compatible addresses, 6over4 addresses, ISATAP addresses, and 6to4 addresses. To allow IPv6 tunneled traffic to be forwarded, configure your routers or firewalls to pass IPv4 traffic that has the Protocol field set to 41.

**See also:** Security features for IPv6; Using IPSec between two local link hosts

**No IPv4-compatible address is configured on my Automatic Tunneling Pseudo-Interface.**
**Cause:** You do not have a public IPv4 address assigned to any of your interfaces or IPv4-compatible addresses are not enabled.

**Solution:** Because IPv4-compatible addresses have a global scope and are globally unique, IPv4-compatible addresses that are derived from private addresses are not allowed. Private addresses for the IPv6 protocol for Windows Server 2003 family and Windows XP are defined by the following ranges: 10.0.0.0/8, 172.16.0.0/12, 192.168.0.0/16, and 169.254.0.0/16. Configure a public IPv4 address on one of your interfaces using the **netsh interface ipv6 set state** command.

**See also:** Netsh commands for Interface IPv6

**Unable to reach other 6to4 sites or the IPv6 Internet by using the 6to4 router.**
**Cause:** Your firewall or Internet router is dropping IPv4 traffic that has the IP Protocol field value set to 41.

**Solution:** All IPv6 traffic that is encapsulated (tunneled) inside of an IPv4 header has the IPv4 Protocol field in the header set to 41. IPv6 tunneled traffic includes traffic that uses IPv4-compatible addresses, 6over4 addresses, and 6to4 addresses. To allow IPv6 tunneled traffic to be forwarded, configure your firewall or Internet router to pass IPv4 traffic that has the Protocol field set to 41.

**Cause:** You are unable to resolve the DNS name 6to4.ipv6.microsoft.com.

**Solution:** By default, the IPv6 Helper service attempts to first resolve the name 6to4.ipv6.microsoft.com to its IPv4 addresses and then choose a relay router. If you cannot resolve the name 6to4.ipv6.microsoft.com, a relay router is not configured and you cannot reach any locations on the IPv6 Internet. Type **ping 6to4.ipv6.microsoft.com** to determine whether you can resolve the name 6to4.ipv6.microsoft.com.

**Cause:** You do not have the correct route.

**Solution:** View the display of the **netsh interface ipv6 show routes** command. You should see a **2002::/16** route that uses the 6to4 Tunneling Pseudo-Interface to send all traffic.

**Cause:** You do not have the correct address.

**Solution:** Verify that you have a 6to4 address assigned before attempting to reach a destination. For example, without a 6to4 address, you might be using a link-local address to reach a 6to4 global address. Use the display of the **netsh interface ipv6 show interface** command to determine your address configuration.

# Internet Protocol Security (IPSec)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Protocol security (IPSec)**
Internet Protocol security (IPSec) is a framework of open standards for ensuring private, secure communications over Internet Protocol (IP) networks, through the use of cryptographic security services.

- For tips about using IPSec, see IPSec Best practices.
- For help with specific tasks, see IPSec How To....
- For general background information, see IPSec Concepts.
- For problem-solving instructions, see IPSec Troubleshooting.

### Note

- Portions of IPSec-related services were jointly developed by Microsoft® and Cisco Systems, Inc.

# IPSec Best practices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices**

- **Establish an IPSec deployment plan**.

  The deployment plan should address the following considerations: which deployment scenarios (such as server-to-server or remote access) require the use of IPSec, what level of security you require for each scenario, which types of data to secure, which computers to secure, which physical links to secure, who will manage IPSec policies, and how you will provide ongoing support and troubleshooting for end users after IPSec is deployed. The deployment plan should also address broader organizational security issues, such as the vulnerability of the network to specific types of attacks, the use of Active Directory, and how security is applied to Group Policy objects.

  For more information about IPSec security planning, see Establishing an IPSec security plan.

  For more information about Active Directory, see Active Directory Overview.

- **Create and test IPSec policies for each deployment scenario**.

  Before deploying IPSec in a production environment, test the IPSec policies in a realistic lab environment. To obtain realistic performance data, run standard workloads on programs. During initial tests, view packet contents with Network Monitor, or use Authentication Header (AH) or Encapsulating Security Payload (ESP) with null encryption to view packet contents for test environments.

- **Do not use preshared keys**.

  For enhanced security, the use of preshared key authentication is not recommended because it is a relatively weak authentication method. In addition, preshared keys are stored in plaintext. Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing and that you use certificates or Kerberos V5 instead in a production environment.

  For more information, see Preshared key authentication.

- **Do not use Diffie-Hellman Group 1 (low)**.

  For enhanced security, do not use Diffie-Hellman Group 1, which provides 768 bits of keying strength. For maximum security, use Group 2048 (high), which provides 2,048 bits of keying strength. Use Group 2 (medium), which provides 1,024 bits of keying strength when required for interoperability with Windows 2000 and Windows XP. Strong Diffie-Hellman groups combined with longer key lengths increase the computational difficulty of determining a secret key.

  For more information, see Key exchange methods.

  **Note**

  - Diffie-Hellman Group 2048 is provided only with the Windows Server 2003 family.

- **Use the Triple Data Encryption Standard (3DES) algorithm for stronger encryption**.

  For enhanced security, when configuring key exchange security methods for IPSec policies, use 3DES, which is a stronger encryption algorithm than DES.

  For information about how to configure key exchange security methods, see Create key exchange security methods.

  **Note**

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

- **Create and assign a persistent IPSec policy for failsafe security**.

  To enhance security, create and assign a persistent IPSec policy, so that computers can be secured if a local IPSec policy or an Active Directory-based IPSec policy cannot be applied. When you create and assign a persistent policy, it is applied before a local policy or an Active Directory-based policy, and it remains in effect regardless of whether the local policy or the Active Directory-based policy is applied (for example, an IPSec policy will not be applied if it is corrupted).

  **Note**

  - You cannot configure this feature in the IP Security Policy Management console. To configure this feature, you must use the Netsh IPSec command-line tool. For more information, see Netsh commands for Internet Protocol security.

- **For computers connected to the Internet, do not send the name of the certification authority (CA) with certificate requests**.

  When certificate authentication is used to establish trust between IPSec peers, each IPSec peer sends to the other peer a list of trusted root CAs from which it accepts a certificate for authentication. Each of these CA names is sent as a certificate request payload (CRP), and it must be sent before trust is established. Although transmitting this list aids in connectivity by facilitating the selection of a CA, it can expose sensitive information about the trust relationships of a computer, such as the name of the company that owns the computer and the domain membership of the computer (if an internal public key infrastructure is being used), to an attacker. Therefore, to secure computers that are connected to the Internet, enable the option to exclude the CA name from the certificate request.

- **For computers connected to the Internet, do not use Kerberos as an authentication method**.

  When Kerberos V5 authentication is used, during main mode negotiation, each IPSec peer sends its computer identity in unencrypted format to the other peer. The computer identity is unencrypted until encryption of the entire identity payload takes place during the authentication phase of the main mode negotiation. An attacker can send an Internet Key Exchange (IKE) packet that causes the responding IPSec peer to expose its computer identity and domain membership. To secure computers that are connected to the Internet, certificate authentication is recommended.

  For more information, see Authentication methods.

- **For computers that are connected to the Internet, do not allow unsecured communication**.

  If you configure a filter action to negotiate IPSec security, ensure that the following options are disabled in order to secure computers that are connected to the Internet:

  - **Accept unsecured communication, but always respond using IPSec**. This option allows initial incoming unsecured traffic (for example, TCP SYN packets) but requires outgoing traffic to be protected. This option should be disabled to prevent denial-of-service attacks.

  - **Allow unsecured communication with non-IPSec-aware computers**. This option allows unsecured communications with computers that cannot negotiate the use of IPSec or process IPSec-secured communications, and it is appropriate only in environments where IPSec-secured communication is not necessary.

    For more information, see Filter action.

- **Restrict the use of administrative credentials in your organization**.

  Members of the local Administrators group can view and modify the IPSec policy settings on their computers. For this reason, and as a general security best practice, ensure that end-users in your organization use the principle of least privilege.

  For information about general best practices for security, see Best practices for security for security.

- **When applying the same IPSec policy to computers running different versions of the Windows operating system, test the policy thoroughly**.

  Several features in the Windows Server 2003 family implementation of IPSec are not provided in Windows 2000 or in Windows XP. These new features include:

  - A stronger Diffie-Hellman group (2,048-bit Diffie-Hellman key exchange).
  - The ability for IPSec policy filters to allow logical addresses for local IP configuration.
  - The removal of default traffic exemptions from IPSec filtering (only Internet Key Exchange traffic is now exempt by default).
  - The ability to exclude the name of the certification authority (CA) from a certificate request.

  To ensure that the same IPSec policy functions as expected on computers running the Windows Server 2003 family and on computers running Windows XPor Windows 2000, test the policy thoroughly on all relevant operating systems before deployment.

  For more information about new features in IPSec, see New features for IPSec.

- **Use the** Windows Server 2003 **IP Security Policy Management console to manage the IPSec policies that use the new features that are available only in the** Windows Server 2003 **family implementation of IPSec**.

  If you plan to apply IPSec policies that use any of the new features that are available only in the Windows Server 2003 family implementation of IPSec, do not use the Windows XP or the Windows 2000 version of the IP Security Policy Management console to manage these policies. The settings in the earlier versions of the IP Security Policy Management console will override the settings in the Windows Server 2003 family IPSec policy, and the new features will not be functional.

- **Use Terminal Services to remotely manage and monitor IPSec on computers running different versions of the Windows operating system**.

  Remote management and monitoring of IPSec is supported only for computers running the same version of the Windows operating system. To remotely manage and monitor IPSec on a computer that is running a different version of Windows than the version of Windows that is running on your computer, use Terminal Services. For example, if your computer is running the Windows Server 2003 family, and you plan to remotely manage and monitor IPSec on computers running Windows 2000 or Windows XP, use Terminal Services to gain remote access to these computers.

  If your computer is running the Windows Server 2003 family, and you plan to manage and monitor IPSec on computers that are also running the Windows Server 2003 family, you can run the IPSec Policy Management console and IP Security Monitor, or you can use the Netsh command-line tool remotely.

# IPSec How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

- Start the IP Security Policy Management snap-in
- Define IPSec Policies
- Assign IPSec Policy
- Manage IPSec Policy
- Use Resultant Set of Policy (RSoP) to View IPSec Policy Assignments
- Monitor IPSec Activity

# Start the IP Security Policy Management snap-in

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start the IP Security Policy Management snap-in**

- To start the IP Security Policy Management snap-in from the Microsoft Management Console:

1. Click **Start**, click **Run**, type **MMC**, and then click **OK**.
2. Click **File**, click **Add/Remove Snap-in**, and then click **Add**.
3. Click **IP Security Policy Management**, and then click **Add**.
4. Select the computer for which you want to manage IPSec policies:

| To | Do this |
|---|---|
| Manage only the computer on which this console is running | Click **Local computer** |
| Manage IPSec policies for any domain members | Click **The Active Directory domain of which this computer is a member**. |
| Manage IPSec policies for a domain of which the computer that is running this console is not a member | Click **Another Active Directory Domain**. |
| Manage a remote computer | Click **Another computer**. |

5. Click **Finish**, click **Close**, and then click **OK**.

- To access the IP Security Policy Management snap-in from Group Policy (Active Directory):

1. Open Active Directory Users and Computers.
2. In the console tree, right-click the domain or organizational unit for which you want to set Group Policy.

   **Where?**

   - Active Directory Users and Computers [*DomainControllerName.DomainName*]/*Domain*/*OrganizationalUnit*/*ChildOrganizationalUnit*...

3. Click **Properties**, and then click the **Group Policy** tab.
4. Click **Edit** to open the Group Policy object that you want to edit. Or, click **New** to create a new Group Policy object, and then click **Edit**.
5. In the Group Policy console tree, click **IP Security Policies on Active Directory**.

   **Where?**

   - *PolicyName* [*ComputerName*] Policy/Computer Configuration/Windows Settings/Security Settings/IP Security Policies on Active Directory

- To access the IP Security Policy Management snap-in from Local Computer Policy:

1. Click **Start**, click **Run**, type **MMC**, and then click **OK**.
2. Click **File**, click **Add/Remove Snap-in**, and then click **Add**.
3. Click **Group Policy Object Editor**, and then click **Add**.
4. Click **Finish**, click **Close**, and then click **OK**.
5. In the Group Policy console tree, click **IP Security Policies on Local Computer**.

   **Where?**

   - Local Computer Policy/Computer Configuration/Windows Settings/Security Settings/IP Security Policies on Local Computer

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- To save console settings, on the **File** menu, click **Save**.
- To view the saved console, see Related Topics.
- You cannot administer Active Directory-based IPSec policy from a computer running Windows XP Home Edition.
- To manage policies in a remote domain, you must be using a computer that is a member of a domain that is trusted by the remote domain. You cannot configure policies in a remote domain from a computer that is a member of a workgroup (also known as a stand-alone computer).
- To revise your initial choice, you can start the Microsoft Management Console, add this snap-in again, and save the console again. If you require multiple configurations, you can save the console with another name.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Define IPSec Policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Define IPSec policies**

- Add, edit, or remove IPSec policies
- Define IPSec Rules
- Define IPSec Key Exchange Settings

# Add, edit, or remove IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add, edit, or remove IPSec policies**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.

2. Choose whether to add a new policy, or edit or remove an existing one:

| To | Do this |
|---|---|
| Add a new policy | In the console tree, click **IP Security Policies on *Name***. Next, on the **Action** menu, click **Create IP Security Policy**. Follow the instructions in the IP Security Policy Wizard until the **Properties** dialog box for your new policy appears. |
| Modify an existing policy | Double-click the policy that you want to modify. |
| Remove a policy | Click the policy that you want to remove, and on the **Action** menu, click **Delete**. |

3. If you are adding or modifying a policy, click the **General** tab, and then in **Name**, type a unique name.

4. In **Description**, type a description of the security policy, such as which groups or domains it affects.

5. To specify how often the IPSec Policy Agent checks for updates, type a value in **Check for policy changes every numberminute(s)**.

6. If you have special requirements for the security of the key exchange, click **Settings**.

7. Click the **Rules** tab, and create or modify any necessary rules for the policy.

8. Activate or deactivate rules as needed.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

- For information about defining IPSec key exchange settings, see Related Topics.

- For information about configuring IPSec rules, see Related Topics.

- For information about how to activate or deactivate rules, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Define IPSec Rules

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Define IPSec rules**

- Add, edit, or remove IPSec rules
- Activate or deactivate IPSec rules
- Define IPSec authentication methods
- Specify IPSec connection types
- Specify an IPSec tunnel
- Define IP Filter Lists
- Define Filter Actions

# Add, edit, or remove IPSec rules

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add, edit, or remove IPSec rules**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. To add a rule, decide whether you want to use the Create IP Security Rule Wizard or add the rule manually:
   - To add a rule by using the Create IP Security Rule Wizard, confirm that the **Use Add Wizard** check box is selected, click **Add**, and then follow the instructions.
   - To add a rule manually, confirm that the **Use Add Wizard** check box is cleared, click **Add**, and then define settings on the **IP Filter List**, **Filter Action**, **Authentication Methods**, **Tunnel Setting**, and **Connection Type** tabs.
4. To edit a rule, select the rule that you want to edit, click **Edit**, and then modify the rule properties as needed.
5. To remove a rule, select the rule that you want to remove, and then click **Remove**.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- New rules are automatically applied to the policy being edited or created.
- The rules for a policy are displayed in IP Security Policies in reverse alphabetical order, based on the name of the filter list selected for each rule. There is no method to specify an order in which to apply the rules in a policy. The IPSec driver automatically orders the rules based on the most specific filter list to the least specific filter list. For example, the IPSec driver places a rule containing a filter list that specifies individual IP addresses and TCP ports above a rule containing a filter list that specifies all addresses on a subnet.
- The default response rule is automatically added to every new IPSec policy. If you do not want this rule to be part of your policy, you can deactivate it by clearing the check box next to **<Dynamic>**. The default response rule cannot be removed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Define IPSec authentication methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To define IPSec authentication methods**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that you want to modify.
4. On the **Authentication Methods** tab, click **Add**. Or, if you are reconfiguring an existing method, click the authentication method, and then click **Edit**.
5. Select the authentication method that you want to add or modify:
   - To use the Kerberos V5 security protocol for authentication services, click **Active Directory default (Kerberos V5 protocol)** if this rule applies to computers that are validated by a Windows 2000 or Windows Server 2003 Active Directory domain or a trusted Active Directory domain.
   - To use a public key certificate for authentication services, click **Use a certificate from this certification authority (CA)**, and then click **Browse** to select a root CA.
   - To prevent the name of the CA from being sent with the certificate request, select the **Exclude the CA name from the certificate request** check box.
   - To enable certificate to account mapping, select the **Enable certificate to account mapping** check box.
   - To specify your own key that will be used for authentication, click **Use this string (preshared key)**.
6. To delete an authentication method or change its preference order, do one of the following:
   - To delete the selected method, click **Remove**.
   - To move the selected method up one level, click **Move up**. Repeat until the method is at the required preference level.
   - To move the selected method down one level, click **Move down**. Repeat until the method is at the required preference level.

**Important**

- The use of preshared key authentication is not recommended because it is a relatively weak authentication method. Preshared key authentication creates a master key that is less secure (that might produce a weaker form of encryption) than certificates or the Kerberos V5 protocol. In addition, preshared keys are stored in plaintext. Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing and that you use certificates or Kerberos V5 instead in a production environment.

**Notes**

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a

computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

- The Kerberos V5 protocol authentication method is not supported on computers running Windows XP Home Edition.

- If you choose to use a certificate for authentication, you must select a CA (most commonly the root CA for your installed computer certificate). You cannot leave this field blank.

- For preshared key authentication, each IPSec peer must use the same preshared key, or authentication will fail.

- If filters in more than one rule apply to traffic between the same two IP addresses, then the authentication methods list should be identical in both rules. Otherwise, security requests that are initiated by one rule might match the filter of the other rule, but have a different authentication method. In this case, the negotiation will fail. After a rule has initiated a successful main mode security association between two IP addresses, other rules that are filtering different traffic will not renegotiate the authentication and master key (the main mode security association). Instead, these other rules will use the same main mode security association to negotiate security (algorithms and session keys) for traffic that matches their particular filter.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Specify IPSec connection types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify IPSec connection types**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that you want to modify.
4. On the **Connection Type** tab, select the type of network connections to which this rule will apply:
   - To apply this rule to all network connections you have created on the computer, click **All network connections**.
   - To apply this rule to all LAN connections you have created on the computer, click **Local area network (LAN)**.
   - To apply this rule to any remote VPN or dial-up connections you have created on the computer, click **Remote access**.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

**Information about functional differences**

# Specify an IPSec tunnel

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify an IPSec tunnel**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that you want to modify.
4. On the **Tunnel Setting** tab, specify the computer that will be the tunnel endpoint:

| To | Do this |
|---|---|
| Disable tunneling for this rule | Click **This rule does not specify an IPSec tunnel**. |
| Use tunneled communications to a specific tunnel endpoint | Click **The tunnel endpoint is specified by this IP address** and type the IP address of the tunnel endpoint. |

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- Because you cannot mirror filters for tunneled traffic, you must configure two rules. One rule is used for the outbound traffic and the other is used for inbound traffic. For the outbound traffic rule, the tunnel endpoint is the IP address of the IPSec peer on the other end of the tunnel. For the inbound traffic rule, the tunnel endpoint is an IP address configured on the local computer.
- IPSec tunnels are not supported for remote access VPN scenarios. L2TP/IPSec or PPTP should be used for remote access VPN connections. IPSec tunnels are used primarily for interoperability with other routers, gateways, or end-systems that do not support L2TP/IPSec or PPTP connections. IPSec tunnel mode is supported as an advanced feature, used only in gateway-to-gateway (also known as router-to-router) tunneling scenarios and for server-to-server or server-to-gateway configurations.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Define IP Filter Lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Define IP filter lists**

- Add, edit, or remove IP filter lists
- Add, edit, or remove IPSec filters
- Configure advanced IPSec filter settings
- Set an active IP filter list for a rule
- Manage multiple IP filter lists

# Add, edit, or remove IP filter lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add, edit, or remove IP filter lists**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that contains the IP filter list that you want to modify.
4. On the **IP Filter List** tab, do one of the following:
   - To add a new IP filter list, click **Add**.
   - To modify an existing IP filter list, click the filter list that you want to modify, and then click **Edit**.
   - To remove an IP filter list, click the filter list that you want to remove, and then click **Remove**.
5. If you are adding or modifying an IP filter list, type a unique name for the list.
6. Type a description to specify which computers and traffic types the IP filter list encompasses (for example, "Matches all TCP packets between this computer and any other computer").
7. Create or modify the filters as needed.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- For procedures on creating filters and advanced filter settings, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add, edit, or remove IPSec filters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add, edit, or remove IPSec filters**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that contains the IP filter list you want to modify.
4. On the **IP Filter List** tab, double-click the IP filter list that contains the IPSec filter you want to modify.
5. In the **IP Filter List** dialog box, do one of the following:
   - To add a filter, click **Add**.
   - To modify an existing filter, select the filter that you want to modify, and then click **Edit**.
   - To remove an existing filter, select the filter that you want to remove, and then click **Remove**.
6. If you are adding or editing a filter, in **IP Filter Properties**, the **Addresses** tab, and then select the **Source Address**:

| Select | To secure packets from |
|---|---|
| **My IP Address** | All IP addresses on the computer for which you are configuring this filter. |
| **Any IP Address** | Any computer. |
| **A Specific DNS Name** | The Domain Name System (DNS) name that you specify in **Host name**. The DNS name is resolved to its IP addresses, and then filters are automatically created for the resolved IP addresses. This option is only available when creating new filters. |
| **A Specific IP Address** | The IP address that you specify in **IP Address**. |
| **A Specific IP Subnet** | The IP subnet, as defined by the IP address that you specify in **IP Address** and the subnet mask that you specify in **Subnet Mask**. |
| **DNS Servers <dynamic>** | The DNS server(s) for the computer for which you are configuring this filter. Changes in DNS server addresses are automatically detected, and the filter is updated as needed. |
| **WINS Servers <dynamic>** | The WINS server(s) for the computer for which you are configuring this filter. Changes in WINS server addresses are automatically detected, and the filter is updated as needed. |
| **DHCP Server <dynamic>** | The DHCP server for the computer for which you are configuring this filter. Changes in DHCP server addresses are automatically detected, and the filter is updated as needed. |
| **Default Gateway <dynamic>** | The default gateway for the computer for which you are configuring this filter. Changes in default gateway server addresses are automatically detected, and the filter is updated as needed. |

7. Click **Destination Address**, and repeat step 6 for the destination address.

8. Select the appropriate **Mirrored** setting:

| To | Do this |
|---|---|
| Automatically create two filters based on the filter settings, one for traffic to the destination and one for traffic from the destination | Select the **Mirrored** check box. |
| Create a single filter based on the filter settings | Clear the **Mirrored** check box. |
| Create a filter for an IPSec tunnel | Clear the **Mirrored** check box. For IPSec tunnels, you must create two filter lists: one list describes the traffic to be sent through the tunnel (outbound traffic) and another describes the traffic to be received through the tunnel (inbound). Then, create two rules that use the inbound and outbound filter lists in your policy. |

9. On the **Description** tab, in **Description**, type a description for this filter (for example, specify to what computers and traffic types it applies).

10. If you require additional IP filtering by a specific protocol or port number, on the **Protocol** tab, configure advanced filter settings.

**Caution**

Filters are the most important part of IPSec policy for a computer which is protected by IPSec. If you do not specify the proper filters in either client or server policies, or if the IP addresses change before the policy's filters are updated, security might not be provided.

- When adding a new static IP address to a protected computer:
    - Modify the IPSec policy filters on all clients and servers that make security requests to the protected computer. Ensure that those clients have updated their policy before adding the new address.
    - Inspect the policy being used on the protected computer. If the filters specify static IP addresses for local connections, after adding the new IP address to the interface, edit and save the new filter list to include the new static IP address. **My IP Address** filters will be automatically updated when the new static IP address is added.
- If the protected computer is a Web server and your clients use a proxy server, make sure that communications over all network paths are secured by IPSec:
    - Between the Web server and all clients that directly connect
    - Between the Web server and the proxy server
    - Between the proxy server and all clients of the proxy server
- The following filter is internally defined to permit (not secure) Internet Key Exchange (IKE) traffic:
    - Source Address = Any
    - Destination Address = Any
    - Protocol = UDP
    - Source port = 500

- Destination port = 500

**Important**

- In the Windows Server 2003 family, IPSec provides new source and destination address options for defining filters. In addition, the default behavior for traffic exemptions has changed. If you require previously exempted traffic types, you must create filters to permit this traffic. For instructions on how to configure permit filters for previously exempted traffic types and information about other IPSec special considerations, see Related Topics.

**Notes**

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

- To configure IP protocol, TCP port, or UDP port settings for a filter, see Related Topics.

- For IPSec tunnel rules, only address-based filters are supported. Protocol-specific and port-specific filters are not supported. Tunnel filters should not be mirrored.

- Filters are applied in the order of most-specific filters first. Filters are not applied in the order in which they appear in the list.

- If an outbound packet does not match any filter, it is sent unsecured.

- If an inbound packet does not match any filter, it is permitted.

- If an IKE security request is received, the source IP address of the request is used to find a matching filter. The security action and tunnel setting that is associated with that filter determines the IKE response.

- The **A specific DNS Name** option is used when creating filters to create IP address-based filters by resolving a DNS name to its IP addresses. The use of a computer name is for the one-time resolution of DNS names to IP addresses when creating the filter. The computer name is not used after the filters are created.

- All filters used in tunnel rules are matched first, before end-to-end transport filters are matched.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure advanced IPSec filter settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure advanced IPSec filter settings**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that contains the IP filter list you want to modify.
4. On the **IP Filter List** tab, double-click the IP filter list that contains the IPSec filter you want to modify.
5. In the **IP Filter List** dialog box, click the filter that you want to modify, and then click **Edit**.
6. In **IP Filter Properties**, click the **Protocol** tab, and then specify settings for **Select a protocol type**:

| To filter | Do this |
|---|---|
| Any packets sent on any protocol | Click **Any**. |
| Traffic sent on a specific protocol | Click the protocol. |
| Packets sent on a custom protocol | Click **Other**, and then type the protocol number. |

7. If you chose TCP or UDP, you can also filter packets by the source port.

   - To filter packets sent on any port used by the protocol type that you selected, click **From any port**.
   - To filter packets sent on a specific port used by the protocol type that you selected, click **From this port**, and then type the port number.

   If you chose TCP or UDP, you can also filter packets by the destination port.

   - To filter packets received on any port used by the protocol type that you selected, click **To any port**.
   - To only filter packets received on the port number that you specify, click **To this port**, and then type the port number.

**Caution**

- An erroneous port number might cause communication to be blocked or unsecured. If you are unsure of the correct value, see the Windows Resource Kits in Related Topics.

**Notes**

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

- For IPSec tunneling, only address-based filters are supported. Protocol-specific and port-specific filters are not supported.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set an active IP filter list for a rule

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set an active IP filter list for a rule**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that contains the IP filter list you want to modify.
4. On the **IP Filter List** tab, select the option that precedes the name of the IP filter list that you want to designate as the active filter list for this rule.

   The IP filter list you selected is now the active filter list for the rule.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- If the option preceding the name of an IP filter list is not selected, the IP filter list will not be set as active for the rule.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage multiple IP filter lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manage multiple IP filter lists**

1. In **IP Security Policies**, in the console tree, click **IP Security Policies on *Name***.
2. On the **Action** menu, click **Manage IP filter lists and filter actions**.
3. On the **Manage IP Filters Lists** tab, click **Add**. Or, if you are modifying an existing list, double-click that list.
4. Define the filters for the filter list.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Define Filter Actions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Define filter actions**

- Add, edit, or remove filter actions
- Add, edit, or remove IPSec security methods
- Configure custom IPSec security methods
- Select a filter action for a rule
- Manage multiple filter actions

# Add, edit, or remove filter actions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add, edit, or remove filter actions**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that you want to modify, and then click the **Filter Action** tab.
4. To add a filter action, decide whether you want to use the IP Security Filter Action Wizard or add the filter action manually:
   - To add a filter action by using the IP Security Filter Action Wizard, confirm that the **Use Add Wizard** check box is selected, click **Add**, and then follow the instructions.
   - To add a filter action manually, confirm that the **Use Add Wizard** check box is cleared, click **Add**, and then define settings on the **Security Methods** and **General** tabs.
5. To modify an existing filter action, select the filter action that you want to modify, and then click **Edit**.
6. To remove a filter action, select the filter action that you want to remove, and then click **Remove**.
7. If you are adding or modifying a filter action, choose a filter action type:
   - Click **Permit** to allow receiving or sending of packets in plaintext (unsecured traffic). Security will not be requested for these packets.
   - Click **Block** to discard packets. Security will not be requested for these packets.
   - Click **Negotiate security** to use the list of security methods in **Security method preference order** to provide security for packets that match this filter. Security requests will be accepted for these packets.
8. If you chose **Negotiate security**, add new security methods or edit the existing ones for the filter action.
9. If you do not want to block incoming, unsecured communications, but you want to ensure that all outgoing communications and subsequent two-way communications are secured, select the **Accept unsecured communication, but always respond using IPSec** check box.
10. To enable communication with other computers that do not support IPSec, and ensure that communication continues if there is no response to a request for IPSec negotiation, select the **Allow unsecured communication with non-IPSec-aware computers** check box. After the initial IPSec negotiation has failed, IPSec negotiation will be retried at five minute intervals.
11. To guarantee that no master keys or master keying material will be reused to generate the session key, select the **Use session key perfect forward secrecy (PFS)** check box.
12. On the **General** tab, in **Name**, type a unique name.
13. In **Description**, type a description. For example, you might type what security levels this filter action represents.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

- The filter action types **Permit** and **Block** and the options to **Allow unsecured communication with non-IPSec-aware computers** and **Accept unsecured communication, but always respond using IPSec** are not available in the default response rule.

- Session key perfect forward secrecy (PFS) renegotiates new master key keying material during every session rekey operation. This is the most secure setting. However, it adds overhead and increases the time required to complete a rekey operation. Both initiator and responder must be configured with the same setting for successful negotiation.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Working with MMC console files

# Add, edit, or remove IPSec security methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add, edit, or remove IPSec security methods**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that you want to modify, and then click the **Filter Action**tab.
4. Double-click the filter action that you want to modify.
5. On the **Security Methods** tab, click **Negotiate security**, and then do one of the following:
   - To add a new security method, click **Add**.
   - To modify an existing security method, click the security method that you want to modify, and then click **Edit**.
   - To remove a security method, click the security method that you want to remove, and then click **Remove**.
6. If you are adding or modifying a security method, on the **Security Method** tab, select the security level:
   - To use the ESP protocol to provide data confidentiality (encryption) with the triple Data Encryption Standard (3DES) algorithm, data integrity and authentication with the Secure Hash Algorithm 1 (SHA1) integrity algorithm, and default key lifetimes (100MB, 1 hour), click **Integrity and Encryption**.
   - To use the ESP protocol to provide data integrity and authentication with the SHA1 integrity algorithm and default key lifetimes (100MB, 1 hour), click **Integrity only**. ESP is not configured to provide data confidentiality (encryption).
   - Click **Custom**, and then click **Settings** to configure a custom security method or key lifetimes. For more information, see Related Topics.
7. Repeat this procedure to configure additional security methods for the filter action.

**Notes**

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should

only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 server operating system support 3DES and do not require installation of the High Encryption Pack.

- Click **Move up** to move the selected security method up one level. Repeat until the security method is at the required preference level.

- Click **Move down** to move the selected security method down one level. Repeat until the security method is at the required preference level.

- For information about how key lifetimes affect security, see **Filter action** in Related Topics.

- When negotiating security, the initiator proposes this list of security methods to the responder. The responder agrees to the first method (from the top down) that is found anywhere in its own security methods list. If none of the proposed security methods match an entry in the responder's list, then the responder fails the negotiation.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure custom IPSec security methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure custom IPSec security methods**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that you want to modify, and then click the **Filter Action** tab.
4. Double-click the filter action that you want to modify.
5. On the **Security Methods** tab, do one of the following:
   - To add a new security method, click **Add**.
   - To modify an existing security method, click the security method that you want to modify, and then click **Edit**.
   - To remove a security method, click the security method that you want to remove, and then click **Remove.**
6. If you are adding or modifying a security method, on the **Security Method** tab, click **Custom**, and then click **Settings**.
7. To provide integrity for both the packet's addressing information (IP header) and the data, select the **Data and address integrity without encryption (AH)** check box, and then, in **Integrity algorithm**, click one of the following:
   - **MD5** to use the Message Digest 5 (MD5) integrity algorithm, which uses a 128-bit key.
   - **SHA1** to use the Secure Hash Algorithm 1 (SHA1) integrity algorithm, which uses a 160-bit key.
8. To provide both integrity and encryption (confidentiality) for the data, select the **Data integrity and encryption (ESP)** check box, and then, in **Integrity algorithm**, click one of the following:
   - **<None>** to use no data integrity.

     If you have enabled **AH**, you can click **None** for the ESP integrity algorithm to improve performance.
   - **MD5** to use the MD5 integrity algorithm, which uses a 128-bit key.
   - **SHA1** to use the SHA1 integrity algorithm, which uses a 160-bit key.
9. If you selected the **Data integrity and encryption (ESP)** check box, in **Encryption algorithm**, click one of the following:
   - **<None>** to use no encryption.
   - **DES** to use Data Encryption Standard (DES) with a 56-bit key.
   - **3DES** to use the triple DES (3DES) with three 56-bit keys.

10. To change the default session key lifetime settings, do one of the following:

    - To specify the number of kilobytes of data transferred before a new session key is generated, select the **Generate a new key every** check box, and then type a value in **Kbytes**.

    - To specify the number of seconds that elapse before a new session key is generated, select the **Generate a new key every** check box, and then type a value in **seconds**.

**Notes**

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

- You cannot choose **<None>** for both the ESP integrity and the encryption algorithm.

- Use caution when specifying lifetimes. The default internal lifetimes should work in most environments and be interoperable with other products. If your security requirements demand shorter lifetime values, you can explicitly set appropriate lifetime values in each security method. The lowest values that are explicitly set on initiator and responder will be used.

- Using shorter lifetime values does not increase the security with which data is protected. Short key lifetimes will only decrease the amount of data that is revealed if an attacker discovers one encryption key. Instead of adjusting the lifetime values lower, consider using a stronger encryption algorithm to protect data, such as 3DES.

- Before changing the default lifetimes, you should understand how lifetimes and rekeying work in detail. For more information, see **Filter action** in Related Topics.

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Select a filter action for a rule

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To select a filter action for a rule**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Double-click the rule that you want to modify.
4. On the **Filter Action** tab, select the option that precedes the name of the filter action that you want to designate as the active filter action for this rule.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- If the option preceding the name of a filter action is not selected, the filter action will not be set as active for the rule.
- If you have not removed them, you can activate one of the three predefined filter actions: **Permit**, **Request Security (Optional)**, or **Require Security**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage multiple filter actions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manage multiple filter actions**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. In the console tree, click **IP Security Policies on *Name***.
3. Click **Action**, and then click **Manage IP filter lists and filter actions**.
4. On the **Manage Filter Actions** tab, do one of the following:
   - To add a new filter action, click **Add**.
   - To modify an existing filter action, click the filter action that you want to modify, and then click **Edit**.
   - To remove a filter action, click the filter action that you want to remove, and then click **Remove**.
5. If you are adding or modifying a filter action, define settings on the **Security Methods** and **General** tabs as needed.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- For more information about defining settings for filter actions, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Define IPSec Key Exchange Settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Define IPSec key exchange settings**

- Configure key exchange settings
- Create key exchange security methods

# Configure key exchange settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure key exchange settings**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Click the **General** tab, and then click **Settings**.
4. To force reauthentication and the negotiation of new master key keying material each time a new session key is required, click **Master key perfect forward secrecy (PFS)**.
5. If you require a different setting, type a value in **Authenticate and generate a new key after every number minutes**, which will cause a reauthentication and new master key generation at that interval.
6. If you require a different setting, type a value in **Authenticate and generate a new key after every number sessions** to set a maximum limit on the number of times a master key or its base keying material can be reused to generate the session key. This limit, when reached, will force a reauthentication and new master key generation. If you have enabled **Master key perfect forward secrecy (PFS)**, the number of sessions is set to 1 and is not configurable.
7. If you have special requirements for security methods on the master key exchange, click **Methods**.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- Portions of IPSec-related services were jointly developed by Microsoft and Cisco Systems, Inc.
- Use **Master key perfect forward secrecy (PFS)** where it is required for interoperability. The default setting is disabled, which should work in most environments and be interoperable with most other products.
- A session limit of zero (0) will cause rekeys to be determined only by the time setting.
- Enabling master key perfect forward secrecy (PFS) might impact performance because each quick mode requires a new main mode negotiation.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create key exchange security methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create key exchange security methods**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Double-click the policy that you want to modify.
3. Click the **General** tab, click **Settings**, and then click **Methods**.
4. In the **Key Exchange Security Methods** dialog box, do one of the following:
   - To add a new key exchange security method, click **Add**.
   - To modify an existing key exchange security method, click the security method that you want to modify, and then click **Edit**.
   - To remove a key exchange security method, click the security method that you want to remove, and then click **Remove**.
5. If you are adding or modifying a key exchange security method, in the **IKE Security Algorithms** dialog box, select an **Integrity algorithm**:
   - Click **MD5** to use a 128-bit key (faster).
   - Click **SHA1** to use a 160-bit key (stronger).
6. Select an **Encryption algorithm**:
   - Click **3DES** to use the triple Data Encryption Standard (3DES) algorithm and three unique 56-bit keys.
   - Click **DES** to use the DES algorithm and a single 56-bit key. Use this option if you are required to connect to computers that do not have 3DES or if you do not need the higher security and overhead of 3DES. For more information, see Notes.
7. Select a **Diffie-Hellman group** to set the length of base keying material used to generate the actual keys:
   - Click **Low (1)** to generate 768 bits of master key keying material.
   - Click **Medium (2)** to generate 1,024 bits of master key keying material (stronger).
   - Click **High (2048)** to generate 2,048 bits of master key keying material (strongest).

**Important**

- For enhanced security, do not use Diffie-Hellman Group 1 (low). For maximum security, use Group 2048 whenever possible. Use Group 2 when required for interoperability with Windows 2000 and Windows XP . When you use a stronger group, the secret key that is derived from the Diffie-Hellman exchange has greater strength. For more

information about Diffie-Hellman groups and key exchange methods, see Related Topics.

### Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.

- Portions of IPSec-related services were jointly developed by Microsoft and Cisco Systems, Inc.

- A key exchange security method is a combination of three settings (integrity algorithm, encryption algorithm, and Diffie-Hellman group). The initiator and the responder must have a method in common (one that uses the same settings) for negotiations to succeed.

- Diffie-Hellman Group 2048 is provided only with the Windows Server 2003 family.

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

- Click **Move up** to move a selected security method up one level. Repeat until the security method is at the required preference level.

- Click **Move down** to move a selected security method down one level. Repeat until the security method is at the required preference level.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Assign IPSec Policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Assign IPSec policy**

- Assign or unassign IPSec policy in Group Policy
- Assign or unassign IPSec policy on a computer

# Assign or unassign IPSec policy in Group Policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To assign or unassign IPSec policy in Group Policy**

- For Active Directory-based Group Policy:

1. Open Active Directory Users and Computers.
2. In the console tree, right-click the domain or organizational unit for which you want to set Group Policy.

   **Where?**

   - Active Directory Users and Computers [*DomainControllerName.DomainName*]/*Domain/OrganizationalUnit/ChildOrganizationalUnit...*

3. Click **Properties**, and then click the **Group Policy** tab.
4. Click **Edit** to open the Group Policy object that you want to edit. Or, click **New** to create a new Group Policy object, and then click **Edit**.
5. In the Group Policy console tree, click **IP Security Policies on Active Directory**.

   **Where?**

   - *PolicyName* [*ComputerName*] Policy/Computer Configuration/Windows Settings/Security Settings/IP Security Policies on Active Directory

6. In the details pane, click the IPSec policy that you want to assign or unassign, and then do one of the following:

   a. To assign the policy, click the **Action** menu, and then click **Assign**.

   b. To unassign the policy, click the **Action** menu, and then click **Unassign**.

- For local computer policy:

1. Click **Start**, click **Run**, type **MMC**, and then click **OK**.
2. Click **File**, click **Add/Remove Snap-in**, and then click **Add**.
3. Click **Group Policy Object Editor**, and then click **Add**.
4. Click **Finish**, click **Close**, and then click **OK**.
5. In the Group Policy console tree, click **IP Security Policies on Local Computer**.

   **Where?**

   - Local Computer Policy/Computer Configuration/Windows Settings/Security Settings/IP Security Policies on Local

Computer

6. In the details pane, click the IPSec policy that you want to assign or unassign, and then do one of the following:

   a. To assign the policy, click the **Action** menu, and then click **Assign**.

   b. To unassign the policy, click the **Action** menu, and then click **Un-assign**.

**Important**

- An IPSec policy might remain active even after the IPSec policy or Group Policy object to which it is assigned has been deleted. Therefore, you should unassign the IPSec policy before you delete either the policy or the Group Policy object. To prevent problems, use the following procedure:

1. Unassign the IPSec policy in the Group Policy object.

2. Wait 24 hours to ensure that the change is propagated.

3. Delete the IPSec policy or Group Policy object.

   If you delete the IPSec policy or Group Policy object without following this procedure, computers in the Active Directory container to which the IPSec policy is assigned might treat the IPSec policy as if it cannot be located and continue to use a cached copy.

**Notes**

- To manage Active Directory-based IPSec policy, you must be a member of the Domain Admins group in Active Directory, or you must have permission to edit Group Policy objects (for information about Group Policy object editing, see Related Topics). To manage local or remote IPSec policy for a computer, you must be a member of the Administrators group on the local or remote computer. For more information, see Default local groups and Default groups.

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.

- You cannot administer Active Directory-based IPSec policy from a computer running Windows XP Home Edition.

- The settings will take effect the next time Group Policy is refreshed.

- If a policy is currently assigned and you assign a new policy, the currently assigned policy is automatically unassigned.

- You cannot assign a policy from the IP Security Policies on Active Directory console; you can only configure policy. To assign policy for Active Directory containers, you must use **IP Security Policies on Active Directory** within the Group Policy console.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Assign or unassign IPSec policy on a computer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To assign or unassign IPSec policy on a computer**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. In the console tree, click **IP Security Policies on *Name***.
3. In the details pane, click the IPSec policy that you want to assign or unassign, and then do one of the following:
   - To assign the policy, click the **Action** menu, and then click **Assign**.
   - To unassign the policy, click the **Action** menu, and then click **Un-assign**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- If a policy is currently assigned and you assign a new policy, the currently assigned policy is automatically unassigned.
- If the computer is a member of a Windows 2000 or Windows Server 2003 domain and IPSec policy is assigned at the domain level, then the assigned local computer policy is not used.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage IPSec Policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage IPSec policy**

- Restart the IPSec services
- Restore default IPSec policies
- Export IPSec policies
- Import IPSec policies
- Refresh the list of IPSec policies
- Delete an IPSec policy
- Rename an IPSec policy
- Export the list of IPSec policies

# Restart the IPSec services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To restart the IPSec service

- Using the Windows interface
- Using a command line

#### Using the Windows interface

1. Open Services.
2. Right-click **IPSec services**.
3. Click **Restart**.

### Important

- Stopping and restarting the IPSec service can disconnect all computers that are using IPSec from the computer on which the IPSec service is stopped, and it can prevent further communication with that computer. For information about how to troubleshoot and resolve loss of connectivity in this situation, see Related Topics.

### Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To open Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Services**.
- You might need to restart the IPSec service in order to do any of the following:
    - Clear old security associations (SAs).
    - Clear soft SAs (unsecured negotiations).
    - Force an IPSec policy to download from Active Directory to domain clients.
- If the IPSec service does not start, then use Event Viewer to determine possible causes of failure. For more information, see Related Topics.

#### Using a command line

1. Open Command Prompt.
2. Type:

   **net stop policyagent & net start policyagent**

**Important**

- Stopping and restarting the IPSec service can disconnect all computers that are using IPSec from the computer on which the IPSec service is stopped, and it can prevent further communication with that computer. For information about how to troubleshoot and resolve loss of connectivity in this situation, see Related Topics.

**Notes**

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command Prompt**.

- On a computer running the Routing and Remote Access service and either Windows 2000 Server or a Windows Server 2003 operating system, you must use the following sequence when restarting the IPSec service:

  1. Stop the Routing and Remote Access service using the **net stop remoteaccess** command.

  2. Stop and restart the IPSec service using the **net stop policyagent & net start policyagent** command.

  3. Start the Routing and Remote Access service using the **net start remoteaccess** command.

- You might need to restart the IPSec service in order to do any of the following:

  - Clear old security associations (SAs).

  - Clear soft SAs (unsecured negotiations).

  - Force an IPSec policy to download from Active Directory to domain clients.

- If the IPSec service does not start, then use Event Viewer to determine possible causes of failure. For more information, see Related Topics.

- For more information about the **net start** and **net stop** commands, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Restore default IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restore default IPSec policies**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. In the console tree, click **IP Security Policies on *Name***.
3. Click **Action**, point to **All Tasks**, and then click **Restore Default Policies**.
4. When prompted, click **Yes**.

### Important

- Restoring default IPSec policies will overwrite any changes to the original default policies, even when the names of the default policies have been changed. If you have modified the default policies and you do not want those modifications to be overwritten, do not restore the default policies.

### Notes

To perform this procedure, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- The option to restore default IPSec policies is only available for computer-based IPSec policy. You cannot restore the default IPSec policies for Active Directory-based IPSec policy.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

# Export IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To export IPSec policies**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. In the console tree, click **IP Security Policies on *Name***.
3. Click **Action**, point to **All Tasks**, and then click **Export Policies**.
4. Type the path and the name of the file to which you want the policy information saved, and then click **Save**.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- To enhance interoperablity in a mixed environment with computers running Windows 2000, limit the name of the file to which you want the policy information saved to 60 characters.
- To export IPSec policies, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Import IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To import IPSec policies**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. In the console tree, click **IP Security Policies on *Name***.
3. Click **Action**, point to **All Tasks**, and then click **Import Policies**.
4. Type the path and the name of the file from which you are importing the IPSec policy information, and then click **Open**.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- Importing IPSec policies replaces existing IPSec policies with the same name.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Refresh the list of IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To refresh the list of IPSec policies**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. In the console tree, click **IP Security Policies on *Name***.
3. Click **Action**, and then click **Refresh**.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- This procedure is only required to update the list of policies for any additions or deletions made by using another management tool.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete an IPSec policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete an IPSec policy**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. Click the policy that you want to remove, click **Action**, and then click **Delete**.
3. When prompted, click **Yes**.

### Important

- For Active Directory-based IPSec policy, an IPSec policy might remain active even after the IPSec policy has been deleted. Therefore, you should unassign the IPSec policy before you delete the policy. To prevent problems, use the following procedure:

  1. Unassign the IPSec policy in the Group Policy object.
  2. Wait 24 hours to ensure that the change is propagated.
  3. Delete the IPSec policy.

  If you delete the IPSec policy without following this procedure, computers in the Active Directory container to which the IPSec policy is assigned might treat the IPSec policy as if it cannot be located and continue to use a cached copy.

### Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. # Export the list of IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To export the list of IPSec policies**

1. Create a console containing IP Security Policies. Or, open a saved console file containing IP Security Policies.
2. In the console tree, click **IP Security Policies on *Name***.
3. Click **Action**, and then click **Export List**.
4. Type the file name to which you want to save the selected IPSec policy or the displayed list of IPSec policies, and then click **Save**.

## Notes

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.
- To create a console containing IP Security Policies, start the IP Security Policies snap-in. To open a saved console file, open MMC. For more information, see Related Topics.
- This procedure does not export the IPSec policies, only a text list of the policies displayed in the details pane.
- To export IPSec policies, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use Resultant Set of Policy (RSoP) to View IPSec Policy Assignments

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Use Resultant Set of Policy (RSoP) to view IPSec policy assignments**

- Use RSoP to view IPSec policy assignments for a computer
- Use RSoP to view IPSec policy assignments for members of a Group Policy container

# Use RSoP to view IPSec policy assignments for a computer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To use RSoP to view IPSec policy assignments for a computer**

1. Open Resultant Set of Policy.

   An RSoP query runs in logging mode. For more information, see Related Topics.

2. In the console tree, click **IP Security Policies**.

   **Where?**

   - Computer Configuration/Windows Settings/Security Settings/IP Security Policies

   The list of all IPSec policies is displayed in the details pane.

3. To view detailed policy settings for the IPSec policy that is being applied, in the details pane, right-click the policy with the highest precedence, and then click **Properties**.

## Notes

- To open RSoP, click **Start**, click **Run**, type **rsop.msc**, and then click **OK**.
- To run an RSoP query in logging mode, see Related Topics.
- The RSoP console displays detailed IPSec policy settings for only the policy that is being applied. The detailed policy settings include the filter rules, filter actions, authentication methods, tunnel endpoints, and connection type.
- The details pane in the RSoP console provides two ways to indicate which IPSec policy is being applied:
  - The lower the number in the **Precedence** column, the higher the precedence of the IPSec policy. The IPSec policy with a precedence number of 1 is the policy that is being applied.
  - In the **Name** column, the folder icon that precedes the name of the IPSec policy that is being applied contains a green dot.
- The settings of the IPSec policy with the highest precedence apply in their entirety; they are not merged with the settings of IPSec policies that are assigned at higher levels of the Active Directory hierarchy. For more information about using RSoP to view IPSec policy assignments, see Related Topics.
- If a local user overrides domain-level IPSec policies with a local IPSec policy, RSoP does not detect the application of the local IPSec policy. As a result, no IPSec policies will be displayed in the RSoP console when a logging mode query is run.
- To hide or display columns in the RSoP console, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Using Resultant Set of Policy to view IPSec policy assignments

# Use RSoP to view IPSec policy assignments for members of a Group Policy container

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To use RSoP to view IPSec policy assignments for members of a Group Policy container**

1. On a domain controller, open Resultant Set of Policy (RSoP) as a Microsoft Management Console (MMC). For more information, see Related Topics.

2. On the **Action** menu, click **Generate RSoP Data**.

3. On the **Welcome to the Resultant Set of Policy Wizard** page, click **Next**.

4. On the **Mode Selection** page, click **Planning mode**, and then follow the instructions in the wizard to run a planning mode query. For more information, see Related Topics.

5. In the console tree, click **IP Security Policies**.

   **Where?**

   - Computer Configuration/Windows Settings/Security Settings/IP Security Policies

   The list of all IPSec policies is displayed in the details pane.

6. To view detailed policy settings for the IPSec policy that is being applied, in the details pane, right-click the policy with the highest precedence, and then click **Properties**.

**Notes**

- The RSoP console displays detailed IPSec policy settings for only the policy that is being applied. The detailed policy settings include the filter rules, filter actions, authentication methods, tunnel endpoints, and connection type.

- The details pane in the RSoP console provides two ways to indicate which IPSec policy is being applied:

  - The lower the number in the **Precedence** column, the higher the precedence of the IPSec policy. The IPSec policy with a precedence number of 1 is the policy that is being applied.

  - In the **Name** column, the folder icon that precedes the name of the IPSec policy that is being applied contains a green dot.

- The settings of the IPSec policy with the highest precedence apply in their entirety; they are not merged with the settings of IPSec policies that are assigned at higher levels of the Active Directory hierarchy. For more information about using RSoP to view IPSec policy assignments, see Related Topics.

- You can run an RSoP planning mode query only on a domain controller (when you run a planning mode query, you must explicitly specify the domain controller name). However, you can specify any IPSec client as the target for the query, provided you have the appropriate permissions to do so.

- To hide or display columns in the RSoP console, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Monitor IPSec Activity

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitor IPSec activity**

- Add the IP Security Monitor snap-in
- Add a computer to the IP Security Monitor console
- View details about active IPSec policies
- View IP security statistics
- View main mode details
- View quick mode details
- Find a matching specific filter
- Change the automatic update refresh interval
- Enable DNS name resolution

# Add the IP Security Monitor snap-in

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add the IP Security Monitor snap-in**

1. Click **Start**, click **Run**, type **MMC**, and then click **OK**.
2. Click **File**, click **Add/Remove Snap-in**, and then click **Add**.
3. Click **IP Security Monitor**, and then click **Add**.
4. Click **Close**, and then click **OK**.

## Notes

- To save the console settings, on the **File** menu, click **Save**.
- To view the saved console, see Related Topics.
- To revise your initial choice, you can start the Microsoft Management Console, add this snap-in again, and save the console again. If you require multiple configurations, you can save the console with another name.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a computer to the IP Security Monitor console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a computer to the IP Security Monitor console**

1. Create a console containing IP Security Monitor. Or, open a saved console file containing IP Security Monitor.
2. In the console tree, right-click **IP Security Monitor**, and then click **Add Computer**.
3. In the **Add Computer** dialog box:
   - For the local computer, click **This computer**.
   - For a remote computer, click **The following computer**, and then type the name of the remote computer. Or, click **Browse** to find it on the network.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- For information about adding the IP Security Monitor snap-in, see Related Topics.
- If the IPSec service is not started on the computer that is being monitored, the server icon is displayed as a stopped service. To refresh IP Security Monitor after the IPSec service on that computer have been restarted, right-click the computer and then click **Reconnect**.
- IP Security Monitor can be used to monitor IPSec only on computers running Windows XP or a Windows Server 2003 operating system. To monitor IPSec on a computer running Windows 2000, use the **IPSecmon** command at a Windows 2000 command prompt.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View quick mode details

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view quick mode details**

1. Create a console containing IP Security Monitor. Or, open a saved console file containing IP Security Monitor.
2. Double-click **Quick Mode**.

   **Where?**

   - IP Security Monitor/*ServerName*/Quick Mode

3. To view quick mode details, do one of the following:

   - For generic filter details, in the console tree, click **Generic Filters**, and then in the details pane, double-click a filter.
   - For specific filter details, in the console tree, click **Specific Filters**. To find a specific quick mode filter, right-click **Specific Filters**, and then click **Find matching filters**.
   - For negotiation policy details, in the console tree, click **Negotiation Policies**, and then in the details pane, double-click a policy.
   - For statistical details, in the console tree, click **Statistics**.
   - For security association details, in the console tree, click **Security Associations**, and then in the details pane, double-click a security association.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- For information about adding the IP Security Monitor snap-in, see Related Topics.
- Quick mode details do not display **Block** or **Permit** filters.
- Although there are two separate quick mode SAs established (one for the inbound traffic and one for the outbound traffic), IP Security Monitor only displays a single quick mode SA.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Find a matching specific filter

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To find a matching specific filter**

1. Create a console containing IP Security Monitor. Or, open a saved console file containing IP Security Monitor.
2. For a specific main mode filter:
   a. Double-click **Main Mode**.(console tree location is: IP Security Monitor/*ServerName*/Main Mode).
   b. In the console tree, right-click **Specific Filters**, and then click **Find matching filters**.
   c. In the **Find Matching Main Mode Filters** dialog box, configure the filter settings, and then click **Search**.
3. For a specific quick mode filter:
   a. Double-click **Quick Mode** (console tree location is: IP Security Monitor/*ServerName*/Quick Mode).
   b. In the console tree, right-click **Specific Filters**, and then click **Find matching filters**.
   c. In the **Find Matching Quick Mode Filters** dialog box, configure the filter settings, and then click **Search**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- For information about adding the IP Security Monitor snap-in, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the automatic update refresh interval

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the automatic update refresh interval**

1. Create a console containing IP Security Monitor. Or, open a saved console file containing IP Security Monitor.
2. Right-click a server name.

   **Where?**

   - IP Security Monitor/*ServerName*

3. Click **Properties**.
4. Configure the automatic update refresh interval, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- For information about adding the IP Security Monitor snap-in, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable DNS name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable DNS name resolution**

1. Create a console containing IP Security Monitor. Or, open a saved console file containing IP Security Monitor.
2. Right-click a server name.

   **Where?**

   - IP Security Monitor/*ServerName*

3. Click **Properties**.
4. Select the **Enable DNS name resolution** check box.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.
- For information about adding the IP Security Monitor snap-in, see Related Topics.
- The **Enable DNS name resolution** check box specifies whether you want to use Domain Name System (DNS) reverse queries and NetBIOS Adapter Status messages to resolve the DNS or NetBIOS computer name that is associated with an IP address when displaying sources or destinations. To resolve the DNS computer name from its IP address, your DNS infrastructure must have the appropriate reverse domains and pointer records configured, either manually or with DNS dynamic update. To resolve the NetBIOS computer name from its IP address, NetBIOS over TCP/IP must be enabled on the computer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# IPSec Concepts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Concepts**

This section provides general background information about Internet Protocol security (IPSec):

- New features for IPSec
- Internet Protocol Security Overview
- Understanding Internet Protocol Security
- Using Internet Protocol Security
- IPSec Resources

# New features for IPSec

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New features for IPSec**
Internet Protocol security (IPSec) provides the following new features for enhanced security, scalability, and availability, and ease of deployment and administration.

### Note

- Because several new IPSec features are available only in the Windows Server 2003 family, as a best practice, if you plan to apply the same IPSec policy to computers running the Windows Server 2003 family and to computers running Windows 2000 or Windows XP, test the policy thoroughly on all relevant operating systems before deployment. For additional best practices for using IPSec, see IPSec Best practices.

**IP Security Monitor**
In Windows 2000, IP Security Monitor was implemented as an executable program (IPSecmon.exe). In Windows XP and the Windows Server 2003 family, IP Security Monitor is implemented as a Microsoft Management Console (MMC) console and includes enhancements that allow you to:

- Monitor IPSec information for your local computer and for remote computers.
- View details about active IPSec policies, including the name, description, date last modified, store, path, organizational unit, and Group Policy object name.
- View main mode and quick mode generic filters and specific filters.
- View main mode and quick mode statistics. For information about the statistics displayed in IP Security Monitor, see Viewing main mode and quick mode statistics in IP Security Monitor.
- View main mode and quick mode security associations.
- Customize refresh rates, and use DNS name resolution for filter and security association output.
- Search for specific main mode or quick mode filters that match any source or destination IP address, a source or destination IP address on your local computer, or a specific source or destination IP address.

For information about adding the IP Security Monitor snap-in, see Add the IP Security Monitor snap-in. For information about additional IPSec troubleshooting tools, see IPSec troubleshooting tools.

**Stronger cryptographic master key (Diffie-Hellman)**
For enhanced security, IPSec now supports the use of a 2048-bit Diffie-Hellman key exchange. With a stronger Diffie-Hellman group, the secret key that is derived from the Diffie-Hellman exchange has greater strength. Strong Diffie-Hellman groups combined with longer key lengths increase the computational difficulty of determining a secret key.

This feature is provided only with the Windows Server 2003 family.

For more information about Diffie-Hellman groups and key exchange, see Key exchange methods and Key management and protection.

**Command-line management with Netsh**
Using commands in the Netsh IPSec context, you can configure static or dynamic IPSec main mode settings, quick mode settings, rules, and configuration parameters. To enter the Netsh IPSec context, type **netsh -c ipsec** at a command prompt. The Netsh IPSec context replaces the Ipsecpol.exe tool, which is provided with the Windows 2000 Server Resource Kit. You can use this feature to script and automate IPSec configuration. For more information, see IPSec troubleshooting tools.

This feature is provided only with the Windows Server 2003 family.

For more information about Netsh commands for IPSec, see Netsh commands for Internet Protocol security.

**Computer startup security**
For enhanced security, IPSec now provides stateful filtering of network traffic during computer startup. With stateful filtering, only the following traffic is permitted during computer startup: the outbound traffic that the computer initiates during startup, the inbound traffic that is sent in response to the outbound traffic, and DHCP traffic. As an alternative to stateful filtering, you can specify that all inbound and outbound traffic be blocked until an IPSec policy is applied. If you use stateful filtering, or if you specify that traffic be blocked during computer startup, you can also specify the traffic types that you want to exempt from IPSec filtering during computer startup.

### Note

- You cannot configure this feature in the IP Security Policy Management console. To configure this feature, you must use the Netsh IPSec command-line tool.

**Persistent policy for enhanced security**
You can now create and assign a persistent IPSec policy to secure a computer if a local IPSec policy or an Active Directory-based IPSec policy cannot be applied. When you create and assign a persistent policy, it is applied before the local policy or the Active Directory-based policy is applied, and it remains in effect regardless of whether the local policy or the Active Directory-based policy is applied (for example, an IPSec policy will not be applied if it is corrupted).

### Note

- You cannot configure this feature in the IP Security Policy Management console. To configure this feature, you must use the Netsh commands for IPSec.

**Removed default traffic exemptions**
In Windows 2000 and Windows XP, by default, all broadcast, multicast, Internet Key Exchange (IKE), Kerberos, and Resource Reservation Protocol (RSVP) traffic is exempt from IPSec filtering. To significantly improve security, in the Windows Server 2003 family, only IKE traffic (which is required for establishing IPSec-secured communication) is exempt from IPSec filtering. All other traffic types are now matched against IPSec filters, and you can configure, block, or permit filter actions specifically for multicast and broadcast traffic (IPSec does not negotiate security associations for multicast and broadcast traffic). For more information, see Special IPSec considerations.

**IPSec certificate to account mapping for network access control**
With the Windows Server 2003 family, if you use either Kerberos V5 or certificate authentication, you can set restrictions on which computers are allowed to connect. This functionality allows you to use IPSec to allow or deny any of the following access to a server running Windows Server 2003 :

- Computers that are members of a specific domain.
- Computers that have a certificate from a specific issuing certification authority.
- A specific group of computers.
- A specific computer.

When you enable certificate to account mapping in IPSec, the IKE protocol associates (maps) a computer certificate to a computer account in an Active Directory domain or forest, and then retrieves an access token, which includes the list of the user rights that are assigned to the computer. You can restrict access by configuring Group Policy security settings and assigning either the **Access this computer from the network** user right or the **Deny access to this computer from the network** user right to individual or multiple computers, as needed.

For more information about certificate to account mapping for IPSec, see Authentication methods.

For information about configuring security settings in Group Policy, see Security settings overview.

### Notes

- Certificate to account mapping for IPSec is provided only with the Windows Server 2003 family.

- Certificate mapping is not supported across forests.

**Ability to exclude the name of the certification authority (CA) from certificate requests**
For enhanced security, when you use certificate authentication to establish trust between IPSec peers, you can now exclude the name of the CA from the certificate request. When you exclude the name of the CA from the certificate request, you prevent the potential disclosure of sensitive information about the trust relationships of a computer, such as name of the company that owns the computer and the domain membership of the computer (if an internal public key infrastructure is being used), to an attacker.

**IPSec policy filters allow logical addresses for local IP configuration**
You can now use the IP Security Policy Management console to configure the source or the destination address fields that the local IPSec policy will interpret as the addresses for the DHCP server, the DNS servers, the WINS servers, and the default gateway. As a result, IPSec policies can now automatically accommodate changes in the IP configuration of the server, by using either DHCP or static IP configurations.

This feature is provided only with the Windows Server 2003 family.

**IPSec functionality over network address translation (NAT)**
IPSec Encapsulating Security Payload (ESP) packets can now pass through NATs that allow User Datagram Protocol (UDP) traffic. The IKE protocol automatically detects the presence of a NAT and uses UDP-ESP encapsulation to allow IPSec traffic to pass through the NAT. This functionality is an implementation of the Internet Engineering Task Force (IETF) IP Security Working Group standard for IPSec.

NATs are widely used for Internet Connection Sharing (ICS) and in locations that provide public Internet access (such as hotels and airports) and that are likely to be used by telecommuters. In addition, some Internet service providers (ISPs) use a centralized NAT to connect their clients to the Internet.

IPSec functionality over NAT enables IPSec-secured connections to be established in the following common deployment scenarios:

- Layer Two Tunneling Protocol (L2TP)/IPSec virtual private network (VPN) clients that are behind NATs can establish IPSec-secured connections over the Internet to their corporate network, using IPSec ESP transport mode.

- Servers running Routing and Remote Access can establish gateway-to-gateway IPSec tunnels when one of the servers running Routing and Remote Access is behind a NAT.

- Clients and servers can send IPSec-secured TCP and UDP packets to other clients or servers using IPSec ESP transport mode, when one or both of the computers are behind a NAT. For example, a program running on a server on a perimeter network can be IPSec-secured when it is used to make connections to the corporate network.

### Note

- Internet Connection Sharing and Network Bridge are not included in Windows Server 2003, Web Edition; Windows Server 2003, Datacenter Edition; and the Itanium-based versions of the original release of the Windows Server 2003 operating systems.

For more information about VPNs and IPSec, see Virtual private networking with IPSec. For more information about IPSec transport mode and tunnel mode, see Transport mode and Tunnel mode.

**Improved IPSec integration with Network Load Balancing**
Improved IPSec integration with Network Load Balancing allows a Network Load Balancing group of servers to provide highly available IPSec-based VPN services. Network Load Balancing can accurately track IPSec-secured sessions, and the IPSec IKE protocol can detect when an IPSec-secured session is being established with a cluster server and quickly recover from a failover. Additionally, Network Load Balancing can now maintain IPSec-secured connections to the correct Network Load Balancing host, even when the number of hosts in the cluster (and the algorithm used to map clients to hosts) changes. Because the IKE protocol automatically detects the Network Load Balancing service, no additional configuration is required to use this feature.

This feature is provided only with Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition.

For more information about Network Load Balancing, see Introduction to Network Load Balancing and How Network Load

Balancing works.

**IPSec support for RSoP**

To enhance IPSec deployment and troubleshooting, IPSec now provides an extension to the Resultant Set of Policy (RSoP) console. RSoP is an addition to Group Policy that you can use to view existing IPSec policy assignments for a computer or for members of a Group Policy container. To view IPSec policy assignments for a computer, run an RSoP logging mode query. To view IPSec policy assignments for members of a Group Policy container, run an RSoP planning mode query. For information about how to view IPSec policy assignments, see Use Resultant Set of Policy (RSoP) to View IPSec Policy Assignments.

After you run an RSoP logging mode query or an RSoP planning mode query, you can view detailed settings (the filter rules, filter actions, authentication methods, tunnel endpoints, and connection types that were specified when the IPSec policy was created) for the IPSec policy that is being applied.

For more information about using RSoP with IPSec, see Using Resultant Set of Policy to view IPSec policy assignments. For general information about RSoP, see RSoP overview.

# Internet Protocol Security Overview

- Simplified deployment

# Security information for IPSec

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for IPSec**
Before deploying IPSec in your organization, consider the following security issues:

- 3DES and computers running Microsoft® Windows® 2000
- Authentication method
- Firewall packet filtering
- Protected traffic (using AH or ESP)
- Unprotected traffic (using the default response rule)
- Diffie-Hellman groups (using Diffie-Hellman Group 1, 2, or 2048)

**3DES and computers running Windows 2000**
IPSec policies allow the choice of a strong encryption algorithm, 3DES, which provides stronger encryption than DES for higher security. Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to perform the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, then the 3DES setting is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should use DES only as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP and the Windows Server 2003 family support 3DES and do not require installation of the High Encryption Pack.

**Authentication method**
If the computers in your organization are part of an Active Directory® domain, IPSec main mode authentication can be accomplished with the default authentication method (Kerberos V5). You do not have to deploy public key certificates for intranet communication. However, computers running Windows XP Home Edition do not support the Kerberos V5 authentication method. Also, if you have computers connected to the Internet, it is recommended that you do not use Kerberos V5 as an authentication method. When Kerberos authentication is used, during main mode negotiation, each IPSec peer sends its computer identity in unencrypted format to the other peer. The computer identity is unencrypted until encryption of the entire identity payload takes place during the authentication phase of the main mode negotiation. An attacker can send an Internet Key Exchange (IKE) packet that causes the responding IPSec peer to expose its computer identity and domain membership. To secure computers that are connected to the Internet, certificate authentication is therefore recommended.

For enhanced security, the use of preshared key authentication is not recommended because it is a relatively weak authentication method. In addition, preshared keys are stored in plaintext. Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing.

For more information, see Authentication methods and Preshared key authentication.

**Firewall packet filtering**
For a firewall, security gateway, router, or any other server or device that is connected to the Internet and providing packet filtering capabilities to computers on a perimeter network (also known as a demilitarized zone or DMZ), special filtering must be enabled on that computer to ensure that packets secured with IPSec are allowed to be forwarded to computers on the perimeter network. The firewall or other device should normally allow the following types of traffic to pass through it:

- IP Protocol ID of 50 (0x32) for IPSec Encapsulating Security Payload (ESP) traffic
- IP Protocol ID of 51 (0x33) for IPSec Authentication Header (AH) traffic
- UDP port 500 (0x1F4) for Internet Key Exchange (IKE) negotiation traffic

Most packet filtering software allows you to be more specific. You can define separate packet filters for inbound traffic (inbound filters), for outbound traffic (outbound filters), and for each interface. Additionally, you can specify IP addresses for the IPSec computers on the perimeter network. The most restrictive packet filters for IPSec traffic exchanged with a single IPSec computer on the perimeter network are outlined in the following sections.

**Filters on the Internet interface**

Configure the following inbound packet filters on the Internet interface of the firewall to allow the specific types of traffic:

- Destination IP address of the IPSec computer's perimeter network interface and UDP destination port of 500 (0x1F4)

  This filter allows IKE traffic to be sent to the IPSec computer on the perimeter network.

- Destination IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 50 (0x32)

  This filter allows IPSec ESP traffic to be sent to the IPSec computer on the perimeter network.

- Destination IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 51 (0x33)

  This filter allows IPSec AH traffic to be sent to the IPSec computer on the perimeter network.

Configure the following outbound packet filters on the Internet interface of the firewall to allow the specific types of traffic:

- Source IP address of the IPSec computer's perimeter network interface and UDP source port of 500 (0x1F4)

  This filter allows IKE traffic to be sent from the IPSec computer on the perimeter network.

- Source IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 50 (0x32)

  This filter allows IPSec ESP traffic to be sent from the IPSec computer on the perimeter network.

- Source IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 51 (0x33)

  This filter allows IPSec AH traffic to be sent from the IPSec computer on the perimeter network.

**Filters on the perimeter network interface**

Configure the following inbound packet filters on the perimeter network interface of the firewall to allow the specific types of traffic:

- Source IP address of the IPSec computer's perimeter network interface and UDP source port of 500 (0x1F4)

  This filter allows IKE traffic to be sent from the IPSec computer on the perimeter network.

- Source IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 50 (0x32)

  This filter allows IPSec ESP traffic to be sent from the IPSec computer on the perimeter network.

- Source IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 51 (0x33)

  This filter allows IPSec AH traffic to be sent from the IPSec computer on the perimeter network.

Configure the following outbound packet filters on the perimeter network interface of the firewall to allow the specific types of traffic:

- Destination IP address of the IPSec computer's perimeter network interface and UDP destination port of 500 (0x1F4)

  This filter allows IKE traffic to be sent to the IPSec computer on the perimeter network.

- Destination IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 50 (0x32)

This filter allows IPSec ESP traffic to be sent to the IPSec computer on the perimeter network.

- Destination IP address of the IPSec computer's perimeter network interface and IP Protocol ID of 51 (0x33)

  This filter allows IPSec AH traffic to be sent to the IPSec computer on the perimeter network.

**Protected traffic (using AH or ESP)**
When deciding whether to use AH or ESP to protect your IP traffic, consider the following:

- AH provides both data authentication and integrity services through the computation and inclusion of a keyed hash for each packet. With AH, the hash calculation includes the entire IP packet and header. Some fields that are allowed to change in transit are excluded. Packet replay protection services are provided through the inclusion of a sequence number for each packet.

- ESP provides data authentication and integrity services through the computation and inclusion of a keyed hash for each packet. With ESP, the hash calculation only includes the ESP header, trailer, and payload. The IP header is not protected with the hash. ESP provides data confidentiality services by encrypting the ESP payload with the DES (Data Encryption Standard) or 3DES (triple DES) encryption algorithms. Packet replay protection services are provided through the inclusion of a sequence number for each packet.

It is less CPU-intensive to verify the hash for each packet than it is to encrypt and decrypt each packet. If performance is a significant consideration, you can use AH to protect most of your traffic. When confidentiality is required, you can use ESP instead. For example, you can use AH to protect traffic on your intranet and ESP for traffic that is sent over the Internet.

**Note**

- This performance consideration assumes that you are not using IPSec offload network adapters in your organization. Offload network adapters perform cryptographic calculations, such as the calculation and verification of the hash and the encryption and decryption services, on the adapter itself, enhancing performance for IPSec-secured traffic.

**Unprotected traffic (using the default response rule)**
You can easily implement an IPSec deployment scenario that secures traffic from a specific set of servers, as follows:

1. Place the servers in an organizational unit and assign an IPSec policy to a Group Policy object of that organizational unit with a rule that requires secured traffic between the servers and any other computer. Within the filter action for the rule, enable the secure servers to accept unsecured communication but always respond using IPSec.

2. Place the client computers in an organizational unit and assign an IPSec policy to a Group Policy object of that organizational unit that uses only the default response rule. For more information, see IPSec Policy Rules.

In this configuration, the following traffic between the client computers and the secure servers is unsecured:

- The initial request (for example, a TCP SYN packet) sent by the client computer to establish communication is unsecured because the client does not have a rule in its policy to initiate secured communication with the secure server.

- Although ongoing communications are secured after secured communication is negotiated between the client and secure server computers, the quick mode security association (SA) that provides security settings for traffic can eventually time out and be removed from both the secure server and the client computer. This occurs when a TCP connection exists and no traffic is sent between the client computer and the secure server for an extended period of time. The dynamic filter created on the client computer by the default response rule is also removed after the dynamic filter has been timed out.

  If the secure server sends new data on the existing connection, it renegotiates the quick mode SA before sending this data to the client computer because a rule exists on the secure server to secure traffic between itself and all other computers. However, if the client computer sends new data after the quick mode SAs and dynamic filter time out, the new data is sent unsecured because the client does not have a rule to initiate secure communications with the secure

server. For TCP connections, one or multiple TCP segments can be sent unsecured by the client computer. To prevent client computers from sending unsecured data to secure servers, you must configure your client computer IPSec policy with additional rules that initiate secured communications to secure servers.

**Diffie-Hellman groups (using Diffie-Hellman group 1, 2, or 2048)**

Diffie-Hellman groups are used to determine the length of the base prime numbers that are used during the key exchange process. Group 2048 (high) is stronger (more secure) than Group 2 (medium), which is stronger than Group 1 (low). Group 1 provides 768 bits of keying strength, Group 2 provides 1,024 bits, and Group 2048 provides 2,048 bits.

Strong Diffie-Hellman groups combined with longer key lengths increase the computational difficulty of determining a secret key.

**Important**

- For enhanced security, do not use Diffie-Hellman Group 1. For maximum security, use Group 2048 whenever possible. Use Group 2 when required for interoperability with Windows 2000 and Windows XP.

**Note**

- Diffie-Hellman Group 2048 is provided only with the Windows Server 2003 family.

For more information about Diffie-Hellman groups and key exchange, see Key exchange methods and Key management and protection.

# Internet Protocol security defined

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Protocol security defined**

Internet Protocol security (IPSec) is a framework of open standards for ensuring private, secure communications over Internet Protocol (IP) networks, through the use of cryptographic security services. The Microsoft® Windows® 2000 , Windows XP, and the Windows Server 2003 family implementations of IPSec are based on standards developed by the Internet Engineering Task Force (IETF) IPSec working group.

IPSec is the long-term direction for secure networking. It provides aggressive protection against private network and Internet attacks through end-to-end security. The only computers that must know about IPSec protection are the sender and receiver in the communication. In Windows XP and the Windows Server 2003 family, IPSec provides the ability to protect communication between workgroups, local area network computers, domain clients and servers, branch offices (which might be physically remote), extranets, and roving clients.

# Introducing IPSec

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Introducing IPSec**

IPSec is the long-term direction for secure networking. It provides a key line of defense against private network and Internet attacks.

IPSec has two goals:

1. To protect the contents of IP packets.

2. To provide a defense against network attacks through packet filtering and the enforcement of trusted communication.

Both goals are met through the use of cryptography-based protection services, security protocols, and dynamic key management. This foundation provides both the strength and flexibility to protect communications between private network computers, domains, sites, remote sites, extranets, and dial-up clients. It can even be used to block receipt or transmission of specific traffic types.

IPSec is based on an end-to-end security model, establishing trust and security from a source IP to a destination IP address. The IP address itself does not necessarily have to be considered an identity, rather the system behind the IP address has an identity that is validated through an authentication process. The only computers that must know about the traffic being secured are the sending and receiving computers. Each computer handles security at its respective end, with the assumption that the medium over which the communication takes place is not secure. Any computers that only route data from source to destination are not required to support IPSec, unless firewall-type packet filtering or network address translation is being done between the two computers. This model allows IPSec to be successfully deployed for the following enterprise scenarios:

- Local area network (LAN): client/server and peer-to-peer

- Wide area network (WAN): router-to-router and gateway-to-gateway

- Remote access: dial-up clients and Internet access from private networks

Typically both sides require IPSec configuration (called an IPSec policy), to set options and security settings that will allow two systems to agree on how to secure traffic between them. The Microsoft® Windows® 2000 , Windows XP, and the Windows Server 2003 family implementations of IPSec is based on industry standards developed by the Internet Engineering Task Force (IETF) IPSec working group. Portions of IPSec-related services were jointly developed by Microsoft and Cisco Systems, Inc.

# Security issues with IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security issues with IP**
Without security, both public and private networks are susceptible to unauthorized monitoring and access. Internal attacks might be a result of minimal or nonexistent intranet security. Risks from outside the private network originate from connections to the Internet and extranets. Password-based user access controls alone do not protect data transmitted across a network.

**Common types of network attacks**
Without security measures and controls in place, your data might be subjected to an attack. Some attacks are passive in that information is only monitored. Other attacks are active and information is altered with intent to corrupt or destroy the data or the network itself. Your networks and data are vulnerable to any of the following types of attacks if you do not have a security plan in place.

**Eavesdropping**
In general, the majority of network communications occur in a plaintext (unencrypted) format, which allows an attacker who has gained access to data paths in a network to monitor and interpret (read) the traffic. When an attacker is eavesdropping on communications, it is referred to as sniffing or snooping. The ability of an eavesdropper to monitor the network is generally the biggest security problem that administrators face in an enterprise. Without strong encryption services that are based on cryptography, data can be read by others as it traverses the network.

**Data modification**
After an attacker has read data, the next logical step is often to modify it. An attacker can modify the data in the packet without the knowledge of the sender or receiver. Even if you do not require confidentiality for all communications, you do not want any of your messages to be modified in transit. For example, if you are exchanging purchase requisitions, you do not want the items, amounts, or billing information to be changed.

**Identity spoofing (IP address spoofing)**
Most networks and operating systems use the IP address to identify a computer as being valid on a network. In some cases, it is possible for an IP address to be falsely used. This is known as identity spoofing. An attacker might use special programs to construct IP packets that appear to originate from valid addresses inside an organization intranet.

After gaining access to the network with a valid IP address, the attacker can modify, reroute, or delete data. The attacker can also conduct other types of attacks, as described in the following sections.

**Password-based attacks**
A commonality among most operating systems and network security plans is password-based access control. Access to both a computer and network resources are determined by a user name and password.

Historically, many versions of operating system components have not always protected identity information as it was passed through the network for validation. This might allow an eavesdropper to determine a valid user name and password and use it to gain access to the network by posing as a valid user.

When an attacker finds and accesses a valid user account, the attacker has the same rights as the actual user. For example, if the user has administrative rights, the attacker can create additional accounts for access at a later time.

After gaining access to a network with a valid account, an attacker can do any of the following:

- Obtain lists of valid user and computer names and network information.
- Modify server and network configurations, including access controls and routing tables.
- Modify, reroute, or delete data.

**Denial-of-service attack**
Unlike a password-based attack, the denial-of-service attack prevents normal use of a computer or network by valid users.

After gaining access to a network, an attacker can do any of the following:

- Distract information systems staff so that they do not immediately detect the intrusion. This gives an attacker the opportunity to make additional attacks.
- Send invalid data to applications or network services, causing applications or services to close or operate abnormally.
- Send a flood of traffic until a computer or an entire network is shut down.
- Block traffic, which results in a loss of access to network resources by authorized users.

**Man-in-the-middle attack**
As the name indicates, a man-in-the-middle attack occurs when someone between two users who are communicating is actively monitoring, capturing, and controlling the communication without the knowledge of the users. For example, an attacker can negotiate encryption keys with both users. Each user then sends encrypted data to the attacker, who can decrypt the data. When computers are communicating at low levels of the network layer, the computers might not be able to determine with which computers they are exchanging data.

**Compromised-key attack**
A key is a secret code or number required to encrypt, decrypt, or validate secured information. Although determining a key is a difficult and resource-intensive process for an attacker, it is possible. After an attacker determines a key, that key is referred to as a compromised key.

An attacker uses the compromised key to gain access to a secured communication without the sender or receiver being aware of the attack. With the compromised key, the attacker can decrypt or modify data. The attacker can also attempt to use the compromised key to compute additional keys, which might allow access to other secured communications.

**Sniffer attack**
A sniffer is an application or device that can read, monitor, and capture network data exchanges and packets. If the packets are not encrypted, a sniffer provides a full view of the data that is inside of the packet. Even encapsulated (tunneled) packets can be opened and read if they are not encrypted.

Using a sniffer, an attacker can do the following:

- Analyze a network and access information, eventually causing the network to stop responding or become corrupted.
- Read private communications.

**Application-layer attack**
An application-layer attack targets application servers by causing a fault in a server's operating system or applications. This results in the attacker gaining the ability to bypass normal access controls. The attacker takes advantage of this situation, gaining control of an application, system, or network, and can do any of the following:

- Read, add, delete, or modify data or an operating system.
- Introduce a virus that uses computers and software applications to copy viruses throughout the network.
- Introduce a sniffer program to analyze the network and gain information that can eventually be used to cause the network to stop responding or become corrupted.
- Abnormally close data applications or operating systems.
- Disable other security controls to enable future attacks.

# Protection against attacks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Protection against attacks**
IPSec protects data so that an attacker finds it extremely difficult or impossible to interpret it. The level of protection provided is determined by the strength of the security levels specified in your IPSec policy structure.

IPSec has a number of features that significantly reduce or prevent the following attacks:

- Sniffers (lack of confidentiality)

  The Encapsulating Security Payload (ESP) protocol in IPSec provides data confidentiality by encrypting the payload of IP packets.

- Data modification

  IPSec uses cryptography-based keys, shared only by the sending and receiving computers, to create a cryptographic checksum for each IP packet. Any modification to the packet data alters the checksum, which indicates to the receiving computer that the packet was modified in transit.

- Identity spoofing, password-based, and application-layer attacks

  IPSec allows the exchange and verification of identities without exposing that information to interpretation by an attacker. Mutual verification (authentication) is used to establish trust between the communicating systems and only trusted systems can communicate with each other. After identities are established, IPSec uses cryptography-based keys, shared only by the sending and receiving computers, to create a cryptographic checksum for each IP packet. The cryptographic checksum ensures that only the computers that have knowledge of the keys could have sent each packet.

- Man-in-the-middle attacks

  IPSec combines mutual authentication with shared, cryptography-based keys.

- Denial-of-service attacks

  IPSec uses IP packet filtering methodology as the basis for determining whether communication is allowed, secured, or blocked, according to the IP address ranges, IP protocols, or even specific TCP and UDP ports.

# Policy-based security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Policy-based security**

Although stronger security methods based on cryptography have become necessary to fully protect communication, they can often greatly increase administrative overhead. To reduce overhead, IPSec uses policy-based administration.

IPSec policies, rather than application programming interfaces (APIs), are used to configure IPSec security services. The policies provide variable levels of protection for most traffic types in most existing networks.

You can configure IPSec policies to meet the security requirements of a computer, application, organizational unit, domain, site, or global corporation. You can use the IP Security Policy Management console provided in Microsoft® Windows® XP and the Windows Server 2003 family to define IPSec policies for computers through Active Directory® (for domain members) or on the local computer (for computers that do not belong to domains).

# Simplified deployment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Simplified deployment**
To achieve secure communications with a low cost of ownership, Microsoft® Windows® XP and the Windows Server 2003 family simplify the deployment of IPSec with the following features:

- Integration with the security framework in Windows 2000 and the Windows Server 2003 family.

  IPSec uses the secure domain in Windows 2000 and the Windows Server 2003 family as a trust model. By default, IPSec policies use the Active Directory® default authentication method (Kerberos V5 authentication) to identify and trust communicating computers. Computers that are members of a Windows 2000 or a Windows Server 2003 domain and are in trusted domains can easily establish IPSec-secured communications.

- Centralized IPSec policy administration through Active Directory

  IPSec policies can be assigned through Group Policy configuration of Active Directory domains and organizational units. This allows the IPSec policy to be assigned at the domain, site, or organizational unit level, eliminating the administrative overhead of configuring each computer separately.

- Transparency of IPSec to users and applications

  Integration at the IP layer (layer 3) provides security for any protocol in the TCP/IP suite of protocols. You do not need separate security for each protocol in the TCP/IP suite of protocols, because applications using TCP/IP pass the data to the IP protocol layer, where it is secured.

- Flexible security configuration

  The security services within each policy can be customized to meet the majority of security requirements for the network and data traffic.

- Automatic key management

  Internet Key Exchange (IKE) services dynamically exchange and manage cryptographic keys between communicating computers.

- Automatic security negotiation

  Internet Key Exchange (IKE) services dynamically negotiate a common set of security settings between communicating computers, eliminating the need for both computers to have identically configured policies.

- Public key infrastructure support

  Using public key certificates for authentication is supported. This allows trust and secure communication for computers that do not belong to a trusted Windows 2000 or Windows Server 2003 domain, non-Microsoft operating systems, computers that have membership in untrusted domains, and instances in which computer access must be restricted to a smaller group than domain authentication allows.

- Preshared key support

  If authentication using the Kerberos V5 protocol or public key certificates is not possible, a preshared authentication key can be configured.

**Important**

- The use of preshared key authentication is not recommended because it is a relatively weak authentication method. Preshared key authentication creates a master key that is less secure (that might produce a weaker form of encryption) than certificates or the Kerberos V5 protocol. In addition, preshared keys are stored in plaintext. Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing and that you use certificates or Kerberos V5 instead in a production environment.

**Note**

- The integration with the security framework in Windows 2000 or the Windows Server 2003 family, centralized IPSec policy administration through Active Directory, and the use of the Kerberos V5 protocol as described here do not apply to computers running Windows XP Home Edition. You cannot administer Active Directory-based IPSec policy from computers running Windows XP Home Edition because these computers cannot join Active Directory domains.

# Understanding Internet Protocol Security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Internet Protocol security**

This section introduces the key concepts and terminology you should review before you deploy IPSec. This section covers:

- The IPSec process
- Virtual private networking with IPSec
- IPSec Security Services
- IPSec Protocol Types
- IPSec Components
- Description of an IPSec Policy

# The IPSec process

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The IPSec process**

This topic provides an overview of IPSec concepts that are central to understanding the IPSec process, including IPSec policy configuration and the Internet Key Exchange (IKE) protocol. In addition, this topic describes how IPSec network traffic processing works, using two intranet computers as an example.

**IPSec Policy Configuration**

In Windows 2000, Windows XP, and the Windows Server 2003 family, IPSec is implemented primarily as an administrative tool that you can use to enforce security policies on IP network traffic. A security policy is a set of packet filters that define network traffic as it is recognized at the IP layer. A filter action defines the security requirements for the network traffic. A filter action can be configured to: **Permit**, **Block**, or **Negotiate security** (negotiate IPSec).

IPSec filters are inserted into the IP layer of the computer TCP/IP networking protocol stack so that they can examine (filter) all inbound or outbound IP packets. Except for a brief delay required to negotiate a security relationship between two computers, IPSec is transparent to end-user applications and operating system services.

A collective set of IPSec security settings is known as an IPSec policy. Windows 2000, Windows XP, and the Windows Server 2003 family provide a graphical user interface and several command-line tools that you can use to configure an IPSec policy, and then assign it to a computer.

To ensure that IPSec communication is successful and that IPSec meets the security requirements of your organization, you must carefully design, configure, coordinate, and manage IPSec policies. In many organizations, one administrator might be responsible for configuring and managing IPSec policies for many, if not all, computers.

**Internet Key Exchange (IKE) security associations**

The IKE protocol is designed to securely establish a trust relationship between each computer, to negotiate security options, and dynamically generate shared, secret cryptographic keying material. The agreement of security settings associated with keying material is called a security association, also known as an SA. These keys will provide authenticity, integrity, and optionally, encryption of IP packets that are sent using the security association. IKE negotiates two types of security associations:

- A main mode security association (the IKE security association that is used to protect the IKE negotiation itself).
- IPSec security associations (the security associations that are used to protect application traffic).

You can configure IPSec policy settings for both types of security associations.

The IPSec service interprets an IPSec policy, expanding it into the components that it needs to control the IKE negotiation. The IPSec policy contains one definition of a packet filter. The packet filter is interpreted in two ways: one uses only the address and identity information to allow IKE to establish a main mode SA (the IKE security association); the other allows IKE to establish the IPSec security associations (also known as quick mode security associations).

**IPSec network traffic processing**

The following illustration shows how IPSec works in terms of the IPSec components for two intranet computers.

For simplicity, this example is of an intranet in which two computers have an active IPSec policy.

1. Alice, using a data application on Computer A, sends an application IP packet to Bob on Computer B.
2. The IPSec driver on Computer A checks its outbound IP filter lists and determines that the packets should be secured.

3. The action is to negotiate security, so the IPSec driver notifies IKE to begin negotiations.

4. The IKE service on Computer A completes a policy lookup, using its own IP address as the source and the IP address of Computer B as the destination. The main mode filter match determines the main mode settings that Computer A proposes to Computer B. Computer A sends the first IKE message in main mode, using UDP source port 500, destination port 500. IKE packets receive special processing by the IPSec driver to bypass filters.

5. Computer B receives an IKE main mode message requesting secure negotiation. It uses the source IP address and the destination IP address of the UDP packet to perform a main mode policy lookup, to determine which security settings to agree to. Computer B has a main mode file that matches, and so replies to begin negotiation of the main mode SA.

6. Computer A and Computer B now negotiate options, exchange identities, verify trust in those identities (authentication), and generate a shared master key. They have now established an IKE main mode SA. Computer A and Computer B must mutually trust each other.

7. Computer A then performs an IKE quick mode policy lookup, using the full filter to which the IPSec driver matched the outbound packet. Computer A selects the quick mode security settings and proposes them, and the quick mode filter, to Computer B.

   Computer B also performs an IKE quick mode policy lookup, using the filter description offered by Computer A. Computer B selects the security settings required by its policy and compares those settings to those offered by computer A. Computer B accepts one set of options and completes the remainder of the IKE quick mode negotiation to create a pair of IPSec security associations.

8. One IPSec SA is inbound and one IPSec SA is outbound. The IPSec SAs are identified by a Security Parameter Index (SPI), which is inserted into the IPSec header of each packet sent.

9. The IPSec driver on Computer A uses the outbound SA to sign and, if required, encrypt the packets. If the network adapter can perform hardware offload of IPSec cryptographic functions, the IPSec driver formats the packets, but does not perform the IPSec cryptographic functions.

10. The IPSec driver passes the packets to the network adapter driver, indicating whether the adapter must perform the IPSec cryptographic functions. The network adapter transmits the packets into the network.

11. The network adapter driver at Computer B receives the encrypted packets from the network. The SPI is used by the receiver of an IPSec packet to find the corresponding IPSec security association, with the cryptographic keys required to verify and decrypt the packets. If the network adapter can decrypt the packets in hardware, it verifies whether it can recognize the SPI. If it cannot decrypt the packets in hardware, or if it cannot recognize the SPI, it passes the packets up to the IPSec driver.

12. The IPSec driver on Computer B uses the inbound SA SPI to retrieve the keys required to validate authentication and integrity and, if required, to decrypt the packets.

13. The IPSec driver converts the packets from IPSec format back to standard IP packet format. It passes the validated and decrypted IP packets to the TCP/IP driver, which passes them to the receiving application on Computer B.

14. The IPSec SAs continue to provide very strong, transparent protection for application data traffic. The IPSec SAs are automatically refreshed by an IKE quick mode negotiation for as long as the application sends and receives data. When the application stops sending and receiving data, the IPSec SAs become idle and are deleted.

15. Typically, the IKE main mode SA is not deleted. By default, the main mode SA has a lifetime of 8 hours. You can configure the main mode SA lifetime to as short as 5 minutes to a maximum of 48 hours. Whenever more traffic is sent, a new quick mode is negotiated automatically to create two new IPSec SAs to protect application traffic. This process is rapid, because the main mode SA already exists. If a main mode SA expires, it is automatically renegotiated as needed.

Any routers or switches in the path between the communicating computers simply forward the encrypted IP packets to their

destination. However, if there is a firewall, security router, or proxy server in the path, IPSec and IKE traffic might not be forwarded. These devices must be configured to allow IPSec and IKE protocol packets through. If the IPSec packets are not encrypted, the firewall or security router can still inspect the TCP or UDP ports or other content in the packets. If the contents of these packets are modified after they are sent, the receiving IPSec computer detects the modification and discards the packets.

However, the Windows Server 2003 family implementation of IPSec provides support for a new Internet specification that allows IPSec packets to be modified by a network address translator (NAT). IPSec Encapsulating Security Payload (ESP) packets can pass through NATs that allow UDP traffic. The IKE protocol automatically detects the presence of a NAT and uses User Datagram Protocol-ESP (UDP-ESP) encapsulation to allow IPSec traffic to pass through the NAT.

# Virtual private networking with IPSec

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual private networking with IPSec**

Tunneling is the entire process of encapsulation, routing, and decapsulation. Tunneling wraps, or encapsulates, the original packet inside a new packet. This new packet might have new addressing and routing information, which enables it to travel through a network. When tunneling is combined with data confidentiality, the original packet data (as well as the original source and destination) is not revealed to those listening to traffic on the network. After the encapsulated packets reach their destination, the encapsulation is removed, and the original packet header is used to route the packet to its final destination.

The tunnel itself is the logical data path through which the encapsulated packets travel. To the original source and destination peer, the tunnel is usually transparent and appears as just another point-to-point connection in the network path. The peers are unaware of any routers, switches, proxy servers, or other security gateways between the tunnel's beginning point and the tunnel's end point. When tunneling is combined with data confidentiality, it can be used to provide a virtual private network (VPN).

The encapsulated packets travel through the network inside the tunnel. In this example, the network is the Internet. The gateway might be an edge gateway that stands between the outside Internet and the private network. The edge gateway can be a router, firewall, proxy server, or other security gateway. Also, two gateways can be used inside the private network to protect traffic across untrusted parts of the network.

**Tunnel types that use IPSec**

In Windows XP and the Windows Server 2003 family, two types of tunneling are provided that use IPSec:

- **The combination of the Layer Two Tunneling Protocol (L2TP) and IPSec (L2TP/IPSec)**

  L2TP is used to tunnel the data across a shared or public network such as the Internet, and IPSec Encapsulating Security Payload (ESP) is used to encrypt the data. L2TP/IPSec can be used to tunnel IP or Internetwork Packet Exchange (IPX) traffic.

- **IPSec in tunnel mode**

  When IPSec is used in tunnel mode, IPSec itself provides encapsulation for IP traffic only. The primary reason for using IPSec tunnel mode is interoperability with other routers, gateways, or end-systems that do not support L2TP/IPSec or PPTP VPN tunneling. IPSec tunnel mode is supported only in gateway-to-gateway tunneling scenarios and for certain server-to-server or server-to-gateway configurations as an advanced feature. IPSec tunnel mode is not supported for remote access VPN scenarios. L2TP/IPSec or PPTP should be used for remote access VPN connections.

  For information about IPSec tunnel mode and configuring IPSec tunnels, see Tunnel mode.

**How L2TP and IPSec work**

L2TP and IPSec are combined to provide both tunneling and security for IP, IPX, and other protocol packets across any IP network. IPSec can also perform tunneling without L2TP, but it is only recommended for interoperability, when one of the gateways does not support L2TP or PPTP.

L2TP encapsulates original packets first inside a PPP frame (performing compression when possible) and then inside a UDP message using port 1701. Because the UDP message is an IP payload, L2TP uses IPSec transport mode to secure the tunnel. This design supports RFC 3193 ("Securing L2TP Using IPSec"), and it is compatible with Windows XP and Windows 2000. The IPSec Internet Key Exchange (IKE) protocol negotiates security for the L2TP tunnel using certificate-based or preshared key authentication. If IPSec main mode and quick mode security associations are successfully established, L2TP negotiates the tunnel, including compression and user authentication options, and performs PPP-based user authentication.

The original packet, shown here as the **PPP payload**, includes the original and ultimate source and destination addresses used

on the private network. The outer IP header, shown as **IP header**, contains the source and destination addresses of the VPN client and server on the public network. The L2TP header includes L2TP tunnel control information. The PPP header identifies the protocol of the original packet (for example, IP or IPX).

### Note

- The IPX/SPX protocol is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

#### Common L2TP/IPSec scenarios

Two common scenarios for L2TP/IPSec are securing communications between remote access clients and the corporate network across the Internet and securing communications between branch offices.

#### Remote access clients with L2TP/IPSec

A common requirement is securing communications between remote access clients and the corporate network across the Internet. Such a client might be a sales consultant who spends most of the time traveling, or an employee working from a home office.

In this figure, the remote gateway is a server that provides edge security for the corporate intranet. The remote client represents a roaming user who requires regular access to network resources and information. An ISP is used as an example to demonstrate the path of communication when the client uses an ISP to access the Internet. L2TP is combined with IPSec to provide a simple, efficient way to build the tunnel and protect the data across the Internet.

For more information about configuring L2TP-based client remote access VPN connections, see Setting Up Remote Access VPNs, Make a virtual private network (VPN) connection, and Virtual Private Network (VPN) Connections.

#### Connecting branch offices with L2TP/IPSec

A large corporation often has multiple sites that require communication--for example, a corporate office in New York and a sales office in Washington. In this case, L2TP is combined with IPSec to provide the VPN connection and protect the data between the sites.

In this figure, the router running the Windows Server 2003 family provides edge security. The routers might have a leased line, dial-up, or other type of Internet connection. The IPSec SA and L2TP tunnel runs between the routers only and provides protected communication through the Internet.

For more information about configuring L2TP-based router-to-router VPN connections, see Deploying Router-to-Router VPNs.

# IPSec Security Services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPSec security services**

IPSec provides a high level of security by using cryptography-based services. Cryptography allows information to be transmitted securely by hashing (to provide integrity and authentication) and encrypting (to provide confidentiality) the information. IPSec provides or uses the following security services:

- Security properties
- Public key certificate-based authentication
- Preshared key authentication
- Data integrity with hash functions
- Data confidentiality with encryption
- Key management and protection

# Security properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security properties**

IPSec provides the following properties for secured communications:

- Anti-replay

  Ensures the uniqueness of each IP packet. Anti-replay is also called replay prevention. Anti-replay ensures that data captured by an attacker cannot be reused or replayed to establish a session or gain information illegally. This protects against attempts to intercept a message and then use the identical message to illegally gain access to resources, possibly months later.

- Integrity

  Protects data from unauthorized modification in transit, ensuring that the data received is exactly the same as the data sent. Hash functions sign each packet with a cryptographic checksum using a shared, secret key. Only the sender and receiver have the key that is used to calculate the checksum. If the packet contents have changed, the checksum verification fails and the packet is discarded.

- Confidentiality (encryption)

  Ensures that data is only disclosed to intended recipients. This is achieved by encrypting the data before transmission, ensuring that the data cannot be read during transmission, even if the packet is monitored or intercepted. Only the communicating computers with the shared, secret key are able to read the data after it has been decrypted. This property is optional and is dependent on IPSec policy settings.

- Authentication

  Verifies that a message could only have been sent from a computer that has knowledge of the shared, secret key. The sender includes (with the message) a message authentication code with a calculation that includes the shared, secret key. The receiver performs the same calculation and, if the receiver's calculation does not match the message authentication code that is included in the message, the message is discarded. The message authentication code is the same as the cryptographic checksum that is used for integrity.

# Public key certificate-based authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Public key certificate-based authentication**

An effectively implemented public key infrastructure, in which security credentials can be presented without compromising them in the process, resolves many security problems. IPSec works with your public key infrastructure to enable certificate-based authentication of computers.

A public key certificate is one type of authentication that reliably provides identity verification. Public key certificates are like digital passports. They are used to verify the identities of non-Microsoft operating system computers, stand-alone computers, clients that are not members of a trusted domain, or computers that are not running the Kerberos V5 authentication protocol (the default authentication method in Windows XP and Windows Server 2003 family) and Routing and Remote Access.

# Preshared key authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Preshared key authentication**

IPSec can use preshared keys for authentication. Preshared means that the parties agree on a shared, secret key that is used for authentication in an IPSec policy.

During security negotiation, information is encrypted before transmission by using a session key. The session key is created by using a Diffie-Hellman calculation and the shared, secret key. Information is decrypted on the receiving end using the same key. One IPSec peer authenticates the other peer's packet by decryption and verification of the hash inside the packet (the hash inside the packet is a hash of the preshared key). If authentication fails, the packet is discarded.

The use of preshared key authentication is not recommended because it is a relatively weak authentication method. Preshared key authentication creates a master key that is less secure (that might produce a weaker form of encryption) than certificates or the Kerberos V5 protocol. In addition, preshared keys are stored in plaintext in the registry. In Active Directory, preshared keys are stored in readable hexadecimal format.

Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing and that you use certificates or Kerberos V5 instead in a production environment. For more information about IPSec authentication methods, see Authentication methods and Public key certificate-based authentication.

# Data integrity with hash functions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Data integrity with hash functions**

Hash message authentication codes (HMAC) sign packets to verify that the information received is exactly the same as the information sent. This is called integrity. HMACs provide integrity through a keyed hash, the result of a mathematical calculation on a message using a hash function (algorithm) combined with a shared, secret key. A hash is commonly described as a signature on the packet. However, a hash differs from a digital signature. A hash uses a secret, shared key, and a digital signature uses public key technology and the private key of the sending computer. A digital signature provides nonrepudiation, and a hash does not. Nonrepudiation ensures that a communication can be proven to have originated from a specific person whose identity can be verified. It also ensures that the communication actually occurred.

Hash functions are also called one-way functions because it is easy to determine the hash from the message but mathematically infeasible to determine the message from the hash. Conversely, in two-way functions, the original message can be determined from its converted form. Encryption and decryption schemes are examples of two-way functions.

The hash is a cryptographic checksum or message integrity code (MIC) that each party must compute to verify the message. For example, the sending computer uses a hash function and shared key to compute the checksum for the message, including it with the packet. The receiving computer must perform the same hash function on the received message and shared key and compare it to the original (included in the packet from the sender). If the message has changed in transit, the hash values are different and the packet is rejected.

For integrity, you can choose between two hash functions when setting policy:

- MD5

  Message Digest 5 (MD5) is based on RFC 1321. MD5 completes four passes over the data blocks, using a different numeric constant for each word in the message on each pass. The number of 32-bit constants used during the MD5 computation ultimately produces a 128-bit hash that is used for the integrity check.

- SHA1

  Secure Hash Algorithm 1 (SHA1) was developed by the National Institute of Standards and Technology as described in Federal Information Processing Standard (FIPS) PUB 180-1. The SHA process is closely modeled after MD5. The SHA1 computation results in a 160-bit hash that is used for the integrity check. Because longer hash lengths provide greater security, SHA is stronger than MD5.

# Data confidentiality with encryption

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Data confidentiality with encryption**
IPSec in Windows XP and the Windows Server 2003 family uses the US Data Encryption Standard (DES) to provide confidentiality (data encryption). The DES algorithm was published in 1977 by the US National Bureau of Standards.

DES is a block cipher that uses a 56-bit key. A block cipher is an encryption algorithm that operates on a fixed size block of data. DES encrypts data in 64-bit blocks using a 64-bit key. The key appears to be a 64-bit key, but one bit in each of the 8 bytes is used for error checking, resulting in 56 bits of usable key.

Cipher block chaining (CBC) is also used to hide patterns of identical blocks of data within a packet. An initialization vector (an initial random number) is used as the first random block to encrypt and decrypt a block of data. Different random blocks are used in conjunction with the secret key to encrypt each successive block. This ensures that identical sets of unsecured data (plaintext) result in unique, encrypted data blocks.

The Windows XP and the Windows Server 2003 family implementation of IPSec supports the use of:

- DES

  Used when the high security and overhead of 3DES are not necessary.

- 3DES

  Used when high security is required. 3DES processes each block three times, using a unique 56-bit key each time:

  1. Encryption on the block with key 1
  2. Decryption on the block with key 2
  3. Encryption on the block with key 3

     This process is reversed if the computer is decrypting a packet.

**Note**

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

# Key management and protection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Key management and protection**
A key is a secret code or number that is required to read, modify, or verify secured data. Keys are used in conjunction with algorithms (a mathematical process) to secure data.

**Key management**
Windows XP and the Windows Server 2003 family automatically handle key generation and implement the following keying properties:

- Variable key lengths

  With IPSec, you can select integrity and encryption algorithms that provide a range of key lengths. Every time the length of a key is increased by one bit, the number of possible keys doubles, making it exponentially more difficult to determine the key. Shorter key lengths are processed more quickly than longer key lengths. Longer key lengths provide a higher level of security, but are more resource-intensive to process.

- Key material generation: The Diffie-Hellman algorithm

  To enable secure communication, two computers must be able to gain the same shared key (session key), without sending the key across a network and compromising the secret.

  The Diffie-Hellman algorithm predates Rivest-Shamir-Adleman (RSA) cryptographic algorithms and offers better performance. It is one of the oldest and most secure algorithms used for key exchange. The two peers publicly exchange keying information, which Windows XP and the Windows Server 2003 family additionally protect with a hash function signature. Neither peer ever exchanges the actual key; however, after their exchange of keying material, each can generate the identical shared key.

  The Diffie-Hellman keying material that is exchanged by the two parties can be based on 768, 1,024, or 2,048 bits of keying material, known as Diffie-Hellman groups 1, 2, and 2048, respectively. The strength of the Diffie-Hellman group is proportional to the strength of the key that is computed from the Diffie-Hellman exchange. Strong Diffie-Hellman groups combined with longer key lengths increase the computational difficulty of determining a secret key.

  IPSec uses the Diffie-Hellman algorithm to provide the keying material for all other encryption keys. Diffie-Hellman does not provide authentication. In the Windows XP and the Windows Server 2003 family implementation of IPSec, identities are authenticated after the Diffie-Hellman exchange takes place, providing protection against man-in-the-middle attacks.

- Dynamic rekeying

  IPSec policy controls how often a new key is generated during communication, by using a method called dynamic rekeying. The communication is sent in blocks, and each block of data is secured with a different key. This prevents an attacker who has obtained part of a communication, and the corresponding session keys, from obtaining the remainder of the communication. This on-demand security negotiation and automatic key management service is provided using IKE, as defined in RFC 2409, "The Internet Key Exchange (IKE)."

  IPSec policy allows you to control how often a new key is generated. If no values are configured, keys are regenerated automatically at default intervals.

**Key protection**
The following features enhance the base prime numbers (keying material) and the strength of the keys for the master and session keys.

- Key lifetimes

  Key lifetimes determine when a new key is generated, rather than how it is generated. A key lifetime allows you to force

an automatic key regeneration after a specific interval of either kilobytes (KB) or seconds, whichever occurs first. This ensures that even if an attacker is able to decipher part of a communication protected by one key, new keys protect the remainder of the communication. Whenever a key lifetime is reached, the security association (SA) is also renegotiated and the key is refreshed or regenerated. For this reason, key lifetimes are also referred to as SA lifetimes. You can specify key lifetimes for the master key and for session keys.

The master key lifetime corresponds to the IKE SA lifetime created by the IKE main mode (phase I) negotiation. It is configured in terms of time and number of quick mode negotiations, and it applies to all security rules in the IPSec policy. The IKE SA and master key typically have a long lifetime (the default value is eight hours). Master keys are much more resource-intensive to generate than session keys, due to the fact that reauthentication and additional Diffie-Hellman exchanges are required.

The session keys correspond to the IPSec SAs that are used to protect program traffic. The session keys and IPSec SAs are quickly derived from the master key by the IKE quick mode (phase II) negotiation. Thus the session keys are used to protect the data, and they have lifetimes based on the amount of data sent and the amount of time elapsed since the key started being used. Typically, session keys have shorter lifetimes than master keys. The default values are 100,000 KB (approximately 100 megabytes) or one hour. When the session keys are refreshed, new IPSec SAs replace the old ones. The IPSec SA session keys must be refreshed before either the data or time lifetime expires, or traffic is discarded. A session key will be deleted if the IPSec SAs become idle (by default, SAs become idle after five minutes). Because the master key lives longer than the session key, it allows new IPSec SAs and session keys to be established quickly. To prevent data loss, the quick mode SA session key is generated shortly before the main mode SA expires. The IKE SA and corresponding master key are not deleted when session keys and IPSec SAs are deleted, unless the specified number of quick mode SA negotiations has elapsed.

For example, if a communication takes one hour (3,600 seconds), and if you specify the minimum session key lifetime of five minutes (300 seconds), more than 12 keys are generated to complete the communication. If a 100 megabytes (MB) file is transferred over a fast corporate LAN using an IPSec security association with a 100 MB and one hour lifetime, at least one, if not two, session rekeys occur.

**Notes**

- To provide maximum protection against cryptographic attacks, the amount of data encrypted using Data Encryption Standard (DES) or Triple DES (3DES) by a single session key should not exceed 100 MB. In a high-security environment, consider using session key lifetimes for MD5 or Secure Hash Algorithm (SHA-1) that are shorter then the default values, to provide stronger protection against future cryptographic attacks.

- In certain scenarios, there might be practical operational limits on key lifetimes. The shorter the key lifetimes, the more CPU cycles are spent refreshing keys. This might limit either the number of active IPSec SAs that a computer can maintain or the throughput performance of IPSec-secured traffic.

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

- Session key refresh limit

  Repeated rekeying off of a session key can compromise the Diffie-Hellman shared secret. Because of this, you might want to set a limit to the number of quick mode session keys that can be derived from a main mode negotiation.

  If you have enabled master key perfect forward secrecy (PFS), the session key limit is not used. Setting a session key limit to 1 is identical to enabling master key PFS. If both a master key lifetime and a session limit are specified, whichever limit is reached first causes a new main mode negotiation. By default, IPSec policy does not specify a session limit.

- Diffie-Hellman groups

Diffie-Hellman groups are used to determine the length of the base prime numbers (key material) for the Diffie-Hellman exchange. The cryptographic strength of any key derived from a Diffie-Hellman exchange depends, in part, on the strength of the Diffie-Hellman group on which the prime numbers are based.

Diffie-Hellman Group 2048 (high) is stronger than Group 2 (medium), which is stronger than Group 1 (low). When a stronger group is used, the key that is derived from a Diffie-Hellman exchange is stronger and more difficult for an attacker to break.

IKE negotiates which specific group to use, ensuring that there are not any negotiation failures that result from a mismatched Diffie-Hellman group between the two peers.

If session key PFS is enabled, a new Diffie-Hellman key is negotiated during the first quick mode SA negotiation. This new key removes the dependency of the session key on the Diffie-Hellman exchange that is performed for the master key.

Both the initiator and responder must have session key PFS enabled, or negotiation fails.

The Diffie-Hellman group is the same for both the main mode and quick mode SA negotiations. When session key PFS is enabled, even though the Diffie-Hellman group is set as part of the main mode SA negotiation, it affects any rekeys during session key establishment.

**Important**

- For enhanced security, do not use Diffie-Hellman Group 1. For maximum security, use Group 2048 whenever possible. Use Group 2 when required for interoperability with Windows 2000 and Windows XP.

  For more information about Diffie-Hellman groups and key exchange, see Key exchange methods.

**Note**

- Diffie-Hellman Group 2048 is provided only with the Windows Server 2003 family.

- Perfect forward secrecy

  Unlike key lifetimes, PFS determines how a new key is generated, rather than when it is generated. Specifically, PFS ensures that the compromise of a single key permits access only to data that is protected by it, not necessarily to the entire communication. To achieve this, PFS ensures that a key used to protect a transmission cannot be used to generate additional keys. In addition, if the key that was used was derived from specific keying material, that material cannot be used to generate other keys.

  Master key PFS requires a reauthentication and is resource intensive. When it is enabled, IKE must reauthenticate identities, increasing overhead for domain controllers when Kerberos V5 is used for authentication. It requires a new main mode negotiation for every quick mode negotiation that occurs.

  Session key PFS can be used without a reauthentication and is less resource intensive. Session key PFS results in a Diffie-Hellman exchange to generate new keying material. It requires only four messages and no authentication.

  Unlike session key PFS, master key PFS does not have to be enabled on both peers. This is because master key PFS is not part of the SA negotiation. If the responder requires PFS, and the quick mode SA of the initiator expires, the responder rejects the message from the initiator and requires a new main mode negotiation. The initiator expires the main mode SA and renegotiates. PFS can be individually set for both the master and session keys.

# IPSec Protocol Types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPSec protocol types**
IPSec protocols provide data and identity protection for each IP packet by adding their own security protocol header to each packet.

For information about AH and ESP when used in transport and tunnel mode, see the following topics:

- Transport mode
- Tunnel mode

# Transport mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Transport mode**
Transport mode is the default mode for IPSec, and it is used for end-to-end communications (for example, for communications between a client and a server). When transport mode is used, IPSec encrypts only the IP payload. Transport mode provides the protection of an IP payload through an AH or ESP header. Typical IP payloads are TCP segments (containing a TCP header and TCP segment data), a UDP message (containing a UDP header and UDP message data), or an ICMP message (containing an ICMP header and ICMP message data).

**Authentication Header transport mode**
Authentication Header (AH) provides authentication, integrity, and anti-replay protection for the entire packet (both the IP header and the data payload carried in the packet). It does not provide confidentiality, which means that it does not encrypt the data. The data is readable, but protected from modification. AH uses keyed hash algorithms to sign the packet for integrity. For more information, see Data integrity with hash functions.

For example, Alice on Computer A sends data to Bob on Computer B. The IP header, the AH header, and the data are protected with integrity. This means Bob can be certain it was really Alice who sent the data and that the data was unmodified.

Integrity and authentication are provided by the placement of the AH header between the IP header and the IP payload, as shown in the following illustration.

AH is identified in the IP header with an IP protocol ID of 51. AH can be used alone or combined with the Encapsulating Security Payload (ESP) protocol.

The AH header contains the following fields:

- Next Header

  Identifies the IP payload by using the IP protocol ID. For example, a value of 6 represents TCP.

- Length

  Indicates the length of the AH header.

- Security Parameters Index (SPI)

  Used in combination with the destination address and the security protocol (AH or ESP) to identify the correct security association for the communication. The receiver uses this value to determine with which security association the packet is identified.

- Sequence Number

  Provides anti-replay protection for the packet. The sequence number is a 32-bit, incrementally increasing number (starting from 1) that indicates the packet number sent over the security association for the communication. The sequence number cannot repeat for the life of the quick mode security association. The receiver checks this field to verify that a packet for a security association with this number has not already been received. If one has been received, the packet is rejected.

- Authentication Data

  Contains the integrity check value (ICV), also known as the message authentication code, which is used to verify both message authentication and integrity. The receiver calculates the ICV value and checks it against this value (which is calculated by the sender) to verify integrity. The ICV is calculated over the IP header, the AH header, and the IP payload.

**Packet signature with the AH header**
AH signs the entire packet for integrity, with the exception of some fields in the IP header which might change in transit (for example, the Time to Live and Type of Service fields). If another IPSec header is being used in addition to AH, the AH header is inserted before any other IPSec headers. The AH packet signature is shown in the following illustration.

**Encapsulating Security Payload transport mode**
Encapsulating Security Payload (ESP) provides confidentiality (in addition to authentication, integrity, and anti-replay protection) for the IP payload. ESP in transport mode does not sign the entire packet. Only the IP payload (not the IP header) is protected. ESP can be used alone or in combination with AH.

For example, Alice on Computer A sends data to Bob on Computer B. The IP payload is encrypted and signed for integrity. Upon receipt, after the integrity verification process is complete, the data payload in the packet is decrypted. Bob can be certain that it was Alice who sent the data, the data is unmodified, and no one else was able to read it.

ESP is identified in the IP header with the IP protocol ID of 50. As shown in the following illustration, the ESP header is placed before the IP payload, and an ESP trailer and ESP authentication trailer is placed after the IP payload.

The ESP header contains the following fields:

- Security Parameters Index

  Identifies the correct security association for the communication when used in combination with the destination address and the security protocol (AH or ESP). The receiver uses this value to determine the security association with which this packet should be identified.

- Sequence Number

  Provides anti-replay protection for the packet. The sequence number is a 32-bit, incrementally increasing number (starting from 1) that indicates the packet number sent over the quick mode security association for the communication. The sequence number cannot repeat for the life of the quick mode security association. The receiver checks this field to verify that a packet for a security association with this number has not already been received. If one has been received, the packet is rejected.

The ESP trailer contains the following fields:

- Padding

  Padding of 0 to 255 bytes is used to ensure that the encrypted payload with the padding bytes are on byte boundaries required by encryption algorithms.

- Padding Length

  Indicates the length of the Padding field in bytes. The receiver uses this field to remove padding bytes after the encrypted payload with the padding bytes has been decrypted.

- Next Header

  Identifies the type of data in the payload, such as TCP or UDP.

The ESP authentication trailer contains the following field:

- Authentication Data

  Contains the integrity check value (ICV), also known as the message authentication code, which is used to verify both

message authentication and integrity. The receiver calculates the ICV value and checks it against this value (which is calculated by the sender) to verify integrity. The ICV is calculated over the ESP header, the payload data, and the ESP trailer.

**Packet signature and encryption**

As shown in the following illustration, ESP provides protection for IP payloads. The signed portion of the packet indicates where the packet has been signed for integrity and authentication. The encrypted portion of the packet indicates what information is protected with confidentiality.

The IP header is not signed and is not necessarily protected from modification. To provide data integrity and authentication for the IP header, use ESP and AH.

# Tunnel mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tunnel mode**

When IPSec tunnel mode is used, IPSec encrypts the IP header and the payload, whereas transport mode only encrypts the IP payload. Tunnel mode provides the protection of an entire IP packet by treating it as an AH or ESP payload. With tunnel mode, an entire IP packet is encapsulated with an AH or ESP header and an additional IP header. The IP addresses of the outer IP header are the tunnel endpoints, and the IP addresses of the encapsulated IP header are the ultimate source and destination addresses.

IPSec tunnel mode is useful for protecting traffic between different networks, when traffic must pass through an intermediate, untrusted network. Tunnel mode is primarily used for interoperability with gateways, or end-systems that do not support L2TP/IPSec or PPTP connections. You can use tunnel mode in the following configurations:

- Gateway-to-gateway
- Server-to-gateway
- Server-to-server

**AH tunnel mode**

As shown in the following illustration, AH tunnel mode encapsulates an IP packet with an AH and IP header and signs the entire packet for integrity and authentication.

**ESP tunnel mode**

As shown in the following illustration, ESP tunnel mode encapsulates an IP packet with both an ESP and IP header and an ESP authentication trailer.

The signed portion of the packet indicates where the packet has been signed for integrity and authentication. The encrypted portion of the packet indicates what information is protected with confidentiality.

Because a new header for tunneling is added to the packet, everything that comes after the ESP header is signed (except for the ESP authentication trailer) because it is now encapsulated in the tunneled packet. The original header is placed after the ESP header. The entire packet is appended with an ESP trailer before encryption occurs. Everything that follows the ESP header, except for the ESP authentication trailer, is encrypted. This includes the original header which is now considered to be part of the data portion of the packet.

The entire ESP payload is then encapsulated within the new tunnel header, which is not encrypted. The information in the new tunnel header is used only to route the packet from origin to tunnel endpoint.

If the packet is being sent across a public network, it is routed to the IP address of the gateway for the receiving intranet. The gateway decrypts the packet, discards the ESP header, and uses the original IP header to route the packet to the intranet computer.

ESP and AH can be combined when tunneling, providing both confidentiality for the tunneled IP packet and integrity and authentication for the entire packet.

**Using IPSec tunnels**

IPSec tunnels provide security for IP traffic only. The tunnel is configured to protect traffic between either two IP addresses or two IP subnets. If the tunnel is used between two computers instead of two gateways, the IP address outside the AH or ESP payload is the same as the IP address inside the AH or ESP payload. In Windows XP and the Windows Server 2003 family, IPSec does not support protocol-specific or port-specific tunnels. You can configure tunnels by using the IP Security Policy Management and Group Policy consoles to configure and enable two rules:

1. A rule for the outbound traffic for the tunnel.

   The rule for the outbound traffic is configured with a filter list that describes the traffic to be sent through the tunnel and a tunnel endpoint of an IP address configured on the IPSec tunnel peer (the computer or router on the other side of the tunnel).

2. A rule for the inbound traffic for the tunnel.

   The rule for the inbound traffic is configured with a filter list that describes the traffic to be received through the tunnel and a tunnel endpoint of a local IP address (the computer or router on the local side of the tunnel).

Additionally, filter actions, authentication methods, and other settings need to be specified for each rule.

For conceptual information about IPSec policy tunnel settings, see Tunnel endpoint. For information about configuring an IPSec tunnel, see Specify an IPSec tunnel. For information about how tunneling is used for virtual private networking, see Virtual private networking with IPSec.

# IPSec Components

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPSec components**

The following topics describe IPSec components that are installed with Windows XP and the Windows Server 2003 family:

- IPSec Policy Agent service
- Internet Key Exchange
- IPSec driver

# IPSec Policy Agent service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPSec Policy Agent service**

The purpose of the IPSec Policy Agent is to retrieve policy information and pass it to other IPSec components that require this information to perform security services, as shown in the following illustration.

The IPSec Policy Agent is a service that resides on each computer running a Windows Server 2003 operating system, appearing as **IPSec services** in the list of system services in the Services console. The IPSec Policy Agent:

- Retrieves the appropriate IPSec policy (if one has been assigned) from Active Directory, if the computer is a domain member, or from the local registry, if the computer is not a member of a domain.
- Polls for changes in policy configuration.
- Sends the assigned IPSec policy information to the IPSec driver.

If the computer is a member of a domain, policy retrieval occurs when the system starts, at the interval specified in the IPSec policy, and at the default Winlogon polling interval. You can also manually poll Active Directory for policy using the **gpupdate /target:computer** command.

The following are additional aspects of IPSec policy behavior for a computer that is a member of a domain:

- If IPSec policy information is centrally configured for computers that are domain members, the IPSec policy information is stored in Active Directory and cached in the local registry of the computer to which it applies.
- If the computer is temporarily not connected to the domain and policy is cached, new policy information for that computer replaces old, cached information when the computer reconnects to the domain.
- If the computer is a stand-alone computer or a member of a domain that is not using Active Directory for policy storage, IPSec policy is stored in the local registry.

The IPSec Policy Agent starts automatically at system start time. If there are no IPSec policies in Active Directory or the registry, or if the IPSec Policy Agent cannot connect to Active Directory, the IPSec Policy Agent waits for policy to be assigned or activated.

# Internet Key Exchange

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Key Exchange**
Before secured data can be exchanged, a security agreement between the two computers must be established. In this security agreement, called a security association (SA), both agree on how to exchange and protect information, as shown in the following illustration.

To build this agreement between the two computers, the IETF has established a standard method of security association and key exchange resolution named Internet Key Exchange (IKE) which:

- Centralizes security association management, reducing connection time.
- Generates and manages shared, secret keys that are used to secure the information.

This process not only protects communication between computers, it also protects remote computers that request secure access to a corporate network. In addition, this process works whenever the negotiation for the final destination computer (endpoint) is performed by a security gateway.

**Security association (SA) defined**
A security association (SA) is the combination of a negotiated key, security protocol, and security parameters index (SPI), which together define the security used to protect the communication from sender to receiver. The SPI is a unique, identifying value in the SA that is used to distinguish among multiple security associations that exist at the receiving computer. For example, multiple associations might exist if a computer is securely communicating with multiple computers at the same time. This is a common occurrence when the computer is a file server or a remote access server that serves multiple clients. In these situations, the receiving computer uses the SPI to determine which SA is used to process the incoming packets.

**Phase I or main mode SA**
In order to ensure successful and secure communication, IKE performs a two-phase operation. Confidentiality and authentication are ensured during each phase by the use of encryption and authentication algorithms that are agreed upon by the two computers during security negotiations. With the duties split between two phases, key creation can be rapidly accomplished.

During the first phase, the two computers establish a secure, authenticated channel. This is called the phase I or main mode SA. IKE automatically provides necessary identity protection during this exchange.

**Phase I or main mode negotiation**
The following are the steps that comprise a main mode negotiation.

1. Policy negotiation

   The following four mandatory parameters are negotiated as part of the main mode SA:

   - The encryption algorithm (DES or 3DES)
   - The integrity algorithm (MD5 or SHA1)
   - The Diffie-Hellman group to be used for the base keying material: Group 1 (768 bits of keying material) Group 2 (1,024 bits), or Group 2048 (2,048 bits)
   - The authentication method (Kerberos V5, certificate, or preshared key authentication)

     If certificates or preshared keys are used for authentication, the computer identity is protected. If Kerberos V5 authentication is used, the computer identity is unencrypted until encryption of the entire identity payload takes

place during authentication.

**Important**

For enhanced security, do not use Diffie-Hellman Group 1. For maximum security, use Group 2048 whenever possible. Use Group 2 when required for interoperability with Windows 2000 and Windows XP.

For more information about Diffie-Hellman groups, see Key exchange methods. For more information about preshared key authentication, see Preshared key authentication.

2. Diffie-Hellman exchange (of public values)

   At no time are actual keys exchanged. Only the base information required by the Diffie-Hellman key determination algorithm to generate the shared, secret key is exchanged. After this exchange, the IKE service on each computer generates the master key that is used to protect authentication.

3. Authentication

   To prevent a successful man-in-the-middle attack, the computers attempt to authenticate the Diffie-Hellman key exchange. Without successful authentication, communication will not proceed. The master key is used, in conjunction with the negotiation algorithms and methods, to authenticate identities. The entire identity payload is hashed and encrypted using the keys generated from the Diffie-Hellman exchange in the second step. The payload includes the identity type (for authentication), port, and protocol. IPSec uses the following identity types for authentication: For certificate authentication, the certificate distinguished name and general name; for Kerberos V5 and preshared key authentication, IPv4 addresses, the fully qualified domain name (FQDN) of the computer, and FQDN of the user. The identity payload, regardless of which authentication method is used, is protected from both modification and interpretation.

The sender presents an offer for a potential security association to the receiver. The responder cannot modify the offer. Should the offer be modified, the initiator rejects the responder's message. The responder sends either a reply accepting the offer or a reply with alternatives.

Messages sent during this phase have an automatic retry cycle that is repeated five times. If a response is received before the retry cycle ends, standard SA negotiation begins. If allowed by IPSec policy, unsecured communications will begin after a brief interval. If unsecured communications begin, after five minutes of idle time (during which no messages are sent), secured communication negotiation is attempted the next time messages are sent. If messages are sent continuously, the communication remains unsecured during the lifetime set for the main mode policy. After the policy time has elapsed, a new secured communication negotiation attempt is made.

There is no preset limit to the number of exchanges that can take place. The number of SAs established is only limited by system resources. When estimating the number of SAs that can be established without significantly degrading computer performance, consider the CPU processing strength and RAM of the computer, the lifetime of the SA, and how much traffic is being sent over the SAs.

For more information about unsecured communications, see Filter action.

**Phase II or quick mode SA**
In this phase, SAs are negotiated on behalf of the IPSec driver.

**Phase II or quick mode negotiation**
The following are the steps that comprise a quick mode negotiation.

1. Policy negotiation occurs.

   The IPSec computers exchange the following requirements for securing the data transfer:

   - The IPSec protocol (AH or ESP)
   - The hash algorithm for integrity and authentication (MD5 or SHA1)

- The algorithm for encryption, if requested (3DES or DES)

  A common agreement is reached, and two SAs are established. One SA is for inbound communication and the other is for outbound communication.

2. Session key material is refreshed or exchanged.

   IKE refreshes the keying material and new shared keys are generated for packet integrity, authentication, and encryption (if negotiated). If rekeying is required, either a second Diffie-Hellman exchange (as described in main mode negotiation) occurs, or a refresh of the original Diffie-Hellman key is used.

3. The SAs and keys, along with the SPI, are passed to the IPSec driver.

The second negotiation of security settings and keying material (for the purpose of securing data) is protected by the main mode SA. As the first phase provided identity protection, the second phase provides protection by refreshing the keying material prior to sending data. IKE can accommodate a key exchange payload for an additional Diffie-Hellman exchange if a rekey is necessary--that is, master key perfect forward secrecy (PFS) is enabled. Otherwise, IKE refreshes the keying material from the Diffie-Hellman exchange completed in main mode.

Quick mode results in a pair of security associations, each with its own SPI and key. One SA is used for inbound communication, and the other for outbound communication.

**Notes**

- Although there are two separate quick mode SAs established, IP Security Monitor only displays a single quick mode SA.

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

The retry algorithm for a message is similar to the process described in main mode negotiation. However, if this process times out for any reason during the second or higher negotiation off of the same main mode SA, a renegotiation of the main mode SA is attempted. If a message for this phase is received without an established main mode SA, it is rejected.

Using a single main mode SA for multiple quick mode SA negotiations increases the speed of the process. As long as the main mode SA does not expire, renegotiation and reauthentication are not necessary. The number of quick mode SA negotiations that can be performed is determined by IPSec policy settings.

**Note**

- Excessive rekeying off of the same main mode SA might make the shared, secret key vulnerable to a known plaintext attack. A known plaintext attack is a sniffer attack in which the attacker attempts to determine the encryption key from encrypted data based on known plaintext.

**SA lifetimes**

The main mode SA is cached to allow multiple quick mode SA negotiations (unless master key PFS is enabled). When a key lifetime is reached for the master or session key, the SA is renegotiated. In addition, the key is refreshed or regenerated.

When the default time-out period elapses for the main mode SA, or the master or session key lifetime is reached, a delete message is sent to the responder. The IKE delete message tells the responder to expire the main mode SA. This prevents additional new quick mode SAs from being created from the expired main mode SA. IKE does not expire the quick mode SA, because only the IPSec driver contains the number of seconds or bytes that have passed to reach the key lifetime.

Use caution when setting very different key lifetimes for master and session keys. For example, setting a master key lifetime of

eight hours and a session key lifetime of two hours might leave a quick mode SA in place for almost two hours after the main mode SA has expired. This occurs when the quick mode SA is generated shortly before main mode SA expiration.

It is generally recommended that all of the IKE settings (for example, master key PFS and key lifetime) and security methods remain at their defaults to avoid unnecessary administrative overhead. This provides a standard (medium) level of security. If your security plan calls for a high level of security, you should consider modifying the default security methods.

# IPSec driver

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPSec driver**

The IPSec driver receives the active IP filter list from the IPSec Policy Agent, as shown in the following illustration, and then attempts to match every inbound and outbound packet against the filters in the list.

When a packet matches a filter, it applies the filter action. When a packet does not match any filters, the packet is passed back without modification to the TCP/IP driver to be received or transmitted.

If the filter action permits transmission, the packet is received or sent with no modifications. If the action blocks transmission, the packet is discarded. If the action requires the negotiation of security, main mode and quick mode SAs are negotiated.

The negotiated quick mode security association (SA) and keys are used with both outbound and inbound processing. The IPSec driver stores all current quick mode SAs in a database. The IPSec driver uses the Security Parameters Index (SPI) field to match the correct SA with the correct packet.

When an outbound IP packet matches the IP filter list with an action to negotiate security, the IPSec driver queues the packet and then notifies Internet Key Exchange (IKE), which begins security negotiations with the destination IP address of that packet. If several outbound packets are going to the same destination and match the same filter before IKE has finished the negotiation, then only the last packet sent is saved.

After a successful negotiation is completed, the IPSec driver on the sending computer:

1. Receives the SA containing the session key from IKE.
2. Locates the outbound SA in its database, and inserts the SPI from the SA into the AH or ESP header.
3. Signs the packets (and encrypts them if confidentiality is required).
4. Sends the packets to the IP layer to be forwarded to the destination computer.

If the negotiation failed, the IPSec driver discards the packet.

When an IPSec-secured inbound packet matches a filter in the IP filter list, the IPSec driver:

1. Receives the session key, SA, and SPI from IKE.
2. Locates the inbound SA in its database by destination address and SPI.
3. Checks the signature and, if required, decrypts the packets.
4. Matches the IP packet searches for a matching filter in the filter list to ensure that no traffic, other than what was agreed upon during the negotiation, is received.
5. Sends packets to the TCP/IP driver to pass to the receiving application.

When an unsecured IP packet is received, the IPSec driver searches for a matching filter in the filter list. If a match occurs and the filter action for that filter either requires IP security or blocks the packet, then the packet is discarded.

**Note**

- The IPSec driver matches all inbound unsecured packets with the list of filters that specify IPSec tunnels first, and then matches the packet with all filters that specify end-to-end (transport) filters. The IPSec driver does not filter certain types of IP packets. For more information, see Add, edit, or remove IPSec filters.

# Description of an IPSec Policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Description of an IPSec policy**
An IPSec policy consists of:

- General IPSec Policy Settings

  Settings that apply regardless of which rules are configured. These settings determine the name of the policy, its description for administrative purposes, key exchange settings, and key exchange methods.

- IPSec Policy Rules

  One or more IPSec rules that determine which types of traffic IPSec must examine, how traffic is treated, how to authenticate an IPSec peer, and other settings.

After the policies are created, they can be assigned and applied at the domain, site, organizational unit, and local level. For more information, see Creating, modifying, and assigning IPSec policies.

# General IPSec Policy Settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**General IPSec policy settings**

The general settings for an IPSec policy consist of the following types:

- Name

  The name for the policy.

- Description

  Optional text that describes the purpose of the IPSec policy. It is recommended that you complete and update this description to provide a summary of the settings and rules for the policy.

- Policy change poll interval

  The number of minutes between consecutive polls for changes in Active Directory-based IPSec policies. This polling does not detect a change in domain or organizational unit membership, or the assigning or unassigning of a new policy. These events are detected when the Winlogon service polls for changes in Group Policy, which occurs by default every 90 minutes.

- Key exchange settings

  The way in which new keys are derived and how often they are renewed.

- Key exchange methods

  The ways in which identities are protected during the key exchange.

The default key exchange settings and methods are configured to work for most IPSec deployments. Unless there are special security requirements, default settings should not have to be changed.

# Key exchange settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Key exchange settings**
The strength of the keys which protect the key exchange phase is enhanced by the following features:

**Key lifetimes**
Lifetime settings determine when a new key is generated. Any time a key lifetime is reached, the associated SA is also renegotiated. The process of generating new keys at intervals is called dynamic rekeying or key regeneration. Lifetimes allow you to force the generation of a new key after a specific interval. For example, if the communication takes 100 minutes and you specify the key lifetime as 10 minutes, 10 keys will be generated (one every 10 minutes) during the exchange. Using multiple keys ensures that if an attacker manages to gain the key to one part of a communication, the entire communication is not compromised. Automatic key regeneration is provided by default. You can override the defaults and either specify a master key lifetime in minutes or by the number of session keys, or enable master key perfect forward secrecy (PFS).

Caution should be taken when setting very different key lifetimes, since they also determine the lifetime of the SA. For example, setting a master key lifetime of 8 hours (480 minutes) and a session key lifetime (set within a filter action) of 2 hours might result in a quick mode SA that is in place for almost 2 hours after the main mode SA has expired. This has the potential to occur if the new quick mode SA is generated just before the main mode SA expires.

- **Session key limit**

  Repeated rekeying off of the same master key might eventually compromise the key. For example, if Alice on Computer A sends a message to Bob on Computer B, and then a few minutes later sends another message to Bob, the same master key material can be reused since an SA was recently established with that computer. If you want to limit the number of times this reuse occurs, you can specify a session key limit.

  If you decide to enable master key perfect forward secrecy (PFS), the session key limit will be set to 1. Master key PFS forces key regeneration each time. If you specify both a master key lifetime in minutes, and a session key limit, whichever interval is reached first will start a new key.

- **Master key perfect forward secrecy (PFS)**

  Master key PFS determines how a new session key is generated. Enabling master key PFS ensures that the master key keying material cannot be used to generate more than one session key.

  Master key PFS should be used with caution because it requires reauthentication and might impact performance. It is not required to be enabled on both peers.

For information about how to configure key exchange settings and methods, see Configure key exchange settings and Create key exchange security methods.

# Key exchange methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Key exchange methods**
In addition to key properties, you can set security methods for main mode IKE negotiation. For example, you can specify which algorithms are used for integrity and confidentiality. The same algorithms that are available for quick mode security methods are available for main mode IKE negotiation: MD5 and SHA1 for integrity; DES and 3DES for confidentiality.

**Diffie-Hellman groups**
In addition to setting integrity and confidentiality algorithms, you can specify which Diffie-Hellman groups to use. Diffie-Hellman groups are used to determine the length of the base prime numbers used during the key exchange process. The cryptographic strength of any key derived depends, in part, on the strength of the Diffie-Hellman group upon which the prime numbers are based.

Group 2048 (high) is stronger (more secure) than Group 2 (medium), which is stronger than Group 1 (low). Group 1 provides 768 bits of keying strength, Group 2 provides 1024 bits, and Group 2048 provides 2048 bits. If mismatched groups are specified on each peer, negotiation fails. The group cannot be switched during the negotiation.

The Diffie-Hellman group is configured as part of the main mode key exchange settings. New session keys generated during quick mode are derived from the Diffie-Hellman main mode master key material, unless master key or session key perfect forward secrecy (PFS) is enabled. If either master key or session key PFS is enabled, a new Diffie-Hellman exchange is performed to obtain new master key keying material for each new session key that is required. The difference between master key PFS and session key PFS is that master key PFS requires a reauthentication of the main mode SA in addition to the Diffie-Hellman exchange.

**Important**

- For enhanced security, do not use Diffie-Hellman Group 1. For maximum security, use Group 2048 whenever possible. Use Group 2 when required for interoperability with Windows 2000 and Windows XP.

**Notes**

- Diffie-Hellman Group 2048 is provided only with the Windows Server 2003 family.
- For a standard level of security, it is generally recommended that all of the IKE settings (for example, master key PFS and key lifetime) and security methods remain at their defaults. For more information about IKE settings, see Internet Key Exchange.
- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

For information about how to configure key exchange settings and methods, see Configure key exchange settings and Create key exchange security methods.

# IPSec Policy Rules

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IPSec policy rules**

An IPSec policy consists of one or more rules that determine IPSec behavior. IPSec rules are configured on the **Rules** tab in the properties of an IPSec policy. Each IPSec rule contains the following configuration items:

- Filter list

  A single filter list is selected that contains one or more predefined packet filters that describe the types of traffic to which the configured filter action for this rule is applied. The filter list is configured on the **IP Filter List** tab in the properties of an IPSec rule within an IPSec policy.

- Filter action

  A single filter action is selected that includes the type of action required (Permit, Block, or Negotiate Security) for packets that match the filter list. For the Negotiate Security filter action, the negotiation data contains one or more security methods that are used (in order of preference) during IKE negotiations and other IPSec settings. Each security method determines the security protocol (such as AH or ESP), the specific cryptographic and hashing algorithms, and session key regeneration settings used. The filter action is configured on the **Filter Action** tab in the properties of an IPSec rule within an IPSec policy.

- Authentication methods

  One or more authentication methods are configured (in order of preference) and used for authentication of IPSec peers during main mode negotiations. The available authentication methods are the Kerberos V5 protocol, use of a certificate issued from a specified certification authority, or a preshared key. The negotiation data is configured on the **Authentication Methods** tab in the properties of an IPSec rule within an IPSec policy.

  **Important**

  - The use of preshared key authentication is not recommended because it is a relatively weak authentication method. Preshared key authentication creates a master key that is less secure (that might produce a weaker form of encryption) than certificates or the Kerberos V5 protocol. In addition, preshared keys are stored in plaintext. Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing and that you use certificates or Kerberos V5 instead in a production environment.

- Tunnel endpoint

  Specifies whether the traffic is tunneled and, if it is, the IP address of the tunnel endpoint. For outbound traffic, the tunnel endpoint is the IP address of the IPSec tunnel peer. For inbound traffic, the tunnel endpoint is a local IP address. The tunnel endpoint is configured on the **Tunnel Setting** tab in the properties of an IPSec rule within an IPSec policy. For more information, see Tunnel mode.

- Connection type

  Specifies whether the rule applies to local area network (LAN) connections, dial-up connections, or both. The connection type is configured on the **Connection Type** tab in the properties of an IPSec rule within an IPSec policy.

The rules for a policy are displayed in IP Security Policies in reverse alphabetical order based on the name of the filter list selected for each rule. There is no method for specifying an order in which to apply the rules in a policy. The IPSec driver automatically orders the rules based on the most specific to the least specific filter list. For example, the IPSec driver would apply a rule containing a filter list that specified individual IP addresses and TCP ports before a rule containing a filter list that specified all addresses on a subnet.

**Default response rule**

The default response rule, which can be used for all policies, has the IP filter list of **<Dynamic>** and the filter action of **Default Response** when the list of rules is viewed with the IP Security Policy Management console. The default response rule cannot be deleted, but it can be deactivated. It is activated by default for all policies.

The default response rule is used to ensure that the computer responds to requests for secure communication. If an active policy does not have a rule defined for a computer that is requesting secure communication, then the default response rule is applied and security is negotiated. For example, when Computer A communicates securely with Computer B, and Computer B does not have an inbound filter defined for Computer A, the default response rule is used.

Security methods and authentication methods can be configured for the default response rule. The filter list of **<Dynamic>** indicates that the filter list is not configured, but that filters are created automatically based on the receipt of IKE negotiation packets. The filter action of **Default Response** indicates that the action of the filter (Permit, Block, or Negotiate security) cannot be configured. Negotiate Security will be used. However, you can configure:

- The security methods and their preference order on the **Security Methods** tab.
- The authentication methods and their preference order on the **Authentication Methods** tab.

# Filter list

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Filter list**

When traffic matches a source, destination, and type of IP traffic in a filter, security negotiations are initiated. This type of IP packet filtering enables a network administrator to precisely define what IP traffic is secured. Each IP filter list contains one or multiple filters, which define IP addresses and traffic types. One IP filter list can be used for multiple communication scenarios.

IPSec requires both an inbound and outbound filter between the computers specified in the filter list. Inbound filters apply to incoming traffic. Outbound filters apply to traffic leaving a computer towards a destination. For example, if Computer A wants to securely exchange data with Computer B:

- The active IPSec policy on Computer A must have a filter for any outbound packets to Computer B. Source=A and Destination=B.
- The active IPSec policy on Computer A must have a filter for any inbound packets from Computer B. Source=B and Destination=A.

Each peer must also have the reverse filter:

- The active IPSec policy on Computer B must have a filter for any inbound packets from Computer A. Source=A and Destination=B.
- The active IPSec policy on Computer B must have a filter for any outbound packets to Computer A. Source=B and Destination=A.

**Filter settings**

Each filter defines a particular subset of inbound or outbound network traffic that should be secured. You must have a filter to cover any traffic to which the associated rule applies. A filter contains the following settings:

- **The source and destination address of the IP packet.** You can specify any IP address assigned to the IPSec peer, a single IP address, IP addresses by DNS name, or groups of addresses to specify IP subnets.
- **The protocol over which the packet is being transferred.** By default, all protocols in the TCP/IP protocol suite are selected. However, you can specify an individual protocol for this filter to meet special requirements, including custom protocols.
- **The source and destination port for TCP and UDP.** By default, all TCP and UDP ports are selected, but you can select a specific TCP or UDP port.

For information about how to configure IP filter lists, see Add, edit, or remove IP filter lists.

Special filters might be required for certain types of traffic, such as SNMP traffic or security gateways. For more information, see Special IPSec considerations.

# Filter action

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Filter action**

A filter action defines the security requirements for the data transmission. A filter action can be configured to:

- Permit traffic (**Permit**)

  IPSec passes this traffic without modification or the requirement for security. This is appropriate for traffic from specific computers that are not IPSec-capable. Be sure to limit the IP filter list to a minimal scope when using this type of filter action, so you do not let traffic through which should be secured.

- Block traffic (**Block**)

  IPSec silently discards this traffic. Be sure to use an IP filter list that appropriately defines the scope of traffic when using a blocking filter action so that you do not block valid computers from communicating.

- Negotiate IPSec (**Negotiate security**)

  IPSec requires the negotiation of security associations and the sending or receiving of IPSec-secured traffic. After you choose to negotiate IPSec, you can also configure the following:

  - Security methods and their order

    For more information, see IPSec security methods.

  - Allowance of initial incoming unsecured traffic (**Accept unsecured communication, but always respond using IPSec**)

    IPSec allows an incoming packet that matches the configured filter list to be unsecured (not protected by IPSec). However, the outgoing response to the incoming packet must be protected. This setting is useful when you are using the default response rule for clients. When a group of servers are configured with a rule that secures communications with any IP address and accepts unsecured communication, responding with only secured communications, enabling the default response rule on client computers ensures that the clients will respond to the server request to negotiate security. This option should be disabled for secure computers connected to the Internet to prevent denial of service attacks.

  - Enabling of communication with non-IPSec-enabled computers (**Allow unsecured communication with non-IPSec-aware computer**)

    IPSec falls back to unsecured communication, if necessary. Again, you might need to limit the IP filter list to a minimal scope. Otherwise, if negotiation fails for any reason, any communications affected by the rule in which this filter action resides could result in data being sent without security. If you are concerned about unsecured communication, you might consider disabling this setting. However, communication with computers that cannot initiate IPSec, such as legacy systems, might be blocked. This option should be disabled for secure computers connected to the Internet.

  - Generation of session keys from new keying material (**Use session key perfect forward secrecy (PFS)**)

    This determines whether existing master key keying material can be used to derive a new session key. Enabling session key perfect forward secrecy (PFS) ensures that master key keying material cannot be used to derive more than one session key. When session key PFS is enabled, a new Diffie-Hellman key exchange is performed to generate new master key keying material before the new session key is created. Session key PFS does not require main mode reauthentication and uses less resources than master key PFS.

For information about how to configure filter actions, see Add, edit, or remove filter actions.

**IPSec security methods**

Each security method defines the security requirements of any communications to which the associated rule applies. Creating multiple security methods increases the chance that a common method can be found between two computers. The IKE component reads the list of security methods in descending order and sends a list of allowed security methods to the other peer. The first method in common is selected. Typically, the most secure methods are placed at the top of the list and the least secure methods are placed at the bottom of the list.

**Predefined security methods**

The following security methods are predefined:

- Encryption and Integrity

  Uses the ESP protocol to provide data confidentiality (encryption) with the triple Data Encryption Standard (3DES) algorithm, data integrity and authentication with the Secure Hash Algorithm 1 (SHA1) integrity algorithm, and default key lifetimes (100MB, 1 hour). If you require both data and addressing (IP header) protection, you can create a custom security method. If you do not require encryption, use **Integrity only**.

- Integrity only

  Uses the ESP protocol to provide data integrity and authentication with the SHA1 integrity algorithm and default key lifetimes (100MB, 1 hour). In this configuration, ESP does not provide data confidentiality (encryption). This is appropriate when your security plan calls for standard levels of security.

**Custom security methods**

If the predefined **Encryption and Integrity** or **Integrity only** settings do not meet your security requirements, you can specify custom security methods. For example, you can use custom methods when encryption and address integrity, stronger algorithms, or key lifetimes need to be specified. When configuring a custom security method, you can configure the following:

- Security protocols

  Both AH (**Data and address integrity without encryption**) and ESP (**Data integrity and encryption**) can be enabled in a custom security method when you require IP header integrity and data encryption. If you chose to enable both, you do not need to specify an integrity algorithm for ESP. The algorithm that you select for AH provides integrity.

- Integrity algorithm

  - Message Digest 5 (MD5), which uses a 128-bit key.
  - Secure Hash Algorithm 1 (SHA1), which uses a 160-bit key.

- Encryption algorithm

  - 3DES is the most secure of the DES combinations, and somewhat slower in performance. 3DES processes each block three times, using three unique 56-bit keys.
  - DES is used when the higher security and overhead of 3DES is not necessary. DES uses a single 56-bit key.

- Session key settings

  Session key settings determine when a new key is generated, rather than how it is generated. You can specify a lifetime in kilobytes, seconds, or both. For example, if the communication takes 10,000 seconds and you specify the key lifetime as 1000 seconds, 10 keys will be generated to complete the transfer. This ensures that, even if an attacker manages to determine one session key and decipher part of a communication, deciphering the entire communication is not possible. By default, new session keys are generated for every 100 MB of data or every hour. Note that any time a key lifetime is reached, the quick mode SA is also renegotiated in addition to the key refresh or regeneration.

**Note**

- When IPSec provides data confidentiality between a Windows XP or Windows Server 2003 family-based computer (or a Windows 2000-based computer that has the High Encryption Pack or Service Pack 2 or higher installed) and another computer that does not use 3DES, your list of security methods must include DES. Otherwise, the computer that you are trying to communicate with might not be able to reach a common security agreement with your computer. If confidentiality of the data is not required, you can select ESP format with an integrity algorithm only and set the encryption to **<None>**. Alternately, you can select an AH format with an integrity algorithm.

For information about how to configure security methods, see Add, edit, or remove IPSec security methods.

# Authentication methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authentication methods**
Each rule defines a list of authentication methods. Each authentication method defines the requirements for how identities are verified in communications to which the associated rule applies. The two peers must have at least one common authentication method or communication will fail. Creating multiple authentication methods increases the chance that a common method between two computers can be found.

Only one authentication method can be used between a pair of computers, regardless of how many are configured. If you have multiple rules that apply to the same pair of computers, you must configure the authentication methods list in those rules to enable the pair to use the same method. For example, if a rule between a pair of computers specifies only Kerberos for authentication and filters only TCP data and, in another rule, specifies only certificates for authentication and filters only UDP data, authentication will fail.

**Overview of authentication methods**
For authentication, IPSec allows you to use the Kerberos V5 protocol, certificate-based authentication, or preshared key authentication.

- The Kerberos V5 security protocol is the default authentication technology. This method can be used for any clients running the Kerberos V5 protocol (whether or not the clients are running Windows 2000, Windows XP Professional, or a Windows Server 2003 operating system) that are members of the same or trusted domains.

- A public key certificate should be used in situations that include Internet access, remote access to corporate resources, external business partner communications, or computers that do not run the Kerberos V5 security protocol. This requires that at least one trusted certification authority (CA) and associated certificate have been configured. Computers running Windows 2000, Windows XP, or a Windows Server 2003 operating system support X.509 Version 3 certificates, including computer certificates generated by commercial CAs.

- A preshared secret key can be specified. It is simple to use and does not require the client to run the Kerberos V5 protocol or have a public key certificate. Both parties must manually configure IPSec to use this preshared key.

  **Important**

  - The use of preshared key authentication is not recommended because it is a relatively weak authentication method. Preshared key authentication creates a master key that is less secure (that might produce a weaker form of encryption) than certificates or the Kerberos V5 protocol. In addition, preshared keys are stored in plaintext. Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing and that you use certificates or Kerberos V5 instead in a production environment.

## Notes

- The ability to authenticate using Kerberos V5 is not supported on computers running Windows XP Home Edition or computers running any other version of Windows 2000, Windows XP, or a Windows Server 2003 operating system that are not a member of an Active Directory domain.

- For information about how to configure authentication methods, see Define IPSec authentication methods.

**IPSec certificate to account mapping**
When you use either Kerberos V5 or certificate authentication, you can set restrictions on which computers are allowed to connect. When you enable IPSec certificate to account mapping, the IKE protocol associates (maps) a computer certificate to a computer account in an Active Directory domain or forest, and then retrieves an access token, which includes the list of user rights assigned to the computer. You can restrict access by configuring Group Policy security settings and assigning either the **Access this computer from the network** user right or the **Deny access to this computer from the network** user right to individual or multiple computers as needed.

When a Windows 2000 or a Windows Server 2003 family certification authority is used for computer certificate autoenrollment, the certificates are automatically stored in Active Directory as a property of the computer account. Alternatively, you can use a non-Microsoft certification authority in which to enroll computers. If you do not use computer certificate autoenrollment, you must manage certificate to account mapping manually.

**Notes**

- If you use the Kerberos V5 protocol for authentication, the IKE protocol verifies access controls, but only if IKE is a responder. Therefore, for access controls to be applied, you must configure the IPSec policy on the client computer to initiate IKE to the server. If you use certificate authentication, access controls are applied if either the server or the client computer initiates IKE to the server.

- For information about configuring security settings in Group Policy, see Security settings overview.

# Tunnel endpoint

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tunnel endpoint**

As discussed in Virtual private networking with IPSec, IPSec can perform layer 3 tunneling for scenarios in which Layer Two Tunneling Protocol (L2TP) cannot be used. If you are using L2TP for remote communications, no tunnel configuration is needed because the client and server VPN components of Windows XP and the Windows Server 2003 family automatically create the appropriate rules to secure L2TP traffic.

To create a layer 3 tunnel using IPSec, use the IP Security Policy Management or Group Policy consoles to configure and enable the following two rules for the appropriate policy:

1. A rule for the outbound traffic for the tunnel.

   The rule for the outbound traffic is configured with both a filter list that describes the traffic to be sent across the tunnel and a tunnel endpoint of an IP address configured on the IPSec tunnel peer (the computer or router on the other side of the tunnel).

2. A rule for the inbound traffic for the tunnel.

   The rule for the inbound traffic is configured with both a filter list that describes the traffic to be received across the tunnel and a tunnel endpoint of a local IP address (the computer or router on this side of the tunnel).

For each rule, you must also specify filter actions, authentication methods, and other settings.

For information about how to configure IPSec tunnel endpoints, see Specify an IPSec tunnel. For more information about IPSec tunnel mode, see Tunnel mode.

For advanced information about configuring IPSec tunnels, see article Q252735, "How to Configure IPSec Tunneling in Windows 2000," in the Microsoft Knowledge Base.

# Connection type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connection type**
For each IPSec rule, you can define which connection types on your computer are affected. The connection types apply to all connections in Network Connections on the computer for which you are configuring IPSec policy.

Each rule has one connection type setting:

- **All Network Connections**. The rule applies to communications sent through any of the network connections that you have configured on the computer.
- **Local Area Network (LAN)**. The rule only applies to communications sent through LAN connections that you have configured on the computer.
- **Remote Access**. The rule only applies to communications sent through any virtual private network (VPN) or dial-up connections that you have configured on the computer.

For information about how to configure connection types, see Specify IPSec connection types.

For information about configuring network connections on a computer, see Configuring a network or dial-up connection.

# Using Internet Protocol Security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Internet Protocol security**

This section covers:

- Managing IPSec from the command line
- Designing and Planning IPSec Policies
- Viewing IPSec Statistics and Details About Active IPSec Policies

# Managing IPSec from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing IPSec from the command line**
The Netsh commands for Internet Protocol security (IPSec) provide a fully equivalent alternative to the console-based management and diagnostic capabilities provided by the IP Security Policy Management and IP Security Monitor consoles. You can use Netsh commands for IPSec to script IPSec policy creation, display details about IPSec policies, and change the IPSec configuration for troubleshooting. In addition, administering IPSec from the command line is useful when you want to extend the security and manageability of IPSec. For example, you can use Netsh commands for IPSec to enable IPSec driver event logging, set default traffic exemptions, and configure computer startup security.

For a comprehensive **netsh ipsec** command reference (including syntax and parameters), see Netsh commands for Internet Protocol security.

### Notes

- For information about how to use Netsh commands for IPSec to change the IPSec configuration for troubleshooting, see the section "Using Netsh to change the IPSec configuration on computers running the Windows Server 2003 family" in IPSec troubleshooting tools.

- You can use the Netsh commands for IPSec to configure IPSec policies only on computers running members of the Windows Server 2003 family. To use the command line to configure IPSec policies on computers running Windows XP, use Ipseccmd.exe. To use the command line to configure IPSec policies on computers running Windows 2000, use Ipsecpol.exe, which is provided with the Windows 2000 Server Resource Kit. For more information, see IPSec troubleshooting tools.

# Designing and Planning IPSec Policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Designing and planning IPSec policies**
This section provides information about planning and deploying IPSec in your organization. You should also review IPSec Best practices for general information about IPSec deployment.

For information on specific topics, see:

- Establishing an IPSec security plan
- Default IPSec policies
- Creating, modifying, and assigning IPSec policies
- Special IPSec considerations
- IPSec troubleshooting tools

# Establishing an IPSec security plan

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Establishing an IPSec security plan**

Whether for a large domain or a small workgroup, implementing IPSec means finding a balance between making information easily available to the largest number of users, and protecting sensitive information from unauthorized access.

Finding the proper balance requires:

- Assessing the risk and determining the appropriate level of security for your organization.
- Identifying valuable information.
- Defining security policies that use your risk management criteria and protect the identified information.
- Determining how the policies can best be implemented within the existing organization.
- Ensuring that management and technology requirements are in place.
- Providing all users with both secure and efficient access to the appropriate resources, according to their needs.

Security considerations are also influenced by the way the computer will be used. For example, the required security might differ, depending on whether the computer is a domain controller, Web server, remote access server, file server, database server, or intranet or remote client. The security framework in Windows 2000, Windows XP, and Windows Server 2003 family is designed to fulfill the most stringent security requirements. However, software alone might be less effective without careful planning and assessment, effective security guidelines, enforcement, auditing, and sensible security policy design and assignment.

There is no exact definition of the measures that define standard security. These can vary widely, depending on an organization's policies and infrastructures. The following security levels can be considered a general basis for planning your IPSec deployment:

- Minimal security

  Computers do not exchange sensitive data. IPSec is not active by default. No administrative action to disable IPSec is required.

- Standard security

  Computers, especially file servers, are used to store valuable data. Security must be balanced so it does not become a barrier to users trying to perform their tasks. Windows XP and the Windows Server 2003 family provide example IPSec policies that secure data, but do not necessarily require the highest level of security: **Client (Respond Only)** and **Server (Request Security)**. Use these as a basis for your IPSec policies. These, or similar custom policies, optimize efficiency without compromising security.

- High security

  Computers that contain highly sensitive data are at risk for data theft, accidental or malicious disruption of the system (especially in remote dial-up scenarios), or any public network communications. **Secure Server (Require Security)**, a default policy, requires IPSec protection for all traffic being sent or received (except initial inbound communication) with stronger security methods. Unsecured communication with a non-IPSec-aware computer is not allowed.

**From planning to policy configuration**

After you have identified the types of traffic that need to be secured and the level of security required, you can begin policy configuration. Windows XP and Windows Server 2003 IPSec policy configuration is the translation of your security

requirements to one or more IPSec policies, only one of which can be assigned at each of the following levels: domain, site, organizational unit, or local levels. Each IPSec policy consists of one or more IPSec rules. Each IPSec rule consists of:

- A selected filter list.
- A selected filter action.
- Selected authentication methods.
- A selected connection type.
- A selected tunnel setting.

You can configure IPSec policy in the following ways:

- Create a new policy and define the set of rules for the policy, adding filter lists and filter actions as required.

  In this method, an IPSec policy is created first and then rules are added and configured. Filter lists (specifying traffic types) and filter actions (specifying how the traffic is treated) are added during rule creation.

  For more information, see Add, edit, or remove IPSec policies and Add, edit, or remove IPSec rules.

- Create the set of filter lists and filter actions, and then create the policies and add rules that combine the filter lists with filter actions.

  In this method, the filter lists and the filter actions are configured first. Next, IPSec policies are created and rules are added that combine the appropriate filter list with the appropriate filter action. Additionally, authentication methods, connection types, and tunnel settings are specified.

  For information about how to individually configure IP filter lists and filter actions, see Manage multiple IP filter lists and Manage multiple filter actions.

For either configuration method, after the IPSec policies have been created, they must be assigned. For more information, see Creating, modifying, and assigning IPSec policies.

**Notes**

- To manage Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. To manage local or remote IPSec policies for a computer, you must be a member of the Administrators group on the local or remote computer. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. For more information, see Default local groups and Default groups.

- The integration of IPSec policies with Active Directory described here does not apply to computers running Windows XP Home Edition. You cannot administer Active Directory-based IPSec policy from a computer running Windows XP Home Edition because these computers cannot join Active Directory domains.

# Default IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Default IPSec policies**

Windows XP and the Windows Server 2003 family provide a set of predefined IPSec filter lists and filter actions and default policies. This is only intended to provide an example. It is not designed for operational use without modification. A knowledgeable IPSec network administrator or advanced user should design new, custom polices for operational use.

Computers that are connected to the Internet must be carefully protected from network attacks with custom policies. The default policies are defined as examples for intranets because they allow a computer to receive unsecured traffic. The default policies are designed for computers that are members of an Active Directory domain.

**Predefined filter lists**

The following predefined filter lists are provided as examples for use in the default policies:

- **All ICMP Traffic**

  A filter list for all ICMP traffic (IP protocol 1) sent and received between this computer and all other computers.

- **All IP Traffic**

  A filter list for all IP traffic sent and received between this computer and all other computers. By default, all Internet Key Exchange (IKE) traffic is excluded. All other traffic types are matched against IPSec filters, however, and you can configure, block, or permit filter actions specifically for multicast and broadcast traffic (IPSec does not negotiate security associations for multicast and broadcast traffic).

**Predefined filter actions**

The following predefined filter actions are provided as examples for use in the default policies:

- **Permit**

  Traffic is permitted (the security method is set to **Permit**).

- **Request Security (Optional)**

  Traffic is secured (the security method is set to **Negotiate security**), however, the following exceptions apply:

  - Initial incoming unsecured communication is allowed. This behavior is known as inbound passthrough.

  - If security negotiation fails after 3 seconds, unsecured communication to a non-IPSec-aware computer is allowed. This filter action secures traffic to IPSec-aware computers, but allows unsecured communication if it is required. This behavior is known as fallback to clear.

  In order to avoid the potential for denial-of-service attacks, this filter action must not be used on the Internet.

  The following table lists the security methods (in preference order) for the **Request Security (Optional)** predefined filter action.

| Type | AH integrity | ESP confidentiality | ESP integrity | Key lifetimes (KB/sec) |
|---|---|---|---|---|
| Custom | None | 3DES | SHA1 | 100000/900 |
| Custom | None | DES | SHA1 | 100000/900 |
| Custom | SHA1 | None | None | 100000/300 |

| | | | | |
|---|---|---|---|---|
| Custom | MD5 | None | None | 100000/300 |

The security negotiation for traffic using this filter action attempts ESP encryption (first 3DES, and then DES) with SHA1 integrity. If those security methods cannot be negotiated with the peer, AH integrity (first SHA1, and then MD5) only is attempted.

- **Require Security**

  Traffic is secured (the security method is set to **Negotiate security**), however, initial incoming unsecured communication is allowed (inbound passthrough is enabled). Unsecured communication with non-IPSec-aware computers is not allowed (fallback to clear is disabled). For example, an incoming connection request packet is allowed. The computer's reply to the connection request matches the outbound filter, causing a request for security to be sent to the sender of the unsecured traffic. If security negotiation is successful, traffic in both directions is required to be secure. If security negotiation is not successful, outgoing traffic is not allowed. The computer might continue to receive incoming unsecured traffic and will continue to attempt to negotiate security.

  In order to avoid the potential for denial-of-service attacks, this filter action must not be used on the Internet.

  The following table lists the security methods (in preference order) for the **Require Security** predefined filter action.

| Type | AH integrity | ESP confidentiality | ESP integrity | Key lifetimes (KB/sec) |
|---|---|---|---|---|
| Custom | None | 3DES | SHA1 | 100000/900 |
| Custom | None | 3DES | MD5 | 100000/900 |
| Custom | None | DES | SHA1 | 100000/900 |
| Custom | None | DES | MD5 | 100000/900 |

The security negotiation for traffic using this filter action will only attempt to negotiate ESP encryption (first 3DES, and then DES) with differing ESP authentication methods (first SHA1, and then MD5).

The most secure filter action is one that negotiates security and neither receives unsecured traffic (inbound passthrough is disabled) nor allows communication with non-IPSec-aware computers (fallback to clear is disabled). This is known as a lockdown filter action. When a server is using this filter action, clients must initiate secured communication before sending any IP traffic. The IPSec policy for client computers must be configured with additional rules that force the client to negotiate security with the server. A client configured with policy that consists of only the default response rule is not able to communicate with a locked down server.

**Predefined rules**

The only predefined rule that is available on all policies is the default response rule. The default response rule is automatically created in a new policy and cannot be created manually. It is used to respond to security requests when no other rule applies. For example, a client policy that enables a client to respond to security requests but does not secure any traffic by default, would have only the default response rule active. In some cases, it is enabled by default. You can disable the default response rule on the **Rules** tab in properties for a policy. You can also modify the authentication method and security methods of the default response rule for specific needs. For more information, see the section "Default response rule" in IPSec Policy Rules.

**Default policies**

The following are provided as examples for use as default policies:

- **Client (Respond Only)**

  This is an example policy for computers that secure communication on request. For example, intranet clients might not require IPSec except when requested by another computer. This policy enables the computer on which it is active to respond to requests for secured communications. This policy contains the default response rule, which creates dynamic IPSec filters for inbound and outbound traffic based on the requested protocol and port traffic for the communication that is being secured.

  This policy has the following settings:

**First rule (default response rule)**

- IP Filter List: <Dynamic>
- Filter Action: Default Response
- Authentication: Kerberos
- Tunnel Setting: None
- Connection Type: All

- **Server (Request Security)**

  This is an example policy for computers that should secure communications in most cases, allowing unsecured communication with non-IPSec-aware computers. With this policy, the computer accepts unsecured traffic, but always attempts to secure additional communications by requesting security from the original sender. This policy allows the entire communication to be unsecured if the other computer is not IPSec-enabled. For example, communication to specific servers can be secure while allowing the server to communicate in an unsecured manner to accommodate a mixture of clients (some of which support IPSec and some of which do not).

  This policy has a rule to request security for all IP traffic, a rule to permit ICMP traffic, and the default response rule to respond to requests for security from other computers.

  This policy has the following settings:

  **First rule**

  - IP Filter List: All IP Traffic
  - Filter Action: Request Security (Optional)
  - Authentication: Kerberos
  - Tunnel Setting: None
  - Connection Type: All

  **Second rule**

  - IP Filter List: All ICMP Traffic
  - Filter Action: Permit
  - Authentication: N/A
  - Tunnel Setting: None
  - Connection Type: All

  **Third rule (default response rule)**

  - IP Filter List: <Dynamic>
  - Filter Action: Default Response

- Authentication: Kerberos
- Tunnel Setting: None
- Connection Type: All

- **Secure Server (Require Security)**

  This is an example policy for computers on an intranet that require secure communications, such as a server that transmits highly sensitive data. Administrators can use this IPSec policy as an example to create their own custom IPSec policy for production use. The filters used in this policy require all outbound communication to be secured, allowing only the initial inbound communication request to be unsecured.

  This policy has a rule to require security for all IP traffic, a rule to permit ICMP traffic, and the default response rule to respond to requests for security from other computers.

  **First rule**

  - IP Filter List: All IP Traffic
  - Filter Action: Require Security
  - Authentication: N/A
  - Tunnel Setting: None
  - Connection Type: All

  **Second rule**

  - IP Filter List: All ICMP Traffic
  - Filter Action: Permit
  - Authentication: Kerberos
  - Tunnel Setting: None
  - Connection Type: All

  **Third rule (default response rule)**

  - IP Filter List: <Dynamic>
  - Filter Action: Default Response
  - Authentication: Kerberos
  - Tunnel Setting: None
  - Connection Type: All

**Notes**

- In the Windows Server 2003 family, IPSec provides new source and destination address options for defining filters. In addition, the default behavior for traffic exemptions has changed. If you require previously exempted traffic types, you

must create filters to permit this traffic. For more information about the new source and destination options provided by IPSec and for instructions on how to configure permit filters for several previously exempted traffic types, see Special IPSec considerations.

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

# Creating, modifying, and assigning IPSec policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating, modifying, and assigning IPSec policies**

IPSec policies can be applied to local computers, domains, sites, organizational units, or any Group Policy object in Active Directory. You can create, modify, and assign IPSec policies by using the IP Security Policy Management console that is available in Microsoft Management Console (MMC) or by using the Netsh commands for IPSec that are available at the command line.

Your organization's IPSec policies should be based on your written guidelines for secure operations. Policies can store multiple rules, so that one policy can be used to affect multiple types of traffic.

The Windows 2000, Windows XP, and Windows Server 2003 family include example IPSec policies. These examples are provided only to show how policies can be designed. They are not designed as default policies for securing a client or a server in a production environment. Instead, you should design and create custom IPSec policies that apply to the specific scenarios in your security plan.

### Notes

- For information about how to use the IP Security Policy Management console, see Define IPSec Policies.
- For information about how to use Netsh, see Netsh commands for Internet Protocol security.
- Although you can assign local IPSec policies for a computer by using the IP Security Policy Management console, you must use Group Policy to assign IPSec policies for groups of computers in Active Directory domains. For more information, see Assign or unassign IPSec policy in Group Policy.

**IPSec driver modes**

To understand how IPSec policies are processed and applied, it is important to understand the modes in which the IPSec driver operates. The IPSec driver operates in computer startup mode and operational mode and, optionally, in a diagnostics mode for troubleshooting.

### Computer startup mode

During computer startup, the Windows operating system loads the IPSec driver to perform in computer startup mode. Computer startup mode is used until the IPSec Policy Agent sets the IPSec driver into an operational mode. The IPSec driver can perform in any one of the following computer startup modes:

- **Permit.** When the IPSec driver operates in permit mode, it does not process any IP packets, and, therefore, no IPSec security is provided. If an IPSec policy has never been assigned to a computer, permit mode is the default mode for the IPSec driver.
- **Stateful.** When the IPSec driver operates in stateful mode, it allows all outbound traffic, and it automatically creates inbound permit filters in response to the outbound traffic. All other inbound unicast, broadcast, and multicast packets are dropped. If an IPSec policy has been assigned to a computer, the IPSec Policy Agent sets the stateful mode for the IPSec driver by default.
- **Block.** When the IPSec driver operates in block mode, it discards all inbound and outbound IP packets, except for those that match specific filters that you can configure to be used during block mode. By default, all inbound and outbound DHCP traffic is permitted so that an IP address can be obtained. You can configure filters for block mode by using the **netsh ipsec dynamic set config bootexemptions** command.

To change the default mode for the IPSec driver during computer startup, use the **netsh ipsec static set config bootmode** command.

### Operational mode

After the IPSec service starts, the IPSec Policy Agent can set the IPSec driver to any one of the following operational modes. The operational mode that is chosen does not change the mode that the IPSec driver uses during computer startup.

- **Secure.** When the IPSec driver operates in secure mode, IPSec policy filters are enforced for standard IPSec operation. The IPSec Policy Agent sets the driver into secure mode after it applies persistent policy (if a persistent policy has been configured) and before it applies the Active Directory-based policy or the local policy. If no persistent policy has been configured and assigned, secure mode does not provide IPSec protection until either the assigned Active Directory-based policy or the local policy is applied. When the Active Directory-based policy or the local policy changes, the IPSec Policy Agent updates the IPSec filter list in the IPSec driver. If no IPSec policy is assigned, the IPSec Policy Agent deletes the filters from the IPSec driver and no IPSec protection is provided in this mode.

- **Permit.** When the IPSec driver operates in permit mode, it does not process any IP packets, and, therefore, no IPSec protection is provided. Permit mode is used when the IPSec service is manually stopped.

- **Block.** When the IPSec driver operates in this mode, the exemptions that might apply during computer startup are not applied. Instead, all inbound and outbound traffic is blocked. This mode is used to enhance security, in the event that the IPSec Policy Agent fails to apply a persistent policy, if a persistent policy has been configured.

The operational mode can be configured only by the IPSec Policy Agent. You cannotuse the Netsh commands for IPSec to configure this mode.

### Diagnostic mode

To record all inbound and outbound dropped packets and other packet processing errors in the Event Viewer System log for troubleshooting, you can enable IPSec driver event logging and specify the level of logging to provide. The types of packet processing errors that the IPSec driver records in the System log depend on the level of logging that is provided. IPSec driver logs can record inbound and outbound per-packet drop events during computer startup mode and operational mode.

IPSec driver event logging is disabled by default, and it should not be used for extended periods. Depending on the logging level that you set, many events might be generated that fill the System log very quickly. For more information, see the section "Using Netsh to change the IPSec configuration on computers running the Windows Server 2003 family" in IPSec troubleshooting tools.

#### Application methods for IPSec policy

IPSec policies are provided in six ways, in the order described in the following sections.

#### IPSec startup policy

When a computer loads the Windows operating system during startup, the IPSec driveris loaded at the same time as the TCP/IP driver. The following table describes thebehavior of the IPSec driver based on the startup type of the IPSec service.

| IPSec service startup type | IPSec driver behavior |
|---|---|
| Disabled | The IPSec driver loads in permit mode, meaning that no IPSec security is applied. In this mode, the IPSec driver does not filter any traffic. |
| Manual | The IPSec driver loads in permit mode, meaning that no IPSec security is applied. In this mode, the IPSec driver does not filter any traffic. |
| Automatic | The IPSec driver loads in a startup mode configured by the IPSec Policy Agent. If no IPSec policy is assigned, by default the IPSec driver loads in permit mode. If IPSec policy is assigned, the IPSec Policy Agent configures the IPSec driver to load in stateful mode.<br><br>After the IPSec service starts, persistent policy (if it has been configured) is applied, and the IPSec driver is set to secure mode (normal operation). |

When the IPSec driver is loaded, it reads the registry to determine the actions that it must perform during computer startup. These actions include:

- Whether to apply stateful filtering, permit all traffic, or block all traffic.

- Whether to exempt specific traffic types from filtering during computer startup.
- Whether to enable IPSec diagnostic logging and, if so, which level of logging to provide.
- Whether to modify the default IPSec traffic exemption. By default, in the Windows Server 2003 family, RSVP, Kerberos, multicast, and broadcast traffic are not exempt from IPSec filtering. Only IKE traffic is exempt.

The IPSec driver remains in a startup mode until the IPSec Policy Agent sets it to an operational mode. After the IPSec driver is set to secure operation mode, the startup stateful mode settings are discarded. You can use the Netsh commands for IPSec to configure IPSec driver settings. For more information, see the **netsh ipsec dynamic set config** section in Netsh commands for Internet Protocol security.

**Persistent policy**

In the Windows Server 2003 family, you can use the Netsh commands for IPSec to add, modify, and maintain IPSec policy settings permanently, after you run the appropriate commands. This type of policy is known as a persistent policy. You can configure persistent policies to extend existing Active Directory-based or local IPSec policies, override Active Directory-based or local IPSec policies, and enhance security during computer startup. Persistent policies enhance security by providing a secure transition from computer startup to Active Directory-based IPsec policy enforcement.

Persistent policies provide the following two key benefits:

- You can configure a persistent policy as your most restrictive IPSec policy. For example, the persistent policy can block all inbound traffic to the Internet IP address of a computer, except for ICMP traffic and communication with a particular management station. To complement the persistent policy, you can design an Active Directory-based policy or a local policy with additional rules that include more specific filters to allow additional communication types.
- You can selectively enforce security rules that are required only for specific servers, due to unique network adapter configurations or program needs. For example, you can enforce security rules specifying that:
    - A specific port always be blocked.
    - Traffic that uses a specific network adapter be permitted without IPSec security, or only with IPSec security.
    - Unsecured traffic to a specific monitoring station be permitted.

Persistent policies, if configured, are stored in the local registry. The persistent store is loaded by the IPSec Policy Agent during service startup. After a persistent policy is successfully applied, the IPSec Policy Agent sets the IPSec driver to secure mode. If an error occurs when a persistent policy is applied, the IPSec Policy Agent removes the persistent policy settings from the IPSec driver and sets the IPSec driver to block operation mode for security. You can update a persistent policy at any time, as long as the IPSec service is running. However, changes in persistent policy are not active immediately. You must restart the IPSec service to load the new persistent policy settings.

If you have configured Active Directory-based policies, you can use a persistent policy as a tool to require that traffic to Active Directory always be secured by IPSec, including the retrieval of Active Directory-based IPSec policies. When an Active Directory-based or local policy is applied, those policy settings are added to the persistent policy settings.

To configure persistent policies, you must use the **netsh ipsec static set store location=persistent** command. To view the IPSec policy that is currently being applied, you can use either IP Security Monitor or the **netsh ipsec dynamic show** commands. For information about how to use Netsh, see Netsh commands for Internet Protocol security.

**Important**

- To provide maximum protection against attacks during computer startup, it is highly recommended that you configure and assign a persistent policy. If you do not configure a persistent policy, no policy can be enforced by the IPSec driver until the IPSec Policy Agent retrieves and applies the assigned Active Directory-based or local IPSec policy.

**Active Directory-based policy**

A Group Policy object defines access, configuration, and usage settings for accounts and resources. IPSec policies can be assigned to the Group Policy object of a site, domain, or organizational unit. When the IPSec policy is applied to one of the

Group Policy objects for the Active Directory object, the IPSec policy is propagated to all of the computer accounts that are affected by that Group Policy object.

You can manage Active Directory-based policy by using the IP Security Policy Management console or by using the **netsh ipsec static set store location=domain** command. IPSec policies that are configured and assigned for the domain take precedence over the local, active IPSec policy on a computer, when that computer is a member of the domain. Active Directory-based policy overrides any local IPSec policy that is assigned, and it adds to the persistent IPSec policy that has already been applied by the IPSec Policy Agent, if a persistent policy has been configured.

**Important**

- Several features in the Windows Server 2003 family implementation of IPSec are not provided in Windows 2000 or in Windows XP. To ensure that the same IPSec policy functions as expected on computers running the Windows Server 2003 family and on computers running Windows 2000 or Windows XP, test the policy thoroughly on all relevant operating systems before deployment. For more information about new features in IPSec, see New features for IPSec.

- If you plan to apply IPSec policies that use the new features that are available only in the Windows Server 2003 family implementation of IPSec, do not use the Windows 2000 or the Windows XP version of the IP Security Policy Management console to manage these policies. The settings in the earlier versions of the IP Security Policy Management console will override the settings in the Windows Server 2003 family IPSec policy, and the new features will not be functional.

When assigning an IPSec policy in Active Directory, consider the following:

- The list of all IPSec policies is available to assign at any level in the Active Directory hierarchy. However, only a single IPSec policy can be assigned at a specific level in Active Directory.

- An IPSec policy that is assigned to an organizational unit in Active Directory takes precedence over a domain-level policy for members of that organizational unit.

- An IPSec policy that is assigned to the lowest-level organizational unit in the domain hierarchy overrides an IPSec policy that is assigned to a higher-level organizational unit, for member computers of that organizational unit.

- An organizational unit inherits the policy of its parent organizational unit unless either policy inheritance is explicitly blocked or policy is explicitly assigned.

- IPSec policies from different organizational units are never merged.

- The highest possible level of the Active Directory hierarchy should be used to assign policies to reduce the amount of configuration and administration required.

- An IPSec policy might remain active even after the Group Policy object to which it is assigned has been deleted. Because of this, you should unassign the IPSec policy before you delete the policy object. To prevent problems, use the following procedure:

  1. Unassign the IPSec policy in the Group Policy object.

  2. Wait 24 hours to ensure that the change is propagated.

  3. Delete the Group Policy object.

     If you delete the Group Policy object without following this procedure, computers in the Active Directory container to which the IPSec policy is assigned treat the IPSec policy as if it cannot be located and continue to use a cached copy.

- You can use Group Policy backup and restore tools to store information about which policy is assigned to a Group Policy

object. To ensure consistency, when you use these tools, make sure that you include IPSec policies. Because these tools do not store the IPSec policies themselves, however, you cannot use them to back up and restore the IPSec policies themselves. You can only back up and restore information about whether the IPSec policies are assigned to Group Policy objects and, if so, to which Group Policy objects. To back up and restore all of the IPSec policies in the IPSec container in Active Directory, use the Export Policies and Import Policies commands in the IP Security Policy Management console. For more information, see Export IPSec policies and Import IPSec policies.

- Before assigning an IPSec policy to a Group Policy object, verify the Group Policy settings that are required for the IPSec policy. For example, if an IPSec policy requires certificate authentication, assign the Group Policy settings that allow computers to enroll for certificates (usually one or two days before you assign the IPSec policy that requires use of the computer certificate). In addition, you should test the certificate enrollment process and resolve any errors before assigning the IPSec policy.

The IPSec Policy Agent on a computer running Windows XP Professional or a Windows Server 2003 operating system polls Active Directory for updates to the assigned IPSec policy. This polling does not detect a change in domain or organizational unit membership or the assigning or unassigning of a new IPSec policy. These events are detected when the Winlogon service polls for changes in Group Policy, which occurs by default every 90 minutes. The Winlogon service discovers these changes, notifies the IPSec Policy Agent, and the IPSec policy changes are applied.

For more information about Group Policy, see Group Policy overview.

### Notes

- The integration of IPSec policies with Active Directory described here does not apply to computers running Windows XP Home Edition because you cannot administer Active Directory-based IPSec policy from a computer running Windows XP Home Edition.

- Careful planning is required when you design Active Directory-based IPSec policies for computers that are used the internal network and on other public or partner networks.

- By default, IPSec policies are read from Active Directory when the connection to Active Directory is interpreted by Group Policy to be a slow link.

#### Directory cache policy

If you assign an Active Directory-based IPSec policy, a copy of the current policy is maintained in a cache in the local registry. If the computer to which the policy is assigned cannot connect to the domain, the cached copy of the Active Directory-based policy is applied. This cached policy adds to the settings of the persistent policy, if a persistent policy has been configured. Note that you cannot configure or manage the cached copy of an Active Directory-based IPsec policy.

#### Local computer policy

Each computer running Windows XP or a Windows Server 2003 operating system has exactly one local Group Policy object, often called the local computer policy. In using this local Group Policy object, Group Policy settings can be stored on individual computers regardless of whether they are members of an Active Directory domain. The local Group Policy object can be overwritten by Group Policy objects associated with sites, domains, or organizational units in an Active Directory environment. On a network without an Active Directory domain (a network that lacks a Windows 2000 or a Windows Server 2003 domain controller), the local Group Policy object settings determine IPSec behavior because they are not overwritten by other Group Policy objects.

You can manage local IPSec policies by using the IP Security Policy Management console or by using the **netsh ipsec static set store location=local** command. The settings of a local IPSec policy are added to the persistent policy, if a persistent policy has been configured. If an Active Directory-based IPSec policy is assigned, and if the computer is connected to an Active Directory domain, the settings of the Active Directory-based policy are applied instead.

For information about how to assign IPSec policy locally, see Assign or unassign IPSec policy on a computer.

#### Netsh dynamic mode policy

You can use the **netsh ipsec dynamic** commands to create, modify, and assign IPSec rules that take effect immediately and are not stored. If the IPSec service is stopped, either administratively or when the computer is restarted, these rules are lost. However, if you use the **netsh ipsec dynamic set config** commands to change the IPSec configuration, those settings are not lost.

# Special IPSec considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Special IPSec considerations**
The following special IPSec considerations can help simplify the administration of IPSec policies.

**Recommended IPSec scenarios and IPSec scenarios that are not recommended**
Following are recommended scenarios and scenarios that are not recommended for the Windows Server 2003 family implementation of IPSec.

**Recommended IPSec scenarios**
The Windows Server 2003 family implementation of IPSec is recommended for use as follows:

- Packet filtering. IPSec provides limited firewall capabilities for end-systems. You can also use IPSec with Internet Connection Firewall, Windows Firewall, and Routing and Remote Access to permit or block inbound or outbound traffic.

- Securing host-to-host traffic on specific paths. You can use IPSec to provide mutual authentication and cryptographic protection for traffic between servers or other static IP addresses or subnets. For example, IPSec can secure traffic between domain controller sites or forests, or between Web servers and database servers.

- Securing traffic to servers. You can use IPSec to require mutual authentication for all client computers that access a server. In addition, you can set restrictions on which computers are allowed to connect to a server running Windows Server 2003 family.

- Using L2TP/IPSec tunneling for VPN connections. You can use the combination of the Layer Two Tunneling Protocol (L2TP) and IPSec (L2TP/IPSec) for all virtual private network VPN scenarios.

- Using IPSec in tunnel mode for gateway-to-gateway tunnels. For interoperability with other routers, gateways, or end-systems that do not support L2TP/IPSec or PPTP VPN tunneling, you can use IPSec in tunnel mode for gateway-to-gateway tunnels.

### Notes

- Windows Firewall is not included in the original release of the Windows Server 2003 operating systems.

- Internet Connection Firewall is included only in the original releases of Windows Server 2003, Standard Edition, and Windows Server 2003, Enterprise Edition.

**IPSec scenarios that are not recommended**
When using IPSec authentication and data protection features, the policy management model in Windows 2000, Windows XP, and Windows Server 2003 family lends itself best to server-to-server and client-to-server scenarios where one end-point has a static address. In large network deployments, when policy involves dynamic addresses at both end–systems, and in some mobility cases, policy management complexity can make IPSec deployment difficult. Because of this, IPSec is not recommended for use as follows:

- Securing communication between domain members and their domain controllers. Because of the complexity of the IPSec policy configuration and management required for this scenario, using IPSec to secure communication between domain members and their domain controllers is not recommended.

- Securing all traffic in a network. Configuring IPSec communications between all client computers and all servers in order to secure many or all computers in a network is difficult. IPSec cannot negotiate security for multicast and broadcast traffic. Traffic from real-time communications, applications that require ICMP, and peer-to-peer applications might be incompatible with IPSec. For these reasons, using IPSec to secure all traffic in a network is not recommended.

Additionally, the IPSec protocol and implementation has characteristics that require special consideration in other scenarios:

- Securing traffic over wireless 802.11 networks. IPSec policies are not optimized for configuration for mobile clients. Because of this, IPSec is not recommended as the only method to secure traffic sent over wireless 802.11 networks. Instead, it is recommended that you use IEEE 802.1X authentication. 802.1X enhances security and ease of deployment by providing support for centralized user identification, authentication, dynamic key management, and accounting. In cases where clients roam between access points on the same network, IPSec can be used in combination with 802.11 and 802.1x. In cases where roaming causes the client IP address to change, IPSec security associations become not valid and new security associations are renegotiated.

- Using IPSec in tunnel mode for remote access VPN connections. Using IPSec in tunnel mode is not recommended for remote access VPN scenarios. Instead, use L2TP/IPSec or PPTP for remote access VPN connections.

**Managing policies that use new features available only in the Windows Server 2003 family**
The following features are available only in the Windows Server 2003 family implementation of IPSec:

- Support for new source and destination address options for defining filters. For example, you can now create:

    - Filters with a source address and destination address of **Any IP Address**.

    - Filters that use a non-standard subnet class as a source address or a destination address.

    - Filters that use a multicast or a broadcast address as a destination address.

    - Filters with a source address or a destination address that corresponds to the local IP configuration for the DNS servers, WINS servers, and the DHCP server and default gateway for the computer to which the filter applies.

- The ability to exclude the name of the certification authority (CA) from certificate requests.

- Certificate-to-account mapping for network access control.

- Support for root CA names that are represented in extended ASCII character sets.

- A stronger Diffie-Hellman group (2048-bit Diffie-Hellman key exchange).

Computers running Windows XP and Windows 2000 cannot use these new policy settings. If you plan to apply Active Directory-based IPSec policies that use features that are only available in the Windows Server 2003 family, use the Windows Server 2003 family version of the IP Security Policy Management console to manage them. If you use the Windows XP or Windows 2000 version of the IP Security Policy Management console to manage these policies, the earlier versions of the IP Security Policy Management console will delete the new feature settings.

In addition, if you want to apply the same IPSec policy to computers running different versions of Windows, test the policy to ensure that it functions as expected on both servers running Windows Server 2003 and computers running Windows XP or Windows 2000.

For information about new features available with the Windows Server 2003 family implementation of IPSec, see New features for IPSec. For more information about best practices for using IPSec, see IPSec Best practices.

**IP filters**
Consider the following when configuring IP filters:

- Use general filters when you want a single filter to apply to a group of computers. For example, when configuring the filter, use **My IP address**, **Any IP Address**, or a subnet address instead of specifying a specific computer's source and destination IP addresses.

- Define filters that allow you to group and secure traffic from logically associated segments or subnets within your network.

- Be aware that when you are viewing the IPSec policy, the order in which the filters apply is not in the order displayed. When the IPSec Policy Agent reads an IPSec policy, filters are processed into one ordered list, sorted from most to least

specific. You can use the IP Security Monitor console to view filters sorted by weight. Filters that have the same weight might appear in any order relative to each other.

During policy updates, the IPSec Policy Agent recalculates the sorted order and updates the IPSec driver with the changes only. If a filter is deleted, or if the filter action is changed for a filter, all security associations related to that filter are deleted. As a result, some packets are lost when a new security association is negotiated. TCP connections, however, should immediately recover by retransmitting the lost packets.

- If you are configuring an IPSec policy to secure Kerberos traffic, IPSec can only negotiate security associations if your authentication method does not use Kerberos. If Kerberos is required for authentication between domain members, special consideration must be given to the traffic required by Kerberos between domain members and domain controllers, and the following requirements must be met:

  - If a domain member and a domain controller are members of different domains, a two-way trust must exist between the domains or Internet Key Exchange (IKE) rekeys will fail.

  - If a client computer or a server in the domain uses Kerberos authentication to negotiate IPSec with all peers, you must create mirrored permit filters for all Kerberos-dependent traffic to all domain controllers. It is recommended that you create permit filters to exempt all traffic to each domain controller IP address in the domain member's domain. You do not need to create permit filters to exempt all traffic to all trusted domain controller IP addresses. Instead, create permit filters to exempt only Kerberos traffic and domain controller site location (LDAP) queries to all domain controller IP addresses in the trust path between the computers. If DNS service is not provided by the domain controller (for which you already permit all traffic), you might also need to exempt DNS traffic to the DNS server IP addresses so that DNS can be used for domain controller discovery.

    To exempt these traffic types in the IPSec policy, create the following filters, each with a permit filter action:

| **Filter** | **Filter Action** |
|---|---|
| All traffic to my domain controllers | • Mirrored<br>• Source Address = My IP Address<br>• Destination Address = **A specific IP Address** (where **A specific IP Address** is the static IP address of each domain controller in the domain)<br>• Protocol = **Any**<br>• This filter permits LDAP site location queries and ICMP, DNS, and Kerberos traffic. In addition, it permits the remote procedure call (RPC) traffic and Group Policy downloads required to manage Active Directory-based IPSec policies. |
| Kerberos | • Mirrored<br>• Source Address = My IP Address<br>• Destination Address = **A specific IP Address** (where **A specific IP Address** is the static IP address of each domain controller in the domain)<br>• Protocol = **Any**<br>• This filter permits LDAP site location queries and ICMP, DNS, and Kerberos traffic. In addition, it permits the remote procedure call (RPC) traffic and Group Policy downloads required to manage Active Directory-based IPSec policies. |

| | |
|---|---|
| Domain controller site location (LDAP) queries | • Mirrored<br>• Source Address = **My IP Address**<br>• Destination Address = **A specific IP Address** (where **A specific IP Address** is the static IP address of each domain controller in trusted domains)<br>• Protocol = **UDP**<br>• Source port = **Any**<br>• Destination port = **88**<br>• After you create this filter, create another filter with the same settings, but specify **TCP** for the protocol. |
| DNS client queries | • Mirrored<br>• Source Address = **My IP Address**<br>• Destination Address = **DNS Servers <dynamic>** (or **A specific IP Address**, where the IP address is the static IP address of each DNS server in the network)<br>• Protocol = **UDP**<br>• Source port = **Any**<br>• Destination port = **53**<br>• After you create this filter, create another filter with the same settings, but specify **TCP** for the protocol. |

**Caution**

- To minimize the security issues, you should allow these exemptions only for the specific IP addresses of the domain controllers and the DNS servers.

When designing an IPSec policy to secure or block ICMP traffic, ensure that you plan carefully and test the policy before implementing it in a production environment. Be aware that ICMP is required for the following scenarios:

- Outbound TCP connections that traverse networks with different link frame sizes require path maximum transmission unit (PMTU) discovery. For PMTU discovery to function correctly, inbound ICMP traffic from routers and other gateways must be received.

- The **tracert** command requires ICMP traffic to determine the path taken to a destination. If IPSec protects ICMP traffic, however, **tracert** output shows only the destination computer--not the path of intermediate routers.

- File sharing and other applications use ICMP traffic to determine whether a destination IP address can be reached.

- Network logon and Group Policy measure ICMP response times to each domain controller IP address. This measurement is performed to both aid in the selection of a domain controller to service a network logon and determine whether to apply Group Policy settings over slow links.

In some cases, even the three-second delay before a soft SA (an unsecured connection) is established might impact upper-

layer communication that requires fast ICMP responses.

- In Windows 2000 and Windows XP, by default, broadcast, multicast, Kerberos, Internet Key Exchange (IKE), and Resource Reservation Protocol (RSVP) traffic are exempt from filter matches. In the Windows Server 2003 family, broadcast, multicast, and Kerberos, are not exempt from filter matches by default (only IKE traffic is exempt). In additon, Resource Reservation Protocol (RSVP) has been turned off. Broadcast and multicast packets will be dropped if they match a filter with a filter action to negotiate security. By default, the Windows Server 2003 family provides limited support for filtering broadcast and multicast traffic. A filter with a source address of **Any IP Address** will match multicast and broadcast addresses. A filter with a source address of **Any IP Address** and a destination address of **Any IP Address** will match inbound and outbound multicast addresses. You can use such a filter to block all traffic. One-way filters that would be used to block or permit specific multicast or broadcast traffic, however, are not supported.

  As a result of the change in default exemption behavior for the Windows Server 2003 family implementation of IPSec, you should verify the behavior of IPSec policies designed for Windows 2000 or Windows XP, and determine whether to configure explicit permit filters to permit specific traffic types. To restore the default Windows 2000 and Windows XP behavior for IPSec policies, you can use the **netsh ipsec dynamic set config command**, or you can modify the registry. For more information, see the section "Using Netsh to change the IPSec configuration on computers running the Windows Server 2003 family" in IPSec troubleshooting tools.

  **Caution**

  - The Windows 2000 and Windows XP default exemption settings for IPSec are designed for corporate LAN environments with a low risk of attack. For this reason, you should only use the Windows 2000 and Windows XP default exemption settings when necessary for troubleshooting, in low-risk environments, or when you cannot solve program compatibility issues by configuring explicit filters in IPSec policies.

**Safe Mode with Networking**

If you start a computer in Safe Mode with Networking, consider the following:

- The IPSec service cannot apply filters from an IPSec policy or negotiate IP security when the computer is in Safe Mode with Networking. As a result, when Directory Services Restore Mode operations are in progress, communication does not occur with remote domain controllers or network backup devices that enforce an IPSec policy to require IPSec.

- When a computer loads the Windows operating system during startup, the IPSec driver is loaded at the same time as the TCP/IP driver. If an IPSec policy is assigned to the computer and the IPSec service is configured for automatic startup, by default, the IPSec driver startup mode is changed to perform stateful filtering. When stateful filtering is performed, all outbound traffic is permitted, but all inbound traffic is blocked, except for DHCP traffic and traffic that is sent in response to the outbound traffic initiated during computer startup. (The IPSec driver automatically creates inbound filters to permit responses to outbound traffic.) The IPSec service itself, however, does not start. As a result, no persistent, local, or Active Directory-based IPSec policies can be applied.

- When the computer is in Safe Mode with Networking, you can allow the IPSec driver to continue to provide stateful filtering protection by configuring inbound exemptions for specific traffic. Or, you can force the IPSec driver to permit all traffic.

- To configure inbound exemptions for specific traffic, restart the computer normally (not in Safe Mode), use the **netsh ipsec dynamic set config bootexemptions** command to specify the traffic types to exempt during computer startup, and then restart the computer. The new exemptions will take effect when the computer is restarted and will remain in effect until they are deleted or changed.

- If you allow the IPSec driver to configure inbound exemptions for specific traffic, keep in mind that unless you configure the appropriate exemptions, the following will occur:

  - Inbound connections will be blocked to network services, such as Remote Desktop Connection and Remote Assistance, which open ports for receiving connections. To allow clients to use Remote Desktop Connection or Remote Assistance, you must configure an exemption to allow inbound traffic to TCP port 3389. To configure this exemption, use the following Netsh command:

**netsh ipsec dynamic set config bootexemptions TCP:any:3389:inbound**

- Some outbound TCP connections, such as those requiring PMTU discovery, might not work. To enable TCP PMTU discovery, you must configure an exemption to allow inbound ICMP traffic. To configure this exemption, use the following Netsh command:

  **netsh ipsec dynamic set config bootexemptions ICMP:inbound**

  **Important**

- Modifying IPSec traffic exemptions from startup security (that is, modifying the **bootexemptions=** parameter) will overwrite all previous exemptions from startup security.

For more information about how to specify traffic types to exempt during computer startup, see Netsh commands for Internet Protocol security.

To force the IPsec driver to permit all inbound traffic while the computer is in Safe Mode with Networking, you must either configure the IPSec service for manual startup or disable it, and then restart the computer in Safe Mode with Networking.

**Filter actions**
Consider the following special requirements when configuring IP filter actions:

- If there is specific traffic that you always want to block, such as traffic to and from either not valid addresses or specific TCP ports, create a blocking filter action with the **Security Method** set to **Block**.

- If there is specific traffic that you always want to be unsecured, create a permit filter action with the **Security Method** set to **Permit**.

- When you are configuring custom security methods for encrypted traffic, you should only set the ESP confidentiality selection to **<None>** when a higher layer protocol provides data encryption.

- When you are planning Internet scenarios, such as IPSec tunneling between branch offices, consider using a list of security methods that specifies high levels of security (for example, 3DES only), short key lifetimes (less than 50 MB), and perfect forward secrecy (PFS) for the session keys. This helps protect against known key attacks.

**Note**

- Computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use the 3DES algorithm. If a computer running Windows 2000 receives a 3DES setting, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the 3DES setting in the security method is set to the weaker DES, to provide some level of confidentiality for communication, rather than blocking all communication. However, you should only use DES as a fallback option if not all computers in your environment support the use of 3DES. Computers running Windows XP or a Windows Server 2003 operating system support 3DES and do not require installation of the High Encryption Pack.

**VPN connections using L2TP**
When you are using Layer Two Tunneling Protocol (L2TP) for your remote access or router-to-router VPN connections, certificates are the default authentication method for main mode security associations. Computer certificates must be installed either on both the VPN server and remote access client (for remote access connections), or on both the calling router and answering router (for router-to-router VPN connections). The simplest method for installing computer certificates is to configure your Windows 2000 and Windows Server 2003 domains to auto-enroll computer certificates for domain members. For more information, see Computer certificates for L2TP/IPSec VPN connections.

When you are using the certificate authentication method for L2TP connections, the list of certification authorities (CAs) is not configurable. Instead, each computer in the L2TP connection sends a list of root CAs to its IPSec peer from which it accepts a certificate for authentication. The root CAs in this list correspond to the root CAs that issued computer certificates to the computer. For example, if Computer A was issued computer certificates by root CAs CertAuth1 and CertAuth2, it notifies its IPSec peer during main mode negotiation that it will accept certificates for authentication from only CertAuth1 and CertAuth2. If the IPSec peer, Computer B, does not have a valid computer certificate issued from either CertAuth1 or CertAuth2, IPSec

main mode negotiation fails. Therefore, ensure one of the following before attempting an L2TP connection:

- Both the VPN client and VPN server were issued computer certificates from the same CA.
- Both the VPN client and VPN server were issued computer certificates from CAs that follow a certificate chain up to the same root CA.

In general, the VPN client must have a valid computer certificate installed that was issued by a CA that follows a valid certificate chain from the issuing CA up to a root CA that the VPN server trusts. Additionally, the VPN server must have a valid computer certificate installed that was issued by a CA that follows a valid certificate chain from the issuing CA up to a root CA that the VPN client trusts.

For example, if the VPN client was issued computer certificates by root CAs CertAuth1 and CertAuth2, it notifies the VPN server during main mode negotiation that it will accept certificates for authentication from only CertAuth1 and CertAuth2. If the VPN server does not have a valid computer certificate issued from a CA that follows a certificate chain to either CertAuth1 or CertAuth2, IPSec main mode negotiation fails.

A single CA commonly issues computer certificates to all computers in an organization. Because of this, all computers within the organization both have computer certificates from a single CA and request certificates for authentication from the same single CA.

Windows XP and Windows Server 2003 family VPN clients also support the use of preshared key authentication to create L2TP/IPSec connections.

**Important**

- The use of preshared key authentication is not recommended because it is a relatively weak authentication method. Preshared key authentication creates a master key that is less secure (that might produce a weaker form of encryption) than certificates or the Kerberos V5 protocol. In addition, preshared keys are stored in plaintext. Preshared key authentication is provided for interoperability purposes and to adhere to IPSec standards. It is recommended that you use preshared keys only for testing or as an interim measure in a production environment, when your public key infrastructure (PKI) is being deployed to obtain computer certificates, or when preshared key authentication is required by your VPN server. For long-term use in production environment, it is recommended instead that you use certificates or Kerberos V5.

For a remote access VPN client running Windows XP or a Windows Server 2003 operating system, you can enable preshared key authentication and configure a preshared key in **IPSec settings** on the **Security** tab in the properties of a VPN connection in Network Connections.

**Domain controllers and DHCP, DNS, or WINS servers**
Before enabling IPSec for a computer that functions as a domain controller or DHCP, DNS, or WINS server, determine whether all of the clients are IPSec-enabled. If the IPSec policy assigned to the domain controller or DHCP, DNS, or WINS server is not configured to allow fall back to clear, which permits unsecured communication with non-IPSec-capable clients, secure negotiation will fail and access to these network services will be blocked.

**SNMP**
If you are using Simple Network Management Protocol (SNMP) and your SNMP management systems or agents include computers running Windows 2000, Windows XP, or a Windows Server 2003 operating system that are configured with IPSec policy, you can add a rule to the appropriate IPSec policy to prevent SNMP messages from being secured. The filter list must specify the source and destination addresses of the SNMP management systems and agents for all UDP traffic that uses ports 161 and 162. The filter action should be set to **Permit**, which passes through any traffic that matches the IP filter list.

# IPSec troubleshooting tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting tools**

This topic provides information about the following IPSec troubleshooting tasks and the troubleshooting tools that you can use to perform each of these tasks:

- Viewing IPSec policy assignment information
- Viewing details about the active IPSec policy and IPSec statistics
- Viewing details about the active IPSec policy and IPSec statistics in IP Security Monitor
- Verifying that security auditing is enabled
- Viewing IPSec-related events in Event Viewer
- Enabling detailed tracing for Internet Key Exchange (IKE) negotiations
- Viewing IPSec and other network communication with Network Monitor
- Using Netsh to change the IPSec configuration on computers running the Windows Server 2003 family
- Using Ipseccmd.exe to manage and monitor IPSec on computers running Windows XP
- Using Netdiag.exe to display IPSec information and to test and view network configuration
- Disabling TCP/IP and IPSec hardware acceleration

Details about each of these subjects are provided in the following sections.

**Notes**

- For general recommended practices that can help you enhance security and minimize the potential for problems when deploying IPSec, see IPSec Best practices.
- For the Windows Server 2003 family, the Netsh commands for IPSec replace and enhance the functionality provided by Netdiag.exe and Ipseccmd.exe. For information about how to use Netsh to script IPSec policy creation and to monitor IPSec activity, see Netsh commands for Internet Protocol security.
- Ipseccmd.exe is a support tool that is provided only on the Windows XP CD. To install this tool, run the Setup.exe file from the Support\Tools folder. You can use this tool to manage and monitor IPSec policies only on computers running Windows XP. For more information about Ipseccmd.exe, see the Microsoft Tech Net Web site.

Netdiag.exe is available in the Windows Server 2003 family, Windows XP, and in Windows 2000, as follows:

- In the Windows Server 2003 family, run the Suptools.msi file from the \Support\Tools folder on the Windows Server 2003 family CD (select the **Complete** setup option). Although you can still use this version of Netdiag.exe to obtain basic networking information that is not IPSec-specific, the Netsh commands for IPSec replace all IPSec-specific functionality.
- In Windows XP, run the Setup.exe file from the \Support\Tools folder on the Windows XP CD (select the **Complete** setup option).

- For Windows 2000, an updated version of Netdiag.exe is available for download from the Web. For more information, see "Windows 2000 Resource Kits," at the Microsoft Windows Resource Kits Web site.

For more information about Netdiag.exe, see Using Netdiag.exe to display IPSec information and to test and view network configuration in this topic.

**Viewing IPSec policy assignment information**

Viewing the name of an active IPSec policy and the name of the Group Policy object to which the active IPSec policy is assigned can be useful for troubleshooting policy precedence issues. The following table summarizes the tools that you can use to view this information for the Windows Server 2003 family, Windows XP, and Windows 2000.

| On computers running | Use these tools to view the name of the active IPSec policy | Use these tools to view the name of the Group Policy object to which the active IPSec policy is assigned |
|---|---|---|
| Windows Server 2003 family | • IP Security Monitor console.<br><br>For more information, see View details about active IPSec policies.<br><br>• Netsh, **netsh ipsec static show gpoassignedpolicy** command.<br><br>For more information, see Netsh commands for Internet Protocol security. | • Resultant Set of Policy (RSoP) console.<br><br>For more information, see Use Resultant Set of Policy (RSoP) to View IPSec Policy Assignments.<br><br>• Netsh, **netsh ipsec static show gpoassignedpolicy** command. |
| Windows XP | • IP Security Policy Management console (for local policies only).<br><br>• Network Connectivity Tester (Netdiag.exe), **netdiag /test:ipsec** command.<br><br>For more information, see Using Netdiag.exe to display IPSec information and to test and view network configuration in this topic. | • Netdiag.exe, **netdiag /test:ipsec** command. |
| Windows 2000 | • Netdiag.exe, **netdiag /test:ipsec** command.<br><br>• In the properties for the relevant network connection, **TCP/IP Properties/Advanced/Options/IPSec**.<br><br>The assigned IPSec policy that is displayed in **TCP/IP Properties** is global. It is not specific to the connection. | • Netdiag.exe, **netdiag /test:ipsec** command.<br><br>• Gpresult.exe (Group Policy Results).<br><br>• Gpotool.exe (Group Policy Verification Tool).<br><br>Gpresult.exe and Gpotool.exe are both available for download from the Web. For more information, see "Windows 2000 Resource Kits," at the Microsoft Windows Resource Kits Web site. |

**Notes**

- To view all IPSec policies that are available (but not necessarily assigned or applied) to computers, use the IP Security Policy Management console. For information about policy precedence and IPSec policy behavior in an Active Directory environment, see the section "Active Directory-based policy" in Creating, modifying, and assigning IPSec policies.

- For the Windows Server 2003 family, to determine which IPSec policies are assigned but are not being applied to IPSec clients, use the RSoP console.

- The Windows XP implementation of the RSoP console does not support the display of IPSec policies. In addition, the **gpresult /scope computer** command does not display the Group Policy object that contains an IPSec policy assignment. For these reasons, you should use Netdiag.exe to view IPSec policy assignment information on computers running Windows 2000 or Windows XP. The **netdiag /test:ipsec** command displays the Group Policy object that contains the IPSec policy assignment, and the organizational unit to which the Group Policy object is assigned.

- Gpotool.exe allows you to monitor the health of Group Policy objects on domain controllers. You can use this tool to check the consistency and replication of Group Policy objects and to display Group Policy object properties. Gpotool.exe is available only for computers running Windows 2000.

**Viewing details about the active IPSec policy and IPSec statistics**

The IP Security Policy Management console, Netdiag.exe, Gpresult.exe, and Gpotool.exe allow you to determine which IPSec policy has been assigned through Group Policy. After you verify this information, you might need to view details about the assigned IPSec policy and IPSec statistics (for example, filters, filter actions, and active security associations). The following table summarizes the tools that you can use to view an active IPSec policy and IPSec statistics for the Windows Server 2003 family, Windows XP, and Windows 2000.

| **On computers running** | **Use these tools to display the active IPSec policy, IPSec statistics, or both** | **Notes** |
|---|---|---|
| Windows Server 2003 family | • IP Security Monitor console.<br><br>For more information, see View IP security statistics<br><br>• Netsh, **netsh ipsec dynamic show all** command. | • To view details about the active IPSec policy and IPSec statistics on a local or remote computer, you must be a member of the Administrators group on that computer. |
| Windows XP | • IP Security Monitor console.<br><br>• IPseccmd.exe, **ipseccmd show all** command. | • To view details about the active IPSec policy and IPSec statistics for a local or remote computer, you must be a member of the Administrators group on that computer. |
| Windows 2000 | • Netdiag.exe, **netdiag /test:ipsec /v /debug** command.<br><br>• Ipsecmon.exe. | • To use the **/debug** option, you must be logged on as a member of the Administrators group on that computer. In addition, to view details about Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory.<br><br>• Ipsecmon.exe only displays active outbound quick mode security associations (SAs). |

**Note**

- To remotely monitor IPSec on a computer that is running a different version of Windows than your computer, use Remote Desktop Connection. For example, if your computer is running the Windows Server 2003 family and you plan to

remotely monitor IPSec on computers running Windows 2000 or Windows XP, use Remote Desktop Connection to gain remote access to these computers. For information about Remote Desktop Connection, see Remote Desktop Connection.

**Viewing details about the active IPSec policy and IPSec statistics in IP Security Monitor**

In Windows XP and the Windows Server 2003 family, IP Security Monitor is implemented as a Microsoft Management Console (MMC) snap-in, and it includes enhancements that allow you to view details about an active IPSec policy that is applied by the domain or locally, as well as quick mode and main mode statistics, and active IPSec SAs. IP Security Monitor also enables you to search for specific main mode or quick mode filters. To troubleshoot complex IPSec policy designs, you can use IP Security Monitor to search for all matches for filters of a specific traffic type.

- For procedures on how to use IP Security Monitor, see Monitor IPSec Activity.
- For detailed information about IP security statistics, see Viewing main mode and quick mode statistics in IP Security Monitor.

### Notes

- You can use IP Security Monitor to monitor only computers that are running Windows XP or the Windows Server 2003 family. In addition, the computer that is being monitored must run the same version of the Windows operating system as the computer on which IP Security Monitor is running. To monitor IPSec on a computer that is running Windows 2000, use the **ipsecmon** command at the Windows 2000 command prompt on the computer that is being monitored.
- For remote monitoring, you can use IP Security Monitor only to monitor computers that are running the same version of the Windows operating system. To remotely monitor IPSec on a computer that is running a different version of Windows than your computer, use Remote Desktop Connection. For information about Remote Desktop Connection, see Remote Desktop Connection.
- If your computer is running the Windows Server 2003 family, and you plan to monitor IPSec on computers that are also running the Windows Server 2003 family, you can run IP Security Monitor or use the Netsh command-line tool remotely.

**Verifying that security auditing is enabled**

You can use Local Security Policy settings (for a local computer) or Group Policy Object Editor (for a domain) to verify that security auditing is enabled, so you can ensure that the success and failure of IKE negotiations is recorded. Auditing for IKE is supported in Windows 2000, Windows XP, and the Windows Server 2003 family (IKE uses the Logon Events category). In the Windows Server 2003 family, you can also enable auditing for the security policy database (SPD). SPD uses the Policy Change category. For more information, see Define or modify auditing policy settings for an event category.

**Viewing IPSec-related events in Event Viewer**

You can use Event Viewer to view the following IPSec-related events:

**IKE events (negotiation success and failure) in the security log.**

To view these events, enable success or failure auditing for the **Audit logon events** audit policy for your domain or local computer. The IKE event category is also used for auditing user logon events in services other than IPSec. For more information, see Define or modify auditing policy settings for an event category.

When you enable success or failure auditing for the **Audit logon events** audit policy, IPSec records the success or failure of each main mode and quick mode negotiation and the establishment and termination of each negotiation as separate events. However, enabling this type of auditing can cause the security log to fill with IKE events. For example, for servers that are connected to the Internet, attacks on the IKE protocol can cause the security log to fill with IKE events. IKE events can also fill the security log for servers that use IPSec to secure traffic to many clients. To avoid this, you can disable auditing for IKE events in the security log by modifying the registry.

- To disable auditing of IKE events in the security log, do the following:

  1. Set the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa\Audit\DisableIKEAudits** registry setting to a value of **1**.

     The **DisableIKEAudits** key does not exist by default and must be created.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

1. Restart the computer, or stop and then restart the IPSec service by running the **net stop policyagent** and **net start policyagent** commands at the command prompt.

**Note**

- Stopping and restarting the IPSec service can disconnect all of the computers that are using IPSec from the computer on which the IPSec service is stopped, and it can prevent further communication with that computer. If you restart the IPSec service immediately, TCP-based communication might resume, due to the retransmit behavior of TCP, after new IKE and IPSec SAs are established. For more information, see "Stopping and restarting the IPSec service," later in this topic.

**IPSec policy change events in the Security log.**

To view these events, enable success or failure auditing for the **Audit policy change** audit policy for your domain or local computer. For more information, see Define or modify auditing policy settings for an event category.

**IPSec driver per-packet drop events in the System log.**

In Windows 2000, Windows XP, and the Windows Server 2003 family, you can enable packet event logging for the IPSec driver by modifying the registry. The IPSec driver reads the registry during computer startup. In the Windows Server 2003 family, you can enable packet event logging for the IPSec driver by using the **Netsh ipsec** command-line tool. To enable logging of dropped inbound and outbound packets, specify a value of **7**. For information about the other levels of IPSec driver event logging, see Notes.

- To enable IPSec driver logging of dropped inbound and outbound packets by modifying the registry, do the following:

  1. Set the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IPSec\EnableDiagnostics DWORD** registry setting to a value of **7**.

  **Caution**

  - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

  1. Restart the computer.

- To enable IPSec driver logging of dropped inbound and outbound packets by using the Netsh IPSec command-line tool in the Windows Server 2003 family, do the following:

  1. At the command prompt, type: **netsh ipsec dynamic set config ipsecdiagnostics 7**

  2. Restart the computer.

You can also change the interval for writing IPSec driver packet events to the System log. By default, the IPSec driver writes events to the System log once an hour or after a threshold for the number of events has been reached. For troubleshooting, you should set this interval to the minimum value, 60 seconds.

- To change the interval for writing IPSec driver packet events by modifying the registry, do the following:

1. Set the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IPSec\LogInterval DWORD** registry setting to **60 decimal**.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

1. Restart the computer.

- To change the interval for writing IPSec driver packet events by using the **Netsh ipsec** command-line tool in the Windows Server 2003 family, do the following:

  1. At the command prompt, type **netsh ipsec dynamic set config ipseclogginterval 60**

  2. Restart the computer.

The IPSec driver reads the registry during computer startup.

By default, packet event logging for the IPSec driver is disabled (that is, the value is set to **0**). When you enable packet event logging for the IPSec driver, you can specify any of the following values, to enable different levels of logging:

| Logging Level | Description |
|---|---|
| **1** | When **1** is specified, bad SPI packets (the total number of packets for which the Security Parameters Index or SPI was incorrect), IKE negotiation failures, IPSec processing failures, packets received with invalid packet syntax, and other errors are recorded in the System log. Unauthenticated hashes (with the exception of the "Clear text received when should have been secured" event) are logged as well. |
| **2** | When **2** is specified, inbound per-packet drop events are recorded in the System log. |
| **3** | When **3** is specified, level 1 and level 2 logging are performed. In addition, unexpected clear text events (packets that are sent or received in plaintext) are also recorded. |
| **4** | When **4** is specified, outbound per-packet drop events are recorded in the System log. |
| **5** | When **5** is specified, level 1 and level 4 logging are performed. |
| **6** | When **6**is specified, level 2 and level 4 logging are performed. |
| **7** | When **7** is specified, all levels of logging are performed. |

For more information about IPSec driver event logging, see the Microsoft Windows Resource Kits Web site.

You cannot configure audit policies on a computer running Windows XP Home Edition. However, success and failure auditing for the **Audit logon events** and **Audit policy change** audit policies for the local computer are enabled by default.

Enabling auditing in the security log or IPSec driver diagnostics in the system log can cause these logs to fill with events quickly. Before you perform either of these tasks, you should do the following:

- Ensure that the size of the log is at least 10 megabytes (MB).

- Save the existing log to a file.

- Clear all events in the log so that the log is empty.

- Consider disabling auditing of IKE events in the security log by modifying the registry, if your computer hosts many simultaneous network connections.

**Enabling detailed tracing for Internet Key Exchange (IKE) negotiations**

Enabling audit logging for IKE events and viewing the events in Event Viewer is the fastest and simplest way to troubleshoot failed main mode or quick mode negotiations. However, some scenarios might require a more detailed analysis of the IKE main mode negotiation and quick mode negotiations for troubleshooting. You can enable tracing for IKE negotiations if the audit failure events do not provide enough information. The IKE tracing log is a very detailed log intended for troubleshooting IKE interoperability under controlled circumstances. Expert knowledge of the ISAKMP RFC 2408 and IKE RFC 2409 is required to interpret this log.

The IKE tracing log appears as the *systemroot*\Debug\Oakley.log file. The log has a fixed size of 50,000 lines and will overwrite as necessary. A new Oakley.log file is created each time the IPSec service is started and the previous version of the Oakley.log file is saved as Oakley.log.sav. When the Oakley.log file becomes full, the current file is saved as Oakley.log.bak, and a new Oakley.log file is created.

Because many IKE negotiations can occur simultaneously, you should minimize the number of negotiations and log for as short a period of time as possible to capture a more easily interpreted log.

**Enabling and disabling the IKE tracing log in the** Windows Server 2003 **family**

In the Windows Server 2003 family, you can enable or disable the IKE tracing log dynamically while the IPSec service is running by doing the following:

- To enable the IKE tracing log, type the following at the command prompt:

  **netsh ipsec dynamic set config ikelogging 1**

  This command creates the IKE tracing log file if it does not exist. If the file does exist, it appends logging information to the existing file.

- To disable the IKE tracing log, type the following at the command prompt:

  **netsh ipsec dynamic set config ikelogging 0**

**Enabling the IKE tracing log in Windows 2000 and** Windows XP

In Windows 2000 and Windows XP, you must enable IKE tracing by modifying the registry. For the changes to take effect, you must also stop and restart the IPSec service:

- To enable the IKE tracing log in Windows XP and Windows 2000, do the following:

  1. Set the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\PolicyAgent\Oakley\EnableLoggingDWORD** registry setting to a value of **1**.

     The Oakley key does not exist by default and must be created.

  **Caution**

  - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

  1. Stop and start the IPSec service by running the **net stop policyagent** and **net start policyagent** commands at the command prompt.

**Stopping and restarting the IPSec service**

Stopping and restarting the IPSec service can disconnect all of the computers that are using IPSec from the computer on which the IPSec service is stopped, and it can prevent further communication with that computer. However, if you restart the IPSec service immediately, TCP-based communication might resume, due to the retransmit behavior of TCP, after new IKE and IPSec SAs are established. If you leave the IPSec service stopped, any clients that used the default response rule to establish security will be unable to communicate with this computer for two hours.

To avoid losing Terminal Services connectivity for computers that are using IPSec over a Terminal Server session, you must stop and restart the IPSec service by using a single command line:

- To stop and restart the IPSec service for computers over a Terminal Server session

    - At the command prompt, type the following:

      **net stop policyagent & net start policyagent**

If you are restarting the IPSec service while an L2TP/IPSec VPN tunnel is connected, the tunnel will lose connectivity and must be reconnected when the IPSec service is restarted. A PPTP tunnel, however, does not use IPSec and therefore will stay connected if you stop the IPSec service.

If you are restarting the IPSec service on a computer that is running the Windows Server 2003 family or the Windows Server 2003 family and that is also running the Routing and Remote Access service, any IPSec configuration for L2TP will be lost and the L2TP tunnels will be disconnected. Therefore, you must stop and restart the Routing and Remote Access service, as well as the IPSec service.

- To stop and restart the IPSec service and the Routing and Remote Access service, do the following:

    1. Stop the Routing and Remote Access service using the **net stop remoteaccess** command.
    2. Stop the IPSec service by using the **net stop policyagent** command.
    3. Start the IPSec service by using the **net start policyagent** command.
    4. Start the Routing and Remote Access service using the **net start remoteaccess** command.

**Viewing IPSec and other network communication with Network Monitor**

You can install and use Network Monitor to view IPSec and other network communication. Note that the version of Network Monitor that is provided with the Windows Server 2003 family can be used only to view the network traffic that is sent to or from the computer on which it is installed. To view network traffic that is sent to or from another computer and is routed through your computer (using the Routing and Remote Access service), you must use the Network Monitor component that is provided with Microsoft Systems Management Server.

The Network Monitor component that is provided with the Windows Server 2003 family includes parsers for the ISAKMP (IKE), AH, and ESP protocols. The Network Monitor parsers for ESP can parse inside the ESP packet only if null-encryption is being used and the full ESP packet is captured. Network Monitor cannot parse the encrypted portions of IPSec-secured ESP traffic when encryption is performed in software. However, if encryption is being performed by an IPSec hardware offload network adapter, the ESP packets are decrypted when Network Monitor captures them and as a result, can be parsed and interpreted into the upper-layer protocols. If you need to diagnose ESP software-encrypted communication, you must disable ESP encryption and use ESP-null encryption by changing the IPSec policy on both computers.

### Notes

- For information about how to install the version of Network Monitor that is provided with the Windows Server 2003 family, see Install Network Monitor.

- For information about Systems Management Server, go to the Microsoft Web site.

**Using Netsh to change the IPSec configuration on computers running the Windows Server 2003 family**

For computers running the Windows Server 2003 family, you can use the Netsh commands for IPSec to script IPSec policy creation, display details about IPSec policies, and change the IPSec configuration for troubleshooting.

For troubleshooting, you can use the Netsh commands for IPSec to change the following settings:

#### Disable Internet Key Exchange (IKE) certificate revocation list (CRL) checking

By default, in Windows 2000 CRLs are not checked during IKE certificate authentication. In Windows XP and the Windows Server 2003 family, CRLs are checked during IKE certificate authentication, but a fully successful check is not required for the certificate to be accepted. In some cases, failures during CRL processing might cause IKE to not accept the certificate. Or, the delay required for CRL checking might delay IKE negotiation enough to cause the connection attempt to time-out. To determine whether certificate authentication will be successful without CRL checking, you can disable IKE CRL checking. To do this, type the following at the command prompt:

**netsh ipsec dynamic set config strongcrlcheck 0**

This setting takes effect immediately. It does not require a restart.

#### Enable IPSec driver event logging

To record all inbound and outbound dropped packets and other packet processing errors in the Event Viewer System log, you can set the IPSec driver event logging level to **7**. To do this, type the following at the command prompt:

**netsh ipsec dynamic set config ipsecdiagnostics 7**

This setting will not take effect until you restart your computer.

### Notes

- If you configured an IPSec filter action on a computer to block traffic, setting the IPSec driver event logging level to **7** on that computer might generate many events that fill the System log very quickly. Accordingly, you should set the IPSec driver event logging level to **7** only for testing.

- All packets that are dropped by IPSec contribute to the **Datagrams Received Discarded** or **Datagrams Outbound Discarded** System Monitor counters for the IP object. IPSec itself does not provide a counter object. You can monitor IPSec performance counters manually by using IP Security Monitor.

#### Permit inbound and outbound traffic during computer startup

To permit inbound and outbound traffic during computer startup (before the IPSec service starts), you can use the following Netsh command:

**netsh ipsec dynamic set config bootmode permit**

This setting will not take effect until you restart your computer.

### Note

- If you start the computer in Safe Mode with Networking, the IPSec service will not start and cannot retrieve IPSec policy settings from Active Directory or the local registry, and persistent policy cannot be applied. As a result, inbound and outbound traffic will continue to be permitted until the computer is no longer in Safe Mode.

#### Exempt all broadcast, multicast, IKE, Kerberos, and RSVP traffic from IPSec filtering

In Windows 2000 and Windows XP, by default, the IPSec driver exempts all broadcast, multicast, IKE, Kerberos, and RSVP traffic from IPSec filtering. In the Windows Server 2003 family, only IKE traffic is exempt from IPSec filtering, and you can configure, block, or permit filter actions specifically for multicast and broadcast traffic (IPSec does not negotiate SAs for multicast and broadcast traffic). To restore the IPSec driver to the default Windows 2000 and Windows XP filtering behavior, you can use the following Netsh command:

**netsh ipsec dynamic set config ipsecexempt 0**

This setting will not take effect until you restart your computer.

### Caution

- The Windows 2000 and Windows XP default exemption settings for IPSec are designed for corporate LAN environments with a low risk of attack. For this reason, you should use only the Windows 2000 and Windows XP default exemption settings when necessary for troubleshooting, in low-risk environments, or when you cannot solve program compatibility issues by configuring explicit filters in IPSec policies.

You can also exempt all broadcast, multicast, IKE, Kerberos, and RSVP traffic from IPSec filtering by modifying the registry as follows:

1. Set the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IPSEC\NoDefaultExempt DWORD** registry setting to a value of **0**.

2. The **NoDefaultExempt** key does not exist by default and must be created.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer

3. Restart the computer.

#### Using Ipseccmd.exe to manage and monitor IPSec on computers running Windows XP

For computers running Windows XP, you can use the Ipseccmd.exe command-line tool to script IPSec policy creation and to display IPSec policy assignments, active SAs, and detailed IPSec policy settings, including filters, filter actions, and authentication methods. Ipseccmd.exe replaces and enhances the functionality provided by the Ipsecpol.exe (used in Windows 2000 for scripting IPSec policy creation) and the Netdiag.exe **/test:ipsec /v /debug** command (used in Windows 2000 to display configuration information and SAs for an active IPSec policy).

To install Ipseccmd.exe on a computer running Windows XP, run the Setup.exe file from the \Support\Tools folder on the Windows XP CD.

**Notes**

- Ipseccmd.exe is provided only with Windows XP, and you can use this tool to manage and monitor IPSec policies only on computers running Windows XP.

- To display all IPSec policy settings and statistics for diagnostics, use the **ipseccmd show all** command.

#### Using Netdiag.exe to display IPSec information and to test and view network configuration

You can use the Netdiag.exe command-line tool to display information about IPSec policies and statistics, report network configuration, and test basic networking capabilities and domain-based functionality. The following table describes how to install Netdiag.exe and provides information about functional changes relevant to IPSec for each version of this tool.

| On computers running | Use this method to install | Notes |
|---|---|---|
| Windows Server 2003 family | For the Windows Server 2003 family, Netdiag.exe is available for installation from the Windows Server 2003 family CD (run the Suptools.msi file from the \Support\Tools folder, and choose the **Complete** setup option. | • Although you can still use Netdiag.exe to obtain basic networking information that is not IPSec-specific, for the Windows Server 2003 family, the **netdiag /test:ipsec** option has been removed, and the Netsh commands for IPSec replace all IPSec-specific functionality. To view details about IPSec policies, use either the **netsh ipsec static show** command or the **netsh ipsec dynamic show** command. |

| | | |
|---|---|---|
| Windows XP | For Windows XP, Netdiag.exe is available for installation from the Windows XP CD (run the Setup.exe file from the \Support\Tools folder, and choose the **Complete** setup option). | • Displays information about IPSec policy assignments, including the name of the active IPSec policy, the name of the Group Policy object that assigned the policy, and the policy path.<br><br>• The display of detailed IPSec policy information and IPSec statistics (provided by the **/debug** and **/v** options in Windows 2000) is not supported in Windows XP. Instead, to view details about IPSec policies, use the Ipseccmd.exe **show** command. |
| Windows 2000 | For Windows 2000, an updated version of Netdiag.exe is available for download from the Web. For information, see "Windows 2000 Resource Kits," at the Microsoft Windows Resource Kits Web site. | • Netdiag.exe was enhanced in Windows 2000 Service Pack 1 to display the number of bytes offloaded by the IPSec driver to a network adapter that is capable of IPSec hardware offload. The hardware offload statistics are Offloaded Bytes Sent and Offloaded Bytes Received.<br><br>• To use the **/debug** option to view details about Active Directory-based IPSec policies, you must be a member of the Domain Admins group in Active Directory. |

You can use the **netdiag /v /l** command to obtain networking information that is not IPSec-specific, for any platform. Typical uses of these options include:

- Reporting the IP configuration and routing configuration for a computer with one command.
- Testing WINS and DNS name resolution and consistency.
- Reporting the build version of a computer and the hotfixes that are installed on that computer.
- Testing the validity of domain membership, whether domain members can successfully contact domain controllers, and trust relationships.

The **/l** option generates a Netdiag.log file. This file is written to the folder in which Netdiag.exe is run.

**Notes**

- To run all Netdiag.exe commands, you must be a member of the Administrators group on the local computer.
- Each version of Netdiag.exe is customized to run on a different version of the Windows operating system (that is, Windows 2000, Windows XP, or the Windows Server 2003 family). You can only run Netdiag.exe on a computer that is running the Windows operating system for which Netdiag.exe has been specifically designed.
- If you are running a version of Netdiag.exe that is designed for Windows 2000 or Windows XP in a Windows Server 2003 domain, Netdiag.exe might not report the correct operating system version of the domain.
- If you run Netdiag.exe on a computer that is assigned an IPSec policy that affects most inbound and outbound IP traffic on that computer, Netdiag.exe might not report results correctly the first time it is run. This is because it might take a few seconds for IPSec to establish SAs to the many remote computers for which Netdiag.exe tests connectivity. If this occurs, wait five seconds, and then run Netdiag.exe again.

**Disabling TCP/IP and IPSec hardware acceleration**

Network adapters can accelerate IPSec processing by performing hardware offload of IPSec cryptographic functions (IPSec offload) and the calculation of TCP checksums (checksum offload). Such adapters might also process large TCP segments for very fast transmission (large-send offload). By default, when a network adapter driver that can perform hardware offload is enabled during the Plug and Play initialization process, the driver advertises this capability to TCP/IP and IPSec. TCP/IP and

IPSec then offload tasks to the network adapter driver as appropriate.

If you use network adapters to perform hardware offload of IPSec cryptographic functions, you might need to verify that hardware acceleration is not causing problems with the packet processing that is performed by the network adapter. To do so, you can:

- Disable hardware offload functions in the network adapter driver (if this function is supported by the driver). This task does not require you to restart the computer.
- Disable TCP/IP and IPSec hardware acceleration. This task requires you to restart the computer.
- Disable only IPSec hardware acceleration. This task requires you to restart the computer.

**Disabling hardware offload functions in the network adapter driver**

To determine whether you can disable hardware offload functions in the network adapter driver, do one of the following:

- Open Device Manager, click **Network Adapters**, right-click the network adapter whose properties you want to view, and then click **Properties**. For more information, see Change network adapter settings
- Open Network Connections, right-click the network adapter that you want to view, click **Properties**, and then, on the **General** tab, click **Configure**.

**Disabling TCP/IP and IPSec hardware acceleration**

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

To disable both TCP/IP and IPSec hardware acceleration by modifying the registry, do the following:

1. Set the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\DisableTaskOffload** DWORD registry setting to a value of **1**.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

2. Restart the computer.

If the **DisableTaskOffload** DWORD registry setting is set to a value of **0**, and if the network adapter advertises hardware offload capabilities, IPSec and TCP/IP will attempt to offload the appropriate functions to the network adapter.

**Disable only IPSec hardware acceleration**

To disable only IPSec hardware acceleration by modifying the registry, do the following:

1. Set the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\IPSEC\EnableOffload** DWORD registry setting to a value of **0**.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

2. Restart the computer.

**Note**

- To help minimize the potential for hardware acceleration to cause problems with packet processing performed by the network adapter, make sure that you use the latest network adapter driver available from the vendor.

# Viewing IPSec Statistics and Details About Active IPSec Policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Viewing IPSec statistics and details about active IPSec policies**
This section covers:

- Viewing main mode and quick mode statistics in IP Security Monitor
- Viewing details about active IPSec policies in IP Security Monitor
- Using Resultant Set of Policy to view IPSec policy assignments

# Viewing main mode and quick mode statistics in IP Security Monitor

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Viewing main mode and quick mode statistics in IP Security Monitor**

**Main Mode (IKE) Statistics**
The following table describes the items in the list of main mode (IKE) statistics in IP Security Monitor.

For information about how to view these statistics, see View IP security statistics.

| Main Mode (IKE) Statistic | Description |
|---|---|
| Active Acquire | The number of pending requests to initiate an Internet Key Exchange (IKE) negotiation in order to establish a security association (SA) between IPSec peers. The Active Acquire statistic includes the outstanding request and the number of any queued requests. Under a heavy load, the number of active acquires is 1 plus the number of requests that are queued by IKE for processing. |
| Active Receive | The number of IKE messages received that are queued for processing. |
| Acquire Failures | The total number of acquire outbound requests that have failed since the IPSec service was last started. Acquires are requests to establish SAs between IPSec peers. |
| Receive Failures | The total number of errors that have occurred during the process of receiving IKE messages since the IPSec service was last started. |
| Send Failures | The total number of errors that have occurred during the process of sending IKE messages since the IPSec service was last started. The number of Send Failures typically increases for computers that establish SAs over temporary network connections, such as dial-up connections, virtual private network tunnels, and wireless connections. |
| Acquire Heap Size | The number of entries in the acquire heap. The acquire heap stores successful acquires. Acquires are outbound requests to establish SAs between IPSec peers. |
| Receive Heap Size | The number of entries in the IKE receive buffers. The receive buffers store incoming IKE messages. |
| Authentication Failures | The total number of identity authentication (Kerberos, certificate, and preshared key) failures that have occurred during main mode negotiation since the IPSec service was last started. If you are having difficulty communicating securely, attempt the communication and determine whether the number of Authentication Failures increases. If it does, check your authentication settings for either an unmatched authentication method or an incorrect authentication method configuration (for example, the use of preshared keys that do not match). |
| Negotiation Failures | The total number of negotiation failures that have occurred during main mode or quick mode negotiation since the IPSec service was last started. If you are having difficulty communicating securely, attempt the communication and determine whether the number of Negotiation Failures increases. If it does, check your authentication and security method settings for an unmatched authentication method, an incorrect authentication method configuration (for example, the use of preshared keys that do not match), or unmatched security methods or settings. |
| Invalid Cookies Received | The total number of cookies that could not be matched with an active main mode SA since the IPSec service was last started. A cookie is a value contained in a received IKE message that is used to help identify the corresponding main mode SA. |
| Total Acquire | The total number of requests that have been submitted to IKE since the IPSec service was last started to establish an SA. This number includes acquires that result in soft SAs. |

| | |
|---|---|
| Total Get SPI | The total number of requests that have been submitted by IKE to the IPSec driver to obtain a unique Security Parameters Index (SPI) since the IPSec service was last started. The SPI matches inbound packets with SAs. |
| Key Additions | The total number of outbound quick mode SAs that have been added by IKE to the IPSec driver since the IPSec service was last started. |
| Key Updates | The total number of inbound quick mode SAs that have been added by IKE to the IPSec driver since the IPSec service was last started. |
| Get SPI Failures | The total number of failed requests that have been submitted by IKE to the IPSec driver to obtain a unique SPI since the IPSec service was last started. |
| Key Addition Failures | The total number of failed outbound quick mode SA addition requests that have been submitted by IKE to the IPSec driver since the IPSec service was last started. |
| Key Update Failures | The total number of failed inbound quick mode SA addition requests that have been submitted by IKE to the IPSec driver since the IPSec service was last started. |
| ISADB List Size | The number of main mode state entries. This number includes successfully negotiated main modes, main mode negotiations in progress, and main mode negotiations that failed or expired and have not yet been deleted. |
| Connection List Size | The number of quick mode negotiations that are in progress. |
| IKE Main Mode | The total number of successful SAs that have been created during main mode negotiations since the IPSec service was last started. |
| IKE Quick Mode | The total number of successful SAs that have been created during quick mode negotiations since the IPSec service was last started. |
| Soft Associations | The total number of SAs formed with computers that have not responded to main mode negotiation attempts since the IPSec service was last started. Although these computers did not respond to main mode negotiation attempts, IPSec policy allowed communications with the computers. Soft SAs are not secured by IPSec. |
| Invalid Packets Received | The total number of invalid IKE messages that have been received since the IPSec service was last started. This number includes IKE messages with invalid header fields, incorrect payload lengths, and incorrect values for the responder cookie. Invalid IKE messages are commonly caused by retransmitted IKE messages or an unmatched preshared key between the IPSec peers. |

**Quick Mode (IPSec) Statistics**

The following table describes the items in the list of quick mode (IPSec) statistics in IP Security Monitor.

| **Quick Mode (IPSec) Statistic** | **Description** |
|---|---|
| Active Security Associations | The number of active quick mode SAs. |
| Offloaded Security Associations | The number of active quick mode SAs offloaded to hardware. Certain network adapters can accelerate IPSec processing by performing hardware offload of IPSec cryptographic functions. |
| Pending Key Operations | The number of IPSec key exchange operations that are in progress but are not yet completed. |
| Key Additions | The total number of keys for quick mode SA negotiations that have been successfully added since the computer was last started. |
| Key Deletions | The total number of keys for quick mode SAs that have been successfully deleted since the computer was last started. |

| | |
|---|---|
| Rekeys | The total number of successful rekey operations for quick mode SAs since the computer was last started. |
| Active Tunnels | The number of active IPSec tunnels. |
| Bad SPI Packets | The total number of packets for which the SPI has been incorrect since the computer was last started. If the SPI is incorrect, it might mean that the inbound SA has expired and a packet using the old SPI has recently arrived. This number is likely to increase if rekey intervals are short and there are a large number of SAs. A large number of packets with bad SPIs that are received within a short amount of time might indicate a packet spoofing attack. |
| Packets Not Decrypted | The total number of packets that could not be decrypted since the computer was last started. A packet might not be decrypted if it fails a validation check. |
| Packets Not Authenticated | The total number of packets for which data could not be verified (for which the integrity hash verification failed) since the computer was last started. Increases in this number might indicate an IPSec packet spoofing or modification attack or packet corruption by network devices. |
| Packets With Replay Detection | The total number of packets that have contained an invalid sequence number since the computer was last started. Increases in this number might indicate a network problem or replay attack. |
| Confidential Bytes Sent | The total number of bytes that have been sent using the Encapsulating Security Payload (ESP) protocol (excluding non-encrypted ESP) since the computer was last started. |
| Confidential Bytes Received | The total number of bytes that have been received using the ESP protocol (excluding non-encrypted ESP) since the computer was last started. |
| Authenticated Bytes Sent | The total number of authenticated bytes that have been sent using the Authentication Header (AH) protocol or the ESP protocol since the computer was last started. |
| Authenticated Bytes Received | The total number of authenticated bytes that have been received using the AH protocol or the ESP protocol since the computer was last started. |
| Transport Bytes Sent | The total number of bytes that have been sent using IPSec transport mode since the computer was last started. |
| Transport Bytes Received | The total number of bytes that have been received using IPSec transport mode since the computer was last started. |
| Bytes Sent in Tunnels | The total number of bytes that have been sent using IPSec tunnel mode since the computer was last started. |
| Bytes Received in Tunnels | The total number of bytes that have been received using IPSec tunnel mode since the computer was last started. |
| Offloaded Bytes Sent | The total number of bytes that have been sent using IPSec hardware offload since the computer was last started. |
| Offloaded Bytes Received | The total number of bytes that have been received using IPSec hardware offload since the computer was last started. |

# Viewing details about active IPSec policies in IP Security Monitor

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Viewing details about active IPSec policies in IP Security Monitor**

IP Security Monitor allows you to view details about the active IPSec policies that are applied to the domain, the local computer, or a remote computer. This topic describes the type of details that IP Security Monitor displays.

For information about how to view details about active IPSec policies, see View details about active IPSec policies. For information about creating, assigning, and assigning IPSec policies, see Creating, modifying, and assigning IPSec policies.

**Active IPSec policies that are applied by the domain**

The following table describes the items that are displayed when you use IP Security Monitor to view details about an active IPSec policy that is applied by the domain.

| Active IPSec policy item | Description |
|---|---|
| **Policy Name** | Specifies the name of the active IPSec policy. |
| **Description** | Optional text that describes the purpose of the active IPSec policy. |
| **Policy Last Modified** | Not applicable (this information is displayed only for active IPSec policies that are applied to a computer). |
| **Policy Store** | Specifies the storage location for the active IPSec policy. For active IPSec policies that are applied by the domain, this location appears as "Domain Store." |
| **Policy Path** | Specifies the LDAP path to the active IPSec policy. |
| **Organizational Unit** | Specifies the organizational unit to which the Group Policy object is applied. |
| **Group Policy Object Name** | Specifies the Group Policy object to which the active IPSec policy is applied. |

**Active IPSec policies that are applied to a computer**

The following table describes the items that are displayed when you use IP Security Monitor to view details about active IPSec policies that are applied to a computer.

| Active IPSec policy item | Description |
|---|---|
| **Policy Name** | Specifies the name of the active IPSec policy. |
| **Description** | Optional text that describes the purpose of the active IPSec policy. |
| **Policy Last Modified** | Specifies the date and the time that the active IPSec policy was last modified. |
| **Policy Store** | Specifies the storage location of the active IPSec policy. For active IPSec policies that are applied to a computer, this location appears as "Local Store." |
| **Policy Path** | Not applicable (this information is only displayed for active IPSec policies that are applied by the domain). |
| **Organizational Unit** | Not applicable (this information is only displayed for active IPSec policies that are applied by the domain). |

| | |
|---|---|
| **Group Policy Object Name** | Not applicable (this information is only displayed for active IPSec policies that are applied to the domain). |

**Note**

- You cannot use IP Security Monitor to add, edit, or remove IPSec policies. For information about how to add, edit, or remove IPSec policies, see Add, edit, or remove IPSec policies.

# Using Resultant Set of Policy to view IPSec policy assignments

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Resultant Set of Policy to view IPSec policy assignments**
Resultant Set of Policy (RSoP) is an addition to Group Policy that you can use to view IPSec policy assignments for a computer or for members of a Group Policy container. This information can help you troubleshoot policy precedence issues and plan your deployment.

To view IPSec policy assignments in RSoP, you must first open the RSoP MMC console, and then run a query. RSoP provides two types of queries: logging mode queries (for viewing IPSec policy assignments for a computer) and planning mode queries (for viewing IPSec policy assignments for members of a Group Policy container).

**Logging mode queries**
You can run an RSoP logging mode query to view all of the IPSec policies that are assigned to an IPSec client. The query results display the precedence of each IPSec policy assignment, so that you can quickly determine which IPSec policies are assigned but are not being applied and which IPSec policy is being applied. The RSoP console also displays detailed settings (that is, the filter rules, filter actions, authentication methods, tunnel endpoints, and connection type) for the IPSec policy that is being applied.

When you run a logging mode query, RSoP retrieves policy information from the Windows Management Instrumentation (WMI) repository on the target computer, and then displays this information in the RSoP console. In this way, RSoP provides a view of the policy settings that are being applied to a computer at a given time.

For information about how to run RSoP logging mode queries for IPSec policies, see Use RSoP to view IPSec policy assignments for a computer. For general information about RSoP logging mode queries, see RSoP logging mode. For general information about RSoP, see RSoP overview.

**Planning mode queries**
You can run an RSoP planning mode query to view all of the IPSec policies that are assigned to members of a Group Policy container. For example, a planning mode query can be useful if you are planning a company reorganization and you want to move computers from one organizational unit to a new organizational unit. By supplying the appropriate information and then running a planning mode query, you can determine which IPSec policies are assigned but are not being applied to the new organizational unit and which IPSec policy is being applied. In this way, you can identify which policy would be applied if you were to move the computers to the new organizational unit. As with logging mode queries, when you run a planning mode query, the RSoP console displays detailed policy settings for the IPSec policy that is being applied.

When you run a planning mode query, RSoP retrieves the names of the target user, computer, and domain controller from the WMI repository on the domain controller. WMI then uses the Group Policy Data Access Service (GPDAS) to create the policy settings that would be applied to the target computer, based on the RSoP query settings that you entered. RSoP reads the policy settings from the WMI repository on the domain controller, and then displays this information in the RSoP console user interface.

For information about how to run RSoP planning mode queries for IPSec policies, see Use RSoP to view IPSec policy assignments for members of a Group Policy container. For general information about RSoP planning mode queries, see RSoP planning mode.

### Note

- You can run an RSoP planning mode query only on a domain controller (when you run a planning mode query, you must explicitly specify the domain controller name). However, you can specify any IPSec client as the target for the query, provided you have the appropriate permissions to do so.

**Assigning and processing IPSec policy in Group Policy**
IPSec policies can be assigned from and stored in Active Directory, as part of Group Policy, or they can be assigned and stored locally, on a computer. When a computer is joined to an Active Directory domain, the domain-level IPSec policy applies. If a computer is not joined to an Active Directory domain, the local IPSec policy applies.

Group Policy settings are contained in Group Policy objects, which are linked with specific Active Directory objects (sites, domains, and organizational units). When an IPSec policy is assigned to a Group Policy object for an Active Directory object (such as an organizational unit), that IPSec policy is propagated to any computer accounts that are affected by the Group Policy

object.

Multiple Group Policy objects, each of which can contain an IPSec policy, can be assigned to a computer account. When multiple IPSec policies are assigned, the last policy that is processed is the policy that is applied (that is, the last policy takes the highest precedence and overrides the settings of any IPSec policy assignments that were processed earlier).

Policy precedence is based on the Group Policy inheritance model. The policy used is the policy assigned at the lowest level of the domain hierarchy for the domain container of which the computer is a member. For example, if there are IPSec policies that are configured for both the domain and for an organizational unit within the domain, the computers that are members of the domain use the domain IPSec policies. The computers that are members of the organizational unit within the domain use the organizational unit IPSec policies. If there are multiple organizational units, members of each organizational unit use the IPSec policy assigned to the organizational unit that is closest in level to their container in the Active Directory hierarchy. If no IPSec policies are configured for Active Directory, or if a computer is not connected to an Active Directory domain, the local IPSec policy is used.

**IPSec policy information displayed in the RSoP console**
The RSoP console simplifies the task of determining which IPSec policy is being applied by displaying the following information for each Group Policy object that contains an IPSec policy assignment: the name of the IPSec policy, the name of the Group Policy object that the IPSec policy is assigned to, the IPSec policy precedence (the lower the number, the higher the precedence), and the name of the site, domain, and organizational unit to which the Group Policy object containing the IPSec policy applies (that is, the scope of management for the Group Policy object).

For information about policy precedence and IPSec policy behavior in an Active Directory environment, see the section "Active Directory-based policy" in Creating, modifying, and assigning IPSec policies. For general information about Group Policy, see Group Policy overview.

### Note

- The settings of the IPSec policy with the highest precedence apply in their entirety; they are not merged with the settings of IPSec policies that are applied at higher levels of the Active Directory hierarchy.

# IPSec Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

**Windows Resource Kits**
The Windows Resource Kits contain extensive technical information on TCP/IP and IPSec. For more information, see Using the Windows Deployment and Resource Kits.

**IPSec-related Web sites**
The following Web sites contain links that relate to IPSec:

- The IPSec Working Group page contains links to RFCs, Internet Drafts, and other IPSec-related links at the Internet Engineering Task Force Web site.
- For information and the latest recommendations on security, see Microsoft Security at the Microsoft Web site.
- For information about the standards and technology for IPSec, as well as other computer security topics, see the National Institute of Standards and Technology Web site.

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# IPSec Troubleshooting

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**
What problem are you having?

- Traffic is not being secured.
- IPSec SA negotiation is failing.
- IPSec SA negotiation is failing when using certificate authentication.
- Some computers are unable to communicate with secure computers.
- Local computer IPSec policy is not being used.
- Unable to assign or unassign an IP Security policy.
- DES is being used when 3DES is needed.
- Unsecured traffic is being sent to a secure server.
- Event Viewer is displaying error messages related to IPSec.
- A policy location error message is displayed.
- Event Viewer is displaying "Bad SPI" error message.
- IP Security Monitor displays the error message "The IPSec server is unavailable or incompatible with the IPSec monitor."

**Traffic is not being secured.**
**Cause:** An IPSec security association (SA) that secures traffic (also known as a hard SA) is not being established.

**Solution:** This might be caused by either filter list misconfiguration or the enabling of unsecured communication with non-IPSec-aware computers. Examine the policies that are assigned to both IPSec peers and determine, based on the rules, filter lists, and filter action settings, whether IPSec requires traffic to be secured. Check to determine whether the **Allow unsecured communication with non-IPSec-aware computer** option on the **Security Methods** tab of the appropriate filter action is enabled. Use audit logging to determine the cause of the failed negotiation.

**See also:** IPSec troubleshooting tools; Add, edit, or remove IPSec security methods

**IPSec SA negotiation is failing.**
**Cause:** An IPSec security association (SA) that secures traffic (also known as a hard SA) is not being established. If unsecured communication with non-IPSec-aware computers is enabled, the negotiation failure is expected.

Negotiation failure between two IPSec-aware computers commonly occurs when the default policies are used on two IPSec peers and one or both are not members of an Active Directory domain. Computers running Windows XP Home Edition do not support Active Directory domain membership or the Kerberos V5 authentication method. Default policies use the Kerberos V5 authentication method, which does not work for computers that are not Active Directory domain members.

**Solution:** A negotiation failure between two IPSec-aware computers is most often caused by a mismatched key exchange method, authentication method, or security method. Examine the policies that are assigned to both IPSec peers and determine, based on the advanced settings, rules, filter lists, and filter action settings, whether IPSec should be securing the traffic. If it should, determine whether there is a mismatched key exchange, authentication method, or security method that is preventing a successful negotiation of a hard SA. Use audit logging to determine the cause of the failed negotiation.

**See also:** IPSec troubleshooting tools; Add, edit, or remove IPSec security methods; Define IPSec authentication methods;

Create key exchange security methods

**IPSec SA negotiation is failing when using certificate authentication.**
**Cause:** The correct computer certificates are not installed on the IPSec peers.

**Solution:** Install the correct computer certificates on the IPSec peers.

**Cause:** An incorrect certification authority (CA) is selected in the authentication method.

**Solution:** For the rules of each IPSec peer, select the CA that issued the computer certificate that is installed on the other IPSec peer.

**Cause:** The certificate chain from the issuing CA to the root CA is broken.

**Solution:** Install a computer certificate on each IPSec peer that follows a valid certificate chain up to a trusted root CA.

**Cause:** The computer certificate on one or both of the IPSec peers has expired.

**Solution:** Install a current computer certificate on each IPSec peer.

**See also:** IPSec troubleshooting tools; Authentication methods; Define IPSec authentication methods; Special IPSec considerations; Using Certificates

**Some computers are unable to communicate with secure computers.**
**Cause:** Secure computers are using a lockdown policy that requires client computers to initiate secure communications. The computers that are unable to communicate are not configured with a rule to initiate secure communication.

**Solution:** Either allow unsecured incoming connection requests on the secure servers or configure additional rules for the computers that are unable to communicate so that they can initiate secure communication with the secure computers.

**Cause:** Client computers are not IPSec-capable and secure computers are not allowing unsecured communications.

**Solution:** Either install client computers that are IPSec-capable or reconfigure the secure computers to allow communication with computers that are not IPSec-capable.

**Cause:** Some computers are configured with a policy that has a key exchange, authentication method, or security method that is mismatched with the policy configured for the secure computers.

**Solution:** Examine the policies that are assigned to both IPSec peers and determine, based on the advanced settings, rules, filter lists, and filter action settings, whether IPSec should be securing the traffic. If it should, determine whether there is a mismatched key exchange, authentication method, or security method that is preventing a successful SA negotiation. Use audit logging to determine the cause of the failed negotiation.

**See also:** Add, edit, or remove filter actions; IPSec troubleshooting tools; Add, edit, or remove IPSec security methods; Define IPSec authentication methods; Create key exchange security methods

**Local computer IPSec policy is not being used.**
**Cause:** The computer is a member of an Active Directory domain and is receiving Active Directory-based IPSec policy.

**Solution:** All domain members receive Active Directory-based IPSec policy, which overrides local IPSec policy settings. To prevent this, remove the computer from the domain.

**Cause:** The IPSec service is not started.

**Solution:** Start or restart the IPSec service.

**See also:** Restart the IPSec services

**Unable to assign or unassign an IP Security policy.**
**Cause:** You cannot assign or unassign policies when IP Security Policies are used for Active Directory.

**Solution:** To assign Active Directory-based policies, use IP Security Policies within Group Policy.

**See also:** Assign or unassign IPSec policy in Group Policy

**DES is being used when 3DES is needed.**
**Cause:** The IPSec peer is a computer running Windows 2000 without either the Windows 2000 High Encryption Pack or Windows 2000 Service Pack 2 (or later) installed.

**Solution:** Install either the Windows 2000 High Encryption Pack or Windows 2000 Service Pack 2 (or later) on the computer

running Windows 2000.

**Unsecured traffic is being sent to a secure server.**
**Cause:** The client computer is using the default response rule.

**Solution:** When the client computer is configured with the default response rule, it sends unsecured packets when it either initiates communication or restarts communication after a delay long enough for the quick mode SA and dynamic filter list to time out. To prevent this, configure additional rules for client computers that always initiate secure communication to secure servers.

**See also:** Security information for IPSec

**Event Viewer is displaying error messages related to IPSec.**
**Cause:** There might be a problem with either the IPSec Policy Agent or the Oakley service.

**Solution:** View the system and security event logs for messages that might help in determining the origin of the problem.

**A policy location error message is displayed.**
**Cause:** This error might occur if the IPSec Policy Agent is attempting to retrieve policy from an incorrect storage location.

**Solution:** Examine both the IPSec Policy Agent events in Event Viewer and the IPSec Policy Agent log for messages that indicate from what location policy is being retrieved (the local registry or the domain). If **HKLM\SOFTWARE\Policies\Microsoft\Windows\IPSec\GPTIPSecPolicy\DSIPSecPolicyFlags** is set to 1, then IPSec policy is obtained from Active Directory. Otherwise, it is obtained from the registry. The local computer warns a user that domain policy is in effect when it starts. If the policy is supposed to be Active Directory-based, but cannot be obtained, you can delete **HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion\Group Policy\History** and then restart the computer.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**See also:** View Event Logs.

**Event Viewer is displaying "Bad SPI" error message.**
**Cause:** This error might occur if a key lifetime value is set too low, or if the SA has expired but the sender continues to transmit data to the receiver.

**Solution:** To determine and correct the problem, use IP Security Monitor to examine the number of rekeys. If the number of rekeys is very large compared to the amount of time the connections have been active, set the key lifetimes in the policy to be longer. Good values for high-traffic Ethernet connections are greater than both 50 megabytes and five minutes. This event is usually logged when an SA has been deleted on one IPSec peer, and the other IPSec peer sends secure traffic on the SA. This is usually a temporary situation that occurs on systems that are busy and fixes itself.

**IP Security Monitor displays the error message "The IPSec server is unavailable or incompatible with the IPSec monitor."**
**Cause:** You are using the IP Security Monitor console to monitor IPSec on a computer running Windows 2000.

**Solution:** The IP Security Monitor console can only be used to monitor IPSec on computers running Windows XP or a Windows Server 2003 operating system. To monitor IPSec on a computer running Windows 2000, use the **IPSecmon** command at the Windows 2000 command prompt on the computer that is being monitored.

# DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS**
Domain Name System (DNS) is the name resolution protocol for TCP/IP networks, such as the Internet. A DNS server hosts the information that enables client computers to resolve memorable, alphanumeric DNS names to the IP addresses that computers use to communicate with each other.

- Before you begin using this computer as a DNS server, see DNS Checklists.
- To find features that have been moved in the Microsoft® Windows Server 2003 family, see New ways to do familiar DNS tasks.
- For tips about using DNS, see DNS best practices.
- For help with specific tasks, see DNS How To....
- For general background information, see DNS Concepts.
- For problem-solving instructions, see Troubleshooting DNS.

# DNS Checklists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklists**

- Checklist: Installing a DNS server
- Checklist: Configuring a DNS server
- Checklist: Deploying DNS
- Checklist: Deploying DNS for Active Directory
- Checklist: Verifying DNS before installing Active Directory
- Checklist: Securing your DNS infrastructure

# Checklist: Installing a DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a DNS server**

| Step | Reference |
|---|---|
| If you are new to working with Domain Name System (DNS), first learn the basic DNS concepts and then examine how to use DNS-related tools to deploy and maintain the client and server features of DNS. | DNS Overview |
| Learn in more detail about how DNS works and understand more about DNS-related features. | Understanding DNS; Deploying DNS; Administering DNS |
| Before installing a DNS server, determine if the server is now a domain controller or whether it will be promoted to one later. | Server planning for DNS; Interoperability issues |
| Install the first DNS server on your network.<br><br>If you want to install Active Directory, the Active Directory Installation Wizard will automatically prompt you to install a DNS server. Otherwise, you can install the DNS Server service as a Windows component. | Install a DNS server |
| Select the checklist that best describes your deployment needs and follow it to complete your DNS installation. | Checklist: Configuring a DNS server; Checklist: Deploying DNS; Checklist: Deploying DNS for Active Directory |

# Checklist: Configuring a DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Configuring a DNS server**

| Step | Reference |
|---|---|
| If you have not installed a DNS server, first follow the DNS server installation checklist, and then return to this checklist to configure your new DNS server. | Checklist: Installing a DNS server |
| **For small office/home office.** If you are setting up a home network with multiple machines connecting to the Internet, have the following on hand:<br>• The name of the zone for which this server will be authoritative<br>• The IP address of your ISP's DNS server | Understanding zones and zone transfer; Dynamic update; Using forwarders |
| **For medium office/large office.** If the DNS server will service requests from clients on a local network that may or may not be available from the internet, have the following on hand:<br>• The name of the zone for which this server will be authoritative<br>• Possibly:<br>  • The name of a reverse lookup zone<br>  • The IP address of a DNS server used for forwarding | Server planning for DNS; Zone planning for DNS; Reverse lookup; Using forwarders; Active Directory integration |
| Before configuring your DNS server, learn DNS server best practices, server features, and the concepts involved in configuring primary and secondary servers. | DNS best practices; Server features; Configuring a new primary server; Using secondary servers |
| Configure your DNS server. | Configure a new DNS server |
| Verify the DNS server's configuration. | Verifying server configuration |

# Checklist: Deploying DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Deploying DNS**

| Step | Reference |
|---|---|
| Review best practices and all planning issues specific to deploying Domain Name System (DNS) servers on your network when not additionally deploying Active Directory. | Deploying DNS; DNS best practices |
| Plan your namespace by specifying a domain name standard for your organization. | Namespace planning for DNS |
| Plan how to divide up your DNS domain name and network address space into forward and reverse lookup zones as needed. | Zone planning for DNS; Reverse lookup |
| Plan your DNS servers, such as determining how many servers you need to use and where to put them on your network. | Server planning for DNS |
| (Optional) Test and evaluate server performance using DNS performance optimizing and monitoring tools. | Monitoring and Optimizing Servers |
| Review migration and interoperability issues, if appropriate. | Migrating servers; Interoperability issues |
| If clients on your network need to be able to resolve external DNS names, consider the use of forwarders for your network. | Using forwarders; Configure a DNS server to use forwarders |
| Register your organization's domain name with the Internet domain name registrar. This name is used to form the DNS names your organization uses on the Internet.<br><br>**Internet DNS**<br><br>**Name:** _____._____<br><br>**Note**<br><br>• Registering a parent or second-level DNS domain name for your organization with an active Internet domain name registration authority is only required if you plan to use this name externally on the Internet. | Namespace planning for DNS; Interoperability issues |
| Determine how to manage DNS client resolver configurations. | Managing Clients |
| Begin adding and configuring zones for your first DNS server. | Configure a new DNS server; Add a forward lookup zone; Add a reverse lookup zone |
| Install and configure additional DNS servers if they are to be used as secondary servers for your initial zones. | Install a DNS server; Add a secondary server for an existing zone; Using secondary servers |
| (For primary zones only) If the previous step was used, add additional secondary servers for your existing zones to the name server (NS) record to make them authoritative for the zone. | Specify other DNS servers as authoritative for a zone |
| (Optional) Install any additional zones (and DNS servers) for subdomains you want to delegate away from your first DNS server and its zones. | Configure a new DNS server; Configuring a new primary server |

| | |
|---|---|
| If the previous step was used, add delegations in parent zones for any subdomains added based on the previous step.<br><br>For example, if adding sub.example.microsoft.com as a new DNS domain, you would need to add to it a delegation at the example.microsoft.com zone. | Create a zone delegation; Delegating zones |
| Add DNS resource records--such as A, PTR, CNAME, and MX records--as needed to complete zone configurations. | Managing resource records; Add a resource record to a zone; Resource records reference |
| Enable or disable dynamic updates for zones as needed. | Allow dynamic updates; Dynamic update |
| (Optional) Enable WINS lookup for selected zones. | Enable DNS to use WINS resolution; WINS lookup integration; Using WINS lookup |
| (Optional) If you want to push updates to secondary servers for a zone, configure DNS notify at the primary server. | Create and manage a notify list for a zone; Understanding zones and zone transfer |
| Use the monitoring features of the DNS console, such as simple or recursive query testing, to verify that DNS servers are operating correctly. | Monitor Servers |
| Troubleshoot common DNS-related problems, if needed. | Troubleshooting DNS |

# Checklist: Deploying DNS for Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Deploying DNS for Active Directory**

| Step | Reference |
|---|---|
| Review best practices for planning your deployment and use of Active Directory with Domain Name System (DNS). | DNS best practices; Active Directory Best practices |
| Understand how Active Directory integration works for DNS servers. | Active Directory integration |
| Consider additional advanced namespace design issues that can affect DNS namespace planning and use before finalizing your Active Directory namespace plans.<br><br>Obtain additional information resources on DNS namespace design available from either the Microsoft Web site or Microsoft Press books before for planning your network. | Namespace planning for DNS |
| Review all planning issues specific to deploying DNS servers on your network for supporting Active Directory. | Deploying DNS |
| Plan your namespace by specifying a domain name standard for your organization. | Namespace planning for DNS |
| If necessary, register your organization's domain name with the Internet domain name registrar. This name is then used to form the basis for DNS names your organization uses on the Internet and might also form the basis for names used internally on your intranet as well.<br><br>**Internet DNS**<br><br>**Name: _____._____**<br><br>**Note**<br><br>• Registering a parent or second-level DNS domain name for your organization with an active Internet domain name registration authority is only required if you plan to use this name externally on the Internet. | Namespace planning for DNS; Namespace planning for DNS; Interoperability issues |
| Plan how to divide up your DNS domain name and network address space into forward and reverse lookup zones as needed. | Zone planning for DNS; Reverse lookup |
| Plan your DNS servers, such as determining how many servers you need to use and where to put them on your network.<br><br>For Active Directory, keep in mind that by default server computers promoted to be domain controllers also operate as DNS servers. | Server planning for DNS |
| (Optional) Test and evaluate server performance before finalizing your server plans. To perform DNS server evaluation, use related performance and event monitoring tools. | Monitoring and Optimizing Servers |
| Review additional migration and interoperability issues, if appropriate. | Migrating servers; Interoperability issues |
| If clients on your network need to be able to resolve external DNS names, consider whether you need to configure and use forwarders at DNS servers on your network. | Using forwarders; Configure a DNS server to use forwarders |
| Determine how to manage DNS client resolver configurations. | Managing Clients |
| If needed, add additional zones for any additional subdomains you need to add and use on your network. | Add a forward lookup zone; Add a reverse lookup zone |

| | |
|---|---|
| (Optional) Modify zone configurations to enable dynamic updates and change zone types to integrate storage of zones in Active Directory. | Allow dynamic updates; Change the zone type; Allow only secure dynamic updates |
| Install and configure domain controllers (or optionally, additional non-integrated DNS servers) and domains if they are to be used for hosting your zones. | Configure a DNS server for use with Active Directory; Install a DNS server; Configure a new DNS server |
| As needed, add delegations in parent zones for any subdomains added based on the previous step.<br><br>For example, if adding sub.example.microsoft.com as a new Active Directory domain, you would need to add to it a delegation at the example.microsoft.com zone. | Create a zone delegation; Delegating zones |
| (For standard primary zones only) Add new DNS servers you need to host your zones to the name server (NS) record at the primary zone/server to make them authoritative for the zone. | Specify other DNS servers as authoritative for a zone |
| Add DNS resource records--such as A, PTR, CNAME, and MX records--as needed to complete zone configurations. | Managing resource records; Add a resource record to a zone; Resource records reference |
| (Optional) Enable WINS lookup for selected zones. | Enable DNS to use WINS resolution |
| (Optional) Install and configure the DNS servers to act as secondary servers for your DNS deployment, if needed. | Install a DNS server; Add a secondary server for an existing zone; Using secondary servers |
| Use the monitoring features of the DNS console, such as simple or recursive query testing, to verify that DNS servers are operating correctly. | Monitor Servers |
| Troubleshoot DNS-related problems, if needed. | Troubleshooting DNS |

# Checklist: Verifying DNS before installing Active Directory

Published: January 21, 2005

Updated: January 13, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Verifying DNS before installing Active Directory**

| Step | Reference |
|---|---|
| Verify that a network connection on the server on which you are installing Active Directory is configured with a DNS server to query for domain names.<br><br>If you are installing Active Directory on a server in an *existing forest,* then the network connection of the server must be configured with one or more DNS servers. If not, then configure the network connection with the IP addresses of one or more DNS servers.<br><br>If you are installing Active Directory to create a *new forest,* and no DNS servers are available on the network, then the Active Directory Installation Wizard can automatically install and configure a local DNS server. The DNS server will be installed on the server where you are running the wizard and the server's preferred DNS server setting will be configured to use the new local DNS server. If you install a local DNS server using the Active Directory Installation Wizard, you may stop using this checklist. | Configure TCP/IP to use DNS; Create a new forest |
| Verify DNS resource records.<br><br>If you are installing Active Directory on a server in an existing forest, verify that the appropriate service (SRV) resource records and the corresponding address (A) resource records exist in DNS.<br><br>• Additional domain controller in an existing domain: _ldap._tcp.dc._mcdcs.*ActiveDirectoryDomainDNSName*<br><br>• First domain controller in a new child domain: _ldap._tcp.dc._mcdcs.*ParentActiveDirectoryDomainDNSName*<br><br>• First domain controller in a new tree: _ldap._tcp.dc._mcdcs.*ForestRootDomainDNSName*<br><br>If the required SRV and A resource records do not exist in DNS, you can add these records. | Verify DNS registration for domain controllers using the nslookup command; Add a host (A) resource record to a zone; Add a resource record to a zone |

| | |
|---|---|
| Verify dynamic update and service (SRV) resource record.<br><br>Verify that the authoritative DNS zone for the domain controller locator (Locator) DNS resource records allows dynamic updates and that the DNS server hosting the zone supports the DNS service (SRV) resource record. To locate the authoritative DNS zone, you will need to locate the primary DNS server hosting that zone.<br><br>If the authoritative DNS zone is not configured to allow dynamic updates, configure the zone to allow dynamic updates.<br><br>**Notes**<br><br>• The authoritative DNS zone for the Locator DNS resource records will have the DNS name of the Active Directory domain or the name of a parent zone. For example, if the DNS name of the Active Directory domain is example.microsoft.com., then the authoritative DNS zone could be one of the following:<br>  • example.microsoft.com<br>  • microsoft.com<br>  • com<br><br>• If you have configured DNS to not dynamically register these resource records in DNS, then these resource records must be added manually. The list of resource records that should be registered by a domain controller are stored in the following location:<br><br>systemroot\System32\Config\Netlogon.dns | Allow dynamic updates |

**Note**

- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Concepts**
Checklist: Installing a DNS server

# Checklist: Securing your DNS infrastructure

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Securing your DNS infrastructure**

| Step | Reference |
|---|---|
| To prevent anyone outside of your company from obtaining internal network information, use separate DNS servers for internal and Internet name resolution. Your internal DNS namespace should be hosted on DNS servers behind the firewall for your network. Your external, Internet DNS presence should be managed by a DNS server in a perimeter network (also known as DMZ, demilitarized zone, or screened subnet). To provide Internet name resolution for internal hosts, you can have your internal DNS servers use a forwarder to send external queries to your external DNS server. | Using forwarders; "Windows Server 2003 DNS" at the Microsoft Windows Resource Kits Web site |
| To prevent anyone outside of your company from obtaining information about your internal DNS namespace, configure your external router and firewall to only allow DNS traffic between your internal and external DNS servers.<br><br>For the DNS servers in your network that are exposed to the Internet, restrict DNS zone transfers to either DNS servers identified in the zone by name server (NS) resource records or to specific DNS servers in your network.<br><br>**Note**<br><br>• If you are using Microsoft Internet Security and Acceleration (ISA) Server, then you may use block filters to define the traffic allowed through the ISA Server. | Modify zone transfer settings; Microsoft Internet Security and Acceleration (ISA) Server Web site |
| If the server running the DNS Server service is a multihomed computer, then restrict the DNS Server service to only listen on the interface IP address used by its DNS clients and internal servers. For example, a server acting as proxy server may have two network interface cards, one for the intranet and one for the Internet. If that server is also running the DNS Server service, you can configure the service to only listen for DNS traffic on the IP address used by the intranet network interface card. | Restrict a DNS server to listen only on selected addresses |
| If the server running DNS Server service is a domain controller, then use Active Directory access control lists (ACLs) to secure access control of the DNS Server service. | Modify security for the DNS Server service on a domain controller; Best practices for assigning permissions on Active Directory objects; Best practices for permissions and user rights; Understanding Groups |
| Use Active Directory-integrated DNS zones. DNS zones stored in Active Directory can take advantage of Active Directory security features, such as secure dynamic update and the ability to apply Active Directory security settings to DNS servers, zones, and resource records. | Change the zone type; Active Directory integration; Allow only secure dynamic updates; Modify security for a directory-integrated zone; Modify security for a resource record |
| If a DNS zone is not stored in Active Directory, then secure the DNS zone file by modifying permissions on the DNS zone file or on the folder where the zone files are stored. The zone file or folder permissions should be configured to only allow Full Control to the System group. By default, zone files are stored in the systemroot\System32\Dns folder. | Set, view, change, or remove permissions on files and folders |
| Secure the DNS registry keys. The DNS registry keys can be found in the following registry location:<br><br>HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\ | Add users or groups to the Permissions list |

| | |
|---|---|
| Disable recursion on DNS servers that do not respond to DNS clients directly and are not configured with forwarders. A DNS server only requires recursion if it responds to recursive queries from DNS clients or is configured with a forwarder. DNS servers use iterative queries to communicate with each other. | Disable recursion on the DNS server |
| Secure the caches of all DNS servers against names pollution. | Secure server cache against names pollution |
| If you have a private internal DNS namespace, then configure the root hints on your internal DNS servers to only point to the DNS servers hosting your internal root domain and not the DNS servers hosting the Internet root domain. | Update root hints on the DNS server; Updating root hints |

# New ways to do familiar DNS tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar tasks**

The following table lists common tasks for configuring Domain Name System (DNS). The user interface for performing these tasks is different in this version of Windows from the way it was in Microsoft® Windows® NT version 4.0.

**Note**

- There are no significant user interface differences between Windows 2000, Windows XP, and the Windows Server 2003 family for this component.

| If you want to | In Windows NT 4.0 use | In this version of Windows use |
|---|---|---|
| Install a DNS server on this computer | **Network** in Control Panel | Open Windows Components wizard.<br><br>For more information, see Install a DNS server. |
| Start DNS Manager | **Start** menu shortcut to **DNS Manager**, listed in **Administrative Tools** | Open the DNS console.<br><br>For more information, see Open the DNS console. |
| Start or stop a DNS server | **Services** in Control Panel | Use the DNS console to start or stop a DNS server.<br><br>For more information, see Start or stop a DNS server. |

# DNS best practices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices**

- **Enter the correct e-mail address of the responsible person for each zone you add to or manage on a DNS server.**

  This field is used by applications to notify DNS administrators for a variety of reasons. For example, query errors, incorrect data returned in a query, and security problems are a few ways in which this field can be used. While most Internet e-mail addresses contain the at sign (**@**) when used in e-mail applications, this symbol must be replaced with a period (**.**) when entering an e-mail address for this field. For example, instead of "administrator@microsoft.com", you would use "administrator.microsoft.com".

  For more information on configuring the responsible person for a zone, see Modify the start of authority (SOA) record for a zone.

- **Be conservative in adding alias records to zones.**

  Avoid using CNAME resource records (RRs) where they are not needed to alias a host name used in a host (A) resource record. Also, ensure that any alias names you use are not used in other RRs.

  DNS allows an owner name of a CNAME resource record to be used as the owner name of the other types of resource records, such as NS, MX, and TXT resource records.

  For more information, see Managing resource records.

- **When designing your DNS network use standard guidelines and, wherever possible, follow preferred practices for managing your DNS infrastructure.**

  DNS was designed to provide a level of fault tolerance for resolving names. If possible, you should have at least two name servers hosting each zone.

- **If you are using Active Directory, use directory-integrated storage for your DNS zones for increased security, fault tolerance, simplified deployment and management.**

  By integrating zones, you can simplify network planning. For example, domain controllers for each of your Active Directory domains correspond in a direct one-to-one mapping to DNS servers. This can simplify planning and troubleshooting DNS and Active Directory replication problems because the same server computers are used in both topologies.

  If you are using directory-integrated storage for your zones, you may select from the different replication scopes that replicate your DNS zone data throughout the directory. If your DNS infrastructure must support Windows 2000 DNS servers, you will use the directory-integrated storage method that replicates DNS zone data to all domain controllers in a domain. If your DNS infrastructure is composed of DNS servers running Windows Server 2003 only, you may also select from replication scopes that replicate your DNS zone data to all DNS servers in the Active Directory forest, all DNS servers in a specified Active Directory domain, or all domain controllers specified in a custom replication scope.

  For more information on directory-integrated DNS zone storage and replication options, see DNS zone replication in Active Directory.

  Any DNS server hosting a directory-integrated zone is a primary DNS server for that zone. This enables a multimaster model where multiple DNS servers may update the same zone data. A multimaster model eliminates a single point of failure associated with a conventional single-master DNS topology, where updates may only be done to a single DNS server for a given zone.

One of the important benefits of directory integration is the support for secure dynamic update of the names within a zone. For more information, see Dynamic update.

- **Consider the use of secondary zones to assist in off-loading DNS query traffic wherever it makes sense.**

  Secondary servers can be used as backups for DNS clients. This allows you to use secondary servers as a means to load balance DNS query traffic on your network and reserve your DNS-enabled primary servers for use only by those clients that need them to perform dynamic registration and updates of their A and PTR RRs.

  For more information about the use of secondary or caching-only servers, see Using secondary servers and Using caching-only servers.

- **If you are planning a large DNS design, such as for a large Internet service provider (ISP) that supports the use of DNS, review the following Request for Comments (RFC) documents published by the Internet Engineering Task Force (IETF).**

| RFC | Title |
|---|---|
| 1912 | Common DNS Operational and Configuration Errors |
| 2182 | Selection and Operation of Secondary DNS Servers |
| 2219 | Use of DNS Aliases for Network Services |

You can obtain these RFCs from the RFC Editor Web site. This Web site is currently maintained by members of the Information Sciences Institute (ISI) who publish a classified listing of all RFCs. RFCs are classified as one of the following: approved Internet standards, proposed Internet standards (circulated in draft form for review), Internet best practices, or For Your Information (FYI) documents.

To see the most current RFCs related to actively defining the DNS standard, see DNS Extension (dsnext) at the Internet Engineering Task Force Web site, which discusses dynamic update, notify, zone transfers, security, and adjustments to address the requirements of IPv6 addressing. Also, see DNS operations (dnsop) at the Internet Engineering Task Force Web site, which provides guidelines for the implementation of DNS by administrators of DNS domains.

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# DNS How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

- Install and Configure Servers
- Install and Configure Clients
- Manage Servers
- Optimize Servers
- Monitor Servers
- Add and Remove Zones
- Configure Zone Properties
- Manage Zones
- Manage Resource Records
- Use Aging and Scavenging

# Install and Configure Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Install and configure servers**

- Install a DNS server
- Configure a DNS server for use with Active Directory
- Verify DNS registration for domain controllers using the nslookup command
- Configure a new DNS server
- Modify security for the DNS Server service on a domain controller
- Add a secondary server for an existing zone
- Install a caching-only DNS server
- Restrict a DNS server to listen only on selected addresses
- Configure a DNS server to use forwarders
- Create the default DNS application directory partitions
- Create a DNS application directory partition
- Enlist a DNS server in a DNS application directory partition
- Remove a DNS server from a DNS application directory partition

# Install a DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install a DNS server**

1. Open Windows Components Wizard.
2. In **Components**, select the **Networking Services** check box, and then click **Details**.
3. In **Subcomponents of Networking Services**, select the **Domain Name System (DNS)** check box, click **OK**, and then click **Next**.
4. If prompted, in **Copy files from**, type the full path to the distribution files, and then click **OK**.

   Required files are copied to your hard disk.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open the Windows Components Wizard, click **Start**, click **Control Panel**, double-click **Add or Remove programs**, and then click **Add/Remove Windows Components**.
- Certain Windows components require configuration before they can be used. If you installed one or more of these components but did not configure them, when you click **Add/Remove Windows Components**, a list of components that need to be configured is displayed. To start the Windows Components Wizard, click **Components**.
- It is recommended that you manually configure the computer to use a static IP address. If the DNS server is configured to use DHCP-assigned dynamic addresses, when the DHCP server assigns a new IP address to the DNS server, the DNS clients configured to use that DNS server's previous IP address will be unable to resolve the previous IP address and locate the DNS server.
- After you install a DNS server, you can decide how to administer it and its zones. Although you can use a text editor to make changes to server boot and zone files, this method is not recommended. The DNS console and the DNS command-line tool, dnscmd, simplify maintenance of these files and should be used whenever possible. Once you begin using console-based or command-line management of these files, manually editing them is not recommended. For more information, see Related Topics.
- DNS zones stored in Active Directory can be administered using the DNS console or the dnscmd command-line tool only. These zones cannot be administered using a text editor.
- If you uninstall a DNS server hosting Active Directory-integrated zones, these zones will be saved or deleted according to their storage type. For all storage types, the zone data is stored on other domain controllers or DNS servers and will not be deleted unless the DNS server that you uninstall in the last DNS server hosting that zone.
- If you uninstall a DNS server hosting standard DNS zones, the zone files will remain in the systemroot\system32\Dns directory, but they will not be reloaded if the DNS server is reinstalled. If you create a new zone with the same name as an old zone, the old zone file is replaced with the new zone file.
- When writing DNS server boot and zone data to text files, DNS servers use the Berkeley Internet Name Domain (BIND) file format recognized by legacy BIND 4 servers, not the more recent BIND 8 format.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure a DNS server for use with Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a DNS server for use with Active Directory**

- When Active Directory is installed using the Active Directory Installation Wizard, the option to automatically install and configure a local DNS server for use is provided.

  To install Active Directory on this computer, use the Active Directory Installation Wizard. For more information, see Related Topics.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- This procedure only applies to server computers used as domain controllers. If member servers are used as DNS servers, they are not integrated with Active Directory.

- If you choose the Active Directory Installation Wizard option to automatically install and configure a local DNS server, the DNS server is installed on the computer where you are running the wizard and the computer's preferred DNS server setting is configured to use the new local DNS server. You will also want to configure any other computers that will join this domain to use this DNS server's IP address as their preferred DNS server.

- For more information about setting up DNS for Active Directory, see Using the Windows Deployment and Resource Kits.

- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Verify DNS registration for domain controllers using the nslookup command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To verify DNS registration for domain controllers using the nslookup command**

1. Open Command Prompt.

2. Type:

   **nslookup**

3. After the previous command completes, at the nslookup (">") prompt type:

   **set q=***rr_type*

4. After the previous command completes, type:

   **_ldap._tcp.dc._msdcs.***Active_Directory_domain_name*

5. Review the output of the previous SRV query and determine if further action is needed based on whether the previous query succeeded or failed:

   - If the query succeeded, review the registered SRV RRs returned in the query to determine if all domain controllers for your Active Directory domain are included and registered using valid IP addresses.

   - If the query failed, continue troubleshooting dynamic update or DNS server related issues to determine the exact cause of the problem.

| Value | Description |
|---|---|
| **nslookup** | The name of the command-line program. |
| **_ldap._tcp.dc._msdcs.** *Active_Directory_domain_name* | The DNS name configured for use with your Active Directory domain and any of its associated domain controllers.<br><br>For example, if the DNS domain name of your Active Directory domain is example.microsoft.com, type:<br><br>**_ldap._tcp.dc._msdcs.example.microsoft.com**. |
| **set q=** | The command to send the query to the root server. |
| *rr_type* | The resource record (RR) type to apply as a filter for subsequent lookups.<br><br>For example, in this instance, because you want to limit subsequent name queries to filter and return only service location (SRV) RRs that use a specified name, type:<br><br>**set q=srv** |

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command**

**prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **nslookup**, press **Enter** and then type **help**

- In some cases, when performing the above procedure, you might see several time-outs reported. This happens when reverse lookup is not configured for DNS servers servicing the same DNS domain as your Active Directory domain.

- The following is an example of command-line output for an Nslookup session, used to verify service location (SRV) resource records that are registered by domain controllers. In this example, the two domain controllers are dc1 and dc2 and are registered for the "example.microsoft.com" domain.

```
C:\nslookup
Default Server:  dc1.example.microsoft.com
Address:  10.0.0.14
 set type=srv
 _ldap._tcp.dc._msdcs.example.microsoft.com
Server:  dc1.example.microsoft.com
Address:  10.0.0.14
_ldap._tcp.dc._msdcs.example.microsoft.com   SRV service location:
          priority       = 0
          weight         = 0
          port           = 389
          svr hostname   = dc1.example.microsoft.com
_ldap._tcp.dc._msdcs.example.microsoft.com   SRV service location:
          priority       = 0
          weight         = 0
          port           = 389
          svr hostname   = dc2.example.microsoft.com
dc1.example.microsoft.com     internet address = 10.0.0.14
dc2.example.microsoft.com     internet address = 10.0.0.15
```

- The **nslookup** command is a standard command-line tool provided in most DNS service implementations. It offers the ability to perform query testing of DNS servers and obtain detailed responses as the command output. This information is useful in troubleshooting name resolution problems, verifying that resource records (RRs) are added or updated correctly in a zone, and debugging other server-related problems.

- Verify that resource records used to register services and critical hosts, such as domain controllers, are correctly added to zones.

  In some cases, you might need to manually add or verify registration of the service location (SRV) resource records used to support Windows Server 2003 domain controllers.

  To add the SRV resource records that have been created for a domain controller, open and view the Netlogon.dns file, created by the Active Directory Installation wizard when a server computer is promoted to a domain controller. It can be found at:

  systemroot\System32\Config\Netlogon.dns

- The resource records used in this file are listed in RFC-compliant text-file format. When verifying these records, look for the following records:

  _ldap._tcp.*Active_Directory_domain_name* IN SRV 0 0 389 *ldap_server_name*
  _ldap._tcp.dc._msdcs.*Active_Directory_domain_name* IN SRV 0 0 389 *domain_controller_name*

In some cases, you might need to modify the Lightweight Directory Access Protocol (LDAP) server name if you are using a non-domain controller as an LDAP server for your network.

- The Net Logon service on each domain controller registers, as appropriate, a number of different DNS resource records with DNS servers. To learn more about these records and how Net Logon updates DNS, obtain additional technical information on DNS available from the Microsoft Web site. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure a new DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a new DNS server**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. If needed, add and connect to the applicable server in the console.
3. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*Applicable DNS server*

4. On the **Action** menu, click **Configure a DNS Server**.
5. Follow the instructions in the Configure a DNS Server Wizard.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- If the DNS server is running locally, you do not need to perform step 2.
- As a best practice, use the checklist for installing a new DNS server. For more information, see Related Topics.
- When you finish configuring the server, you might need to complete additional tasks, such as enabling dynamic updates for its zones or adding resource records to its zones.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/Config** {*ZoneName*|**..AllZones**} *Property* {**1**|**0**}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |

| | |
|---|---|
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/Config** | Specifies the configuration command. |
| {*ZoneName*\|**..AllZones**} | Specifies the name of the zone to be configured. To apply the configuration for all zones hosted by the specified DNS server, type **..AllZones**. |
| *Property* | Specifies the server property or zone property to be configured. There are different properties available for servers and zones. For a list of the available properties, at the command prompt, type: **dnscmd /Config /help**. |
| {**1**\|**0**} | Sets configuration options to either **1** (on) or **0** (off). Note that some server and zone properties must be reset as part of a more complex operation. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/Config/help**

- As a best practice, use the checklist for installing a new DNS server provided in the online Help. For more information, see Related Topics.
- When you finish configuring the server, you might need to complete additional tasks, such as enabling dynamic updates for its zones or adding resource records to its zones.

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify security for the DNS Server service on a domain controller

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify security for the DNS Server service on a domain controller**

1. Open DNS.
2. In the console tree, right-click the applicable server, and then click **Properties**.
3. On the **Security** tab, modify the list of member users or groups that are allowed to administer the applicable server.

## Notes

- To perform this procedure, you must be a member of the DnsAdmins or the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Active Directory access control lists (ACLs) are only supported for the DNS Server service when it is running on a domain controller.
- The security settings determine who can administer the server, but do not affect the ACLs for the zones and resource records hosted on the server. To apply security settings for DNS zones and resource records, see Related Topics.
- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a secondary server for an existing zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a secondary server for an existing zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*Applicable DNS server*

3. On the **Action** menu, click **New Zone**.
4. Follow the instructions in the New Zone Wizard.

   When adding the zone, select **Secondary zone** as the zone type.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- If the DNS server is running locally, you do not need to perform step 2.
- In order to add a secondary server for an existing zone, you need to have network access to the server acting as the master server for this server and its use of the zone. The master server acts as the source for zone data. It is contacted periodically to assist in renewing the zone and to transfer zone updates whenever they are needed.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName* **/ZoneAdd** *ZoneName* **/Secondary** *MasterIPaddress*...[**/file** *FileName*]

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |

| | |
|---|---|
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/ZoneAdd** | Required. Adds a zone. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the secondary zone you are adding. The zone name must be the same as the primary zone from which the secondary zone is created. |
| **/Secondary** | Required. Adds a secondary zone type. |
| *MasterIPaddress...* | Required. Specifies one or more IP addresses for the master servers of the secondary zone, from which it copies zone data. |
| **/file** | Specifies the command to use a file. |
| *FileName* | Specifies the name of the file to use for creating the secondary zone. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/ZoneAdd /help**

- To add a secondary server for an existing zone, you need to have network access to the server acting as the master server for this server and its use of the zone. The master server acts as the source for zone data. It is contacted periodically to assist in renewing the zone and to transfer zone updates whenever they are needed.

**Formatting legend**

| Format | Meaning |

# Install a caching-only DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install a caching-only DNS server**

1. To install a caching-only DNS server, install a DNS server on the server computer.
2. Do not configure the DNS server (as you might normally) to load any zones.
3. Verify server root hints are configured or updated correctly.

   For more information, see Related Topics.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- Caching-only DNS servers do not host any zones and are not authoritative for a particular domain. They are DNS servers that build a local server cache of names learned while performing recursive queries on behalf of their clients. This information is then available from its cache when answering subsequent client queries.
- A caching-only DNS server can be valuable at a site where DNS functionality is needed locally but it is not administratively desirable to create a separate domain or zone for that location.
- It is strongly recommended that, when operating the computer as a DNS server, you manually configure TCP/IP and use a static IP address.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Restrict a DNS server to listen only on selected addresses

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restrict a DNS server to listen only on selected addresses**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. On the **Interfaces** tab, click **Only the following IP addresses**.
5. In **IP address**, type an IP address for the DNS server to be enabled for use, and then click **Add**.
6. As needed, repeat the previous step to specify other server IP addresses to be enabled for use by this DNS server.

   If you need to remove an IP address from the list, click it and then click **Remove**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, the DNS Server service listens for DNS message communications on all configured IP addresses for the server computer.
- Server IP addresses that are added here need to be statically managed. If later you change or remove addresses specified here from TCP/IP configurations maintained at this server, update this list accordingly.
- After you update or revise the list of restricted interfaces, you need to stop and restart the DNS server to apply the new list.
- Restricting the DNS Server service to only listen on specific IP addresses is an effective security measure because only hosts on the same network subnet, or hosts with a router that connects them to that same segment, will have access to the server.

**Using a command line**

1. Open Command Prompt.

2. Type:

   **dnscmd** *ServerName* **/ResetListenAddresses** [*ListenAddress* ...]

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/ResetListenAddresses** | Required. Resets the IP addresses of the interfaces on which the DNS server listens. |
| *ListenAddress...* | Specifies one or more IP addresses for the interfaces on which you want the DNS server to listen. By default, the DNS Server service listens for DNS message communications on all configured IP addresses for the server computer. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd** *ServerName* **/ResetListenAddresses /help**

- Server IP addresses that are added here need to be statically managed. If later you change or remove addresses specified here from TCP/IP configurations maintained at this server, update this list accordingly.

- After you update or revise the list of restricted interfaces, you need to stop and restart the DNS server to apply the new list.

- Restricting the DNS Server service to only listen on specific IP addresses is an effective security measure because only hosts on the same network subnet, or hosts with a router that connects them to that same segment, will have access to the server.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |

| | |
|---|---|
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure a DNS server to use forwarders

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a DNS server to use forwarders**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open the DNS snap-in.
2. In the console tree, click the applicable Domain Name System (DNS) server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. On the **Forwarders** tab, click **Edit**.
5. Type the IP address for the fully qualified domain name (FQDN) of a forwarder, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, the DNS server will wait 5 seconds for a response from one forwarder IP address before trying another forwarder IP address. In **Number of seconds before forward queries time out**, you can change the number of seconds the DNS server will wait. When the server has exhausted all forwarders, it will attempt standard recursion.
- If you want the DNS server to only use forwarders and not attempt any further recursion if the forwarders fail, select the **Do not use recursion for this domain** check box.

  You can disable recursion for the DNS server so that it will not perform recursion on any query. If you disable recursion on the DNS server, you will not be able to use forwarders on the same server. For more information about disabling recursion on the DNS server, see Related Links.

- Do not enter a forwarder's IP address more than once in a DNS server's forwarders list because it is a more reliable or geographically closer server. If one of the forwarders is preferred, that forwarder should be ordered first in the series of forwarder IP addresses.
- Problems associated with forwarders often result from inefficient configurations and overuse.

**Using a command line**

1. Open Command Prompt.

2. Type:

   **dnscmd***ServerName***/ZoneAdd***ZoneName***/Forwarder***MasterIPaddress* ... [**/TimeOut** *Time*] [**/Slave**]

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/ZoneAdd** | Required. Adds a zone. |
| *ZoneName* | Required. Specifies the FQDN of the zone. |
| **/Forwarder** | Required. Specifies the command to configure a forwarder. When configuring forwarders on DNS servers running on Active Directory domain controllers, you must use **/DsForwarder** in place of **/Forwarder**. **/DsForwarder** will replicate the forwarder setting to all DNS servers running on domain controllers in an Active Directory domain. |
| *MasterIPaddress*... | Required. Specifies a space-separated list of one or more IP addresses of the DNS servers where queries for *ZoneName* are forwarded. You may specify a list of space-separated IP addresses. |
| **/TimeOut** | Specifies the timeout setting. The timeout setting is the number of seconds before unsuccessful forward queries time out. |
| *Time* | Specifies the value for the **/TimeOut** parameter. The value is in seconds. The default timeout is 5 seconds. |
| **/Slave** | Determines whether or not the DNS server uses recursion when querying for the domain name specified by *ZoneName*. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Links.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/ZoneAdd/help**

- To view a zone added for use as only a conditional forwarder, use the following command:

  **dnscmd***ServerName***/ZoneInfo***ZoneName*

- To reset the forwarder IP addresses for a conditional forwarder domain name, type:

  **dnscmd***ServerName***/ZoneResetMasters***ZoneName* [**/Local**] [*ServerIPs*]

  The **/Local** parameter sets the local master list for Active Directory–integrated forwarders, and the *ServerIPs* parameter is the list of one or more IP addresses of master servers for the zone. Master servers may include DNS servers that host primary or secondary copies of the zone, but they should not include DNS server IP addresses in such a way that two

DNS servers hosting copies of a zone use each other as master servers. Such a configuration would make the forwardering path cyclical.

- To reset the standard, nonconditional forwarder for a DNS server, type:

  **dnscmd***ServerName***/ResetForwarders** [*IPAddress* ...] [ **/**[**No**]**Slave** ] [**/TimeOut** *Time*]

  The parameter *IPAddress* is the IP address where the DNS server will forward unsolvable DNS queries. The **/Slave** parameter sets the DNS server as a subordinate server. The **/NoSlave** parameter (default setting) sets the DNS server as a nonsubordinate server, meaning that it will perform recursion. The **/Timeout** and *Time* parameters are described in the table above.

- You cannot use a domain name in a conditional forwarder if the DNS server hosts a primary, secondary, or stub zone for that domain name. For example, if a DNS server is authoritative for the domain name *example.microsoft.com* (hosts the primary zone for that domain name), you cannot configure that DNS server with a conditional forwarder for *example.microsoft.com*.

- Problems associated with forwarders often result from inefficient configurations and overuse.

**Formatting legend**

| Format | Meaning |
|---|---|

# Create the default DNS application directory partitions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create the default DNS application directory partitions**

Using the Windows interface

Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server.
   - **Where?**
   - **DNS**/*applicable DNS server*
3. Click **Create Default Application Directory Partitions**.
4. Follow the instructions to create the DNS application directory partitions.

**Notes**

- By default, only members of the Enterprise Admins group can create a DNS application directory partition.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, the DNS Server service will attempt to locate and create the default DNS application directory partitions in Active Directory. If the DNS Server service is unable to do this, the administrator can manually create the application directory partitions using this procedure.
- If the default DNS application directory partitions are currently available in Active Directory, the option to create the default application directory partitions in the DNS console will not be available.
- The following table describes the options available when creating the DNS default application directory partitions.

| Option | Partition name | Description |
|---|---|---|
| Create a single application directory partition that stores DNS zone data and replicates that data to all DNS servers in the domain | DomainDnsZones.*DnsDomainName* | DNS application directory partition for each domain in the forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the domain. |
| Create a single application directory partition that stores DNS zone data and replicates that data to all DNS servers in the forest | ForestDnsZones.*DnsForestName* | DNS application directory partition for the entire forest. It contains all the DNS servers running on the domain controllers in the forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the forest. |

**Notes**

- By default, the Net Logon service registers domain controller locator (Locator) DNS resource records for any application directory partitions hosted on a domain controller in the same manner as it registers domain controller locator (Locator) DNS resource records for any domain hosted on a domain controller. Once the default DNS application directory partitions are created, Net Logon will register domain controller locator (Locator) DNS resource records on behalf of the domain controller hosting the default DNS application directory partitions.

- For more information about creating and deleting an application directory partition, see Related Topics.

**Using a command line**

1. Open Command Prompt.

2. Type:

   **dnscmd** ServerName **/CreateBuiltinDirectoryPartitions** {**/Domain**|**/Forest**|**/AllDomains**}

| **Value** | **Description** |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/CreateBuiltinDirectoryPartitions** | Required. Creates a default application directory partition. |
| {**/Domain**\|**/Forest**\|**/AllDomains**} | Required. Specifies which default application directory partition to create. Do one of the following:<br><br>To create a default domain-wide DNS application directory partition for the Active Directory domain where the specified DNS server is located, type **/Domain**.<br><br>To create a default forest-wide DNS application directory partition for the Active Directory forest where the specified DNS server is located, type **/Forest**.<br><br>To create a default domain-wide DNS application directory partitions on a DNS server in each domain in the Active Directory forest where the user running this command is logged on, type **/AllDomains**.<br><br>The *ServerName* parameter is ignored for **/AllDomains**. The computer on which this command is run must be joined to a domain in the forest where you want to create all of the default domain-wide application directory partitions. |

**Notes**

- By default, only members of the Enterprise Admins group can create a DNS application directory partition.

- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

- **dnscmd /CreateDirectoryPartition /?**

- By default, the DNS Server service will attempt to locate and create the default DNS application directory partitions in Active Directory. If the DNS Server service is unable to do this, the administrator can manually create the application directory partitions using this procedure.

- If the default DNS application directory partitions are currently available in Active Directory, the option to create the default application directory partitions in the DNS console will not be available.

- The following table describes the options available when creating the DNS default application directory partitions.

| Option | Partition name | Description |
|---|---|---|
| Create a single application directory partition that stores DNS zone data and replicates that data to all DNS servers in the domain | DomainDnsZones.*DnsDomainName* | DNS application directory partition for each domain in the forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the domain. |
| Create a single application directory partition that stores DNS zone data and replicates that data to all DNS servers in the forest | ForestDnsZones.*DnsForestName* | DNS application directory partition for the entire forest. It contains all the DNS servers running on the domain controllers in the forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the forest. |

**Notes**

- By default, the Net Logon service registers domain controller locator (Locator) DNS resource records for any application directory partitions hosted on a domain controller in the same manner as it registers domain controller locator (Locator) DNS resource records for any domain hosted on a domain controller. Once the default DNS application directory partitions are created, Net Logon will register domain controller locator (Locator) DNS resource records on behalf of the domain hosting the default DNS application directory partitions.

- For more information about creating and deleting an application directory partition, see Related Topics.

**Formatting legend**

# Enlist a DNS server in a DNS application directory partition

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enlist a DNS server in a DNS application directory partition**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/EnlistDirectoryPartition***FQDN*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/EnlistDirectoryPartition** | Required. Enlists a DNS server in a DNS application directory partition. |
| *FQDN* | Required. Specifies the fully qualified domain name (FQDN) of the DNS application directory partition. |

**Notes**

- To perform this procedure, you must be a member of the DnsAdmins or the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /EnlistDirectoryPartition /?**
- For more information about creating and deleting an application directory partition, see Related Topics.

# Remove a DNS server from a DNS application directory partition

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove a DNS server from a DNS application directory partition**

1. Open Command Prompt.

2. Type:

   **dnscmd***ServerName***/UnenlistDirectoryPartition***FQDN*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/UnenlistDirectoryPartition** | Required. Removes a DNS server from a DNS application directory partition. |
| *FQDN* | Required. Specifies the fully qualified domain name (FQDN) of the DNS application directory partition from which you are removing the DNS server specified by *ServerName*. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /UnenlistDirectoryPartition /?**

- For more information about creating and deleting an application directory partition, see Related Topics.

**Formatting legend**

| Format | Meaning |

# Install and Configure Clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Install and configure clients**

- Configure DNS for static clients
- Enable DNS for DHCP-enabled clients
- Configure the primary DNS suffix for a client computer
- Preload the client resolver cache
- Display and view a client resolver cache using the ipconfig command
- Flush and reset a client resolver cache using the ipconfig command
- Renew DNS client registration using the ipconfig command

# Configure DNS for static clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure DNS for static clients**

- To configure DNS for clients with statically configured IP addresses, you likely need to configure the following:

  1. DNS host name (or names) for the client computer.
  2. Primary and alternate DNS servers that the client uses to assist in resolving DNS domain names.
  3. A list of DNS suffixes to be appended for use in completing unqualified DNS names, which are used for searching and submitting DNS queries at the client for resolution.
  4. Connection-specific dynamic update and registration behavior, such as whether specific network adapters installed at the client dynamically register their configured IP addresses with a DNS server.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- For more information about how to configure DNS for static clients not running Windows XP, see the applicable TCP/IP or DNS documentation provided by the appropriate vendor for these clients.
- By default, the DNS client on Windows XP does not attempt dynamic update over a Remote Access Service (RAS) or virtual private network connection. To modify this configuration, you can modify the advanced TCP/IP settings of the particular network connection or modify the registry. For more information, see Related Topics.
- By default, the DNS client does not attempt dynamic update of top-level domain (TLD) zones. Any zone named with a single-label name is considered a TLD zone, for example, com, edu, blank, my-company. To configure the DNS client to allow the dynamic update of TLD zones, you can use the **Update Top Level Domain Zones** policy setting or modify the registry.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Configure TCP/IP to use DNS

# Enable DNS for DHCP-enabled clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable DNS for DHCP-enabled clients**

- To configure DNS for clients with dynamically configured IP addresses provided by a DHCP server, you generally need to configure the following at either the DHCP server or applicable clients:

  1. **DNS host name (or names) for the client computer.**

     For DHCP clients, this must be set at the client computer or assigned during unattended setup.

  2. **Primary and alternate DNS servers that the client uses to assist in resolving DNS domain names.**

     For DHCP clients, this can be set by assigning the DNS server option (option 6) and providing a configured list of ordered IP addresses for the DNS servers that the client is configured to use.

  3. **A list of DNS suffixes to be appended for use in completing unqualified DNS names used for searching and submitting DNS queries at the client for resolution.**

     For DHCP clients, this can be set by assigning the DNS domain name option (option 15) and providing single DNS suffix for the client to append and use in searches. To configure additional DNS suffixes, configure TCP/IP manually for DNS configuration.

  4. **Connection-specific dynamic update and registration behavior, such as whether specific network adapters installed at the client dynamically register their configured IP addresses with a DNS server.**

     For DHCP clients, the default is for client connections to register their configured IP addresses with a DNS server. To modify this behavior at the client, configure TCP/IP manually for DNS configuration.

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- For more information on how to configure other DNS for DHCP clients, see the applicable TCP/IP or DNS documentation provided by the appropriate vendor.

- By default, the DNS client on Windows XP does not attempt dynamic update over a Remote Access Service (RAS) or virtual private network connection. To modify this configuration, you can modify the advanced TCP/IP settings of the particular network connection or modify the registry. For more information, see Related Topics.

- By default, the DNS client does not attempt dynamic update of top-level domain (TLD) zones. Any zone named with a single-label name is considered a TLD zone, for example, com, edu, blank, my-company. To configure the DNS client to allow the dynamic update of TLD zones, you can use the **Update Top Level Domain Zones** policy setting or modify the registry.

- For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure the primary DNS suffix for a client computer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the primary DNS suffix for a client computer**

1. Open System in Control Panel.
2. Click the **Computer Name** tab.

   This tab displays the computer name, the workgroup or domain to which it belongs, and a brief description of the computer.
3. Click **Change**, and then click **More**.
4. In **DNS Suffix and NetBIOS Computer Name**, do the following:

   For **Primary DNS suffix of this computer**, specify the DNS suffix to be appended to the name of this computer when completing its fully qualified domain name (FQDN).
5. After applying these changes, restart the computer to initialize it with its new DNS domain name.
6. If the computer has been previously installed and configured as a DNS server, verify that zone authority records are updated.

   These include the start of authority (SOA) and name server (NS) resource records, substituting the new FQDN to replace the single label name previously in use. For more information, see Related Topics.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open System, click **Start**, point to **Settings**, and then click **Control Panel**. In Control Panel, double-click **System**.
- For more information about how to configure the primary DNS suffix for other clients and servers, see the applicable TCP/IP or DNS documentation provided by the appropriate vendor for your other clients.
- By default, the primary DNS suffix portion of a computer's FQDN is the same as the name of the Active Directory domain to which the computer is joined. To allow different primary DNS suffixes, a domain administrator can create a restricted list of allowed suffixes by modifying the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is managed by the domain administrator using Active Directory Service Interfaces (ADSI) or the Lightweight Directory Access Protocol (LDAP).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Preload the client resolver cache

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To preload the client resolver cache**

1. At the client computer, open Command Prompt.

2. At the command prompt, type the following command:

   **notepad %systemroot%\system32\drivers\etc\hosts**

3. Using the default entry in the file (a mapping for the local host to the loopback IP address, 127.0.0.1), add additional host name-to-address mappings on separate lines to be preloaded into the resolver cache of the client. For example, you might add:

   10.0.0.1  host-a  host-a.example.microsoft.com

4. On the **File** menu, click **Save**, and then **Exit**.

5. As an option, you can verify that your changes have been updated in the resolver cache by viewing its contents.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To open Notepad, click **Start**, point to **All programs**, point to **Accessories**, and then click **Notepad**.

- Entries you add are always answered first from the local resolver cache and not sent to the DNS query when queries are made locally to resolve these names to host (A) resource records.

- Every line in the Hosts file should contain an IP address followed by one or more host names. For example, you could add a line such as the following with an IP address (10.0.0.1) that maps to more than one DNS host name:

  10.0.0.1  host-a  host-a.example.microsoft.com  host-b.example2.microsoft.com

  Likewise, a single DNS host name can correspond to more than one IP address if each of the addresses is mapped and used in separate lines. For example, you could add lines for the following multi-homed or multi-addressable DNS host computer:

  10.0.0.1  host-a.example.microsoft.com

  10.0.0.2  host-a.example.microsoft.com

  10.0.0.3  host-a.example.microsoft.com

- When multiple names or IP addresses are used in the file, the DNS Client service must be running for all entries to be returned or used in answering queries. If the DNS Client service is not running, only the first entry in the file is used to resolve the query.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Display and view a client resolver cache using the ipconfig command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To display and view a client resolver cache using the ipconfig command**

1. Open Command Prompt.

2. Type:

   **ipconfig /displaydns**

| Value | Description |
|---|---|
| **ipconfig** | The name of the command-line program. |
| **/displaydns** | The command to display a client resolver cache. |

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **ipconfig /help**

- To pause the display of the command output to one screen at time, type **ipconfig /displaydns|more**.

- The **ipconfig /displaydns** command provides you with a means to view the contents of the DNS client resolver cache, which includes entries preloaded from the local Hosts file, as well as any recently obtained resource records for name queries resolved by the system. This information is used by the DNS Client service to quickly resolve frequently queried names before it queries its configured DNS servers.

- When the **ipconfig /displaydns** command is used to display current resolver cache contents, the resultant output generally includes the local host and loopback IP address (127.0.0.1) mappings. This is because these mappings typically exist in the default (unmodified) contents of the local Hosts file.

- After you can add host mapping entries to the local Hosts file and save the file, these entries are added to the displayed output of this command. For more information, see Related Topics.

- The resolver cache can also support negative caching of unresolved or non-valid DNS names. These entries are added by the DNS Client service when it receives a negative answer from a DNS server for a queried name. The negative result is cached for a short period of time so that it is not again queried, which could cause query performance problems.

  During DNS troubleshooting, you can flush and reset the cache to discard negative entries from the cache and any other dynamically added entries that were not preloaded. For more information, see Related Topics.

- Although the **ipconfig** command is provided for earlier versions of Windows, the **/displaydns** option is only available for use on computers running Windows 2000, Windows XP, or Windows Server 2003 operating systems.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Flush and reset a client resolver cache using the ipconfig command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To flush and reset a client resolver cache using the ipconfig command**

1. Open Command Prompt.
2. Type:

   **ipconfig /flushdns**

| Value | Description |
|---|---|
| **ipconfig** | The name of the command-line program. |
| **/flushdns** | The command to flush and reset a client resolver cache. |

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- To view the complete syntax for this command, at a command prompt, type:

  **ipconfig /help**
- The **ipconfig /flushdns** command provides you with a means to flush and reset the contents of the DNS client resolver cache. During DNS troubleshooting, if necessary, you can use this procedure to discard negative cache entries from the cache, as well as, any other dynamically added entries.
- Resetting the cache does not eliminate entries that are preloaded from the local Hosts file. To eliminate those entries from the cache, remove them from this file. For more information, see Related Topics.
- Although the **ipconfig** command is provided for earlier versions of Windows, the **/flushdns** option is only available for use on computers running Windows 2000, Windows XP, or Windows Server 2003 operating systems.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Renew DNS client registration using the ipconfig command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To renew DNS client registration using the ipconfig command**

1. Open Command Prompt.

2. Type:

   **ipconfig /registerdns**

| Value | Description |
|---|---|
| **ipconfig** | The name of the command-line program. |
| **/registerdns** | The command to renew DNS client registration. |

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **ipconfig /help**

- An additional command to **/registerdns** is to type:

  **ipconfig /registerdns** [*adapter*]

  Where *adapter* is the name of a specific network adapter installed on the computer for which you want to renew or update registrations.

- The **ipconfig /registerdns** command provides you with a means to manually initiate dynamic registration for the DNS names and IP addresses configured at a computer. This option can assist in troubleshooting a failed DNS name registration or in resolving a dynamic update problem between a client and the DNS server without restarting the client.

- By default, the **ipconfig /registerdns** command refreshes all DHCP address leases and registers all related DNS names configured and used by the client computer.

- To learn the names of adapters that you can optionally specify with this command, first type the **ipconfig** command by itself (that is, do not specify any additional parameters). The command output displays all adapters by name that are available for use at the computer.

- Although the **ipconfig** command is provided for earlier versions of Windows, the **/registerdns** option is only available for use on computers running Windows 2000, Windows XP, or Windows Server 2003 operating systems.

- On computers running Windows 2000, Windows XP, or Windows Server 2003 operating systems, the DHCP Client service is used to perform dynamic registrations and updates, regardless of whether the computer uses a DHCP server or static configuration to obtain its IP address.

- If you are troubleshooting a failed DNS dynamic registration for a client computer and its DNS names, it might help to verify that the cause is not related to one of the following commonly known causes for such failures:

    1. The zone where the client requires update or registration is not able to accept dynamic updates.

    2. The DNS servers that the client is configured to use do not support or recognize the DNS dynamic update protocol.

    3. The primary (or directory-integrated) DNS server for the zone refused the update request. This can most likely occur because the client is not permitted under current zone or resource records security sufficient access rights to update its own name.

    4. The server or zone is not available because of other problems, such as a network or server failure.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage servers**

- Open the DNS console
- Start or stop a DNS server
- Add a server to the DNS console
- Remove a server from the DNS console
- Manually update server data files
- Change the boot method used by the DNS server
- Change the name-checking method used by the DNS server
- Restrict NS resource record registration
- Allow NS record creation for specific domain controllers
- Restrict DNS resource records updated by Netlogon

# Open the DNS console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To open the DNS console**

- Open DNS.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The DNS console is an administrative tool for managing DNS servers running Windows Server 2003 family operating systems only. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start or stop a DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start or stop a DNS server**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*Applicable DNS server*

3. On the **Action** menu, point to **All Tasks** and then click one of the following:

   - To start the service, click **Start**.
   - To stop the service, click **Stop**.
   - To interrupt the service, click **Pause**.
   - To stop and then automatically restart the service, click **Restart**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- After you pause or stop the service, on the **Action** menu, in **All Tasks**, you can click **Resume** to immediately resume service.
- When using registry-based configuration, changes are applied to DNS servers only when the DNS Server service is re-initialized. In these cases, if a DNS value is manually changed directly in the registry, the DNS Server service must always be restarted for the new value to be used.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a server to the DNS console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a server to the DNS console**

1. Open DNS.
2. On the **Action** menu, click **Connect To DNS Server**.
3. In **Connect to DNS Server**, click either:
   - **This computer**, if the server you want to connect to and manage is located on the same computer you are using to manage it.
   - **The following computer**, if the server you want to connect to and manage is located on a remote computer.

   If you choose to connect to a remote server, specify either its DNS computer name or its IP address.
4. Select the **Connect to the specified computer now** check box, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The DNS console is a Microsoft Management Console (MMC) administrative tool for managing DNS servers running Windows Server 2003 operating systems only. For more information, see Related Topics.
- If you use the Windows Server 2003 DNS console to administer a Windows 2000 DNS server, any new features will not be available when viewing the Windows 2000 DNS server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove a server from the DNS console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove a server from the DNS console**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Delete**.
4. When prompted to confirm you want to delete this server from the list, click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manually update server data files

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manually update server data files**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Update Server Data Files**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- For standard primary zones, this procedure causes the DNS server to immediately write its in-memory changes out to disk for storage with the zone file. Normally these changes are only written at predefined update intervals and when the DNS server is shut down.
- For Active Directory-integrated zones, this procedure does not apply. To update Active Directory-integrated zones, see the command-line procedure below.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **Dnscmd** *ServerName* **/ZoneUpdateFromDs** *ZoneName*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/ZoneUpdateFromDs** | Required. Updates the zone file with data from Active Directory. |

| | |
|---|---|
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone you are updating. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/ZoneUpdateFromDs/help**

- The command-line procedure updates Active Directory-integrated zones only. For standard zones, see the Windows interface procedure above.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the boot method used by the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the boot method used by the DNS server**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, then click **Properties**.
3. Click the **Advanced** tab.
4. In the **Load zone data on startup** list, select **From registry**, **From file**, or **From Active Directory and registry**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, DNS servers use information stored in the registry to initialize for service and load any zone data for use at the server. As added options, you can configure the DNS server to boot from a file or, in Active Directory environments, you can supplement local registry data with zone data retrieved for directory-integrated zones stored in the Active Directory database. If you use the file method, the file used must be a text file named Boot, located on this computer in the systemroot\Windows\System32\Dns folder.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the name-checking method used by the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the name-checking method used by the DNS server**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, then click **Properties**.
3. Click the **Advanced** tab.
4. In the **Name checking** list, select **Strict RFC (ANSI)**, **Non RFC (ANSI)**, **Multibyte (UTF8)**, or **All names**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The DNS Server service supports different possible methods for checking the names it receives and processes during normal operations:
  - **Strict RFC (ANSI)** This method strictly enforces RFC-compliant naming rules for all DNS names that the server processes. Names that are not RFC-compliant are treated as erred data by the server.
  - **Non RFC (ANSI)** This method allows names that are not RFC-compliant to be used with the DNS server, such as names that use ASCII characters but are not compliant with RFC host naming requirements.
  - **Multibyte (UTF8)** This method allows names that use the Unicode 8-bit translation encoding scheme, which is a proposed RFC draft, to be used with the DNS server.

    By default, the server uses **Multibyte (UTF8)** to check names.
  - **All names** Allows **Non RFC (ANSI)**, **Strict RFC (ANSI)**, and **Multibyte (UTF8)** naming conventions.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Restrict NS resource record registration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restrict NS resource record registration**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Registry Editor.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

2. In Registry Editor, navigate to the following registry key:

   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Parameters

3. Add the following REG_DWORD value:

   **DisableNSRecordsAutoCreation**

4. Assign a value of **0x1**.

   The REG_DWORD value is a local DNS server setting and applies to DNS zones for which this DNS server is authoritative.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Registry Editor, click **Start**, click **Run**, type **regedit**, and then click **OK**.
- This procedure restricts NS resource records registered for Active Directory domain controllers only.
- To configure the DNS server to automatically add NS resource records corresponding to itself when loading a zone, you may assign a value of **0x0** or enter no value (default setting). This setting has the same effect as not creating the **DisableNSRecordsAutoCreation** registry entry.
- If you have configured the registry to restrict the DNS server from registering NS resource records for authoritative zones, any existing NS resource records for the authoritative zones located on the DNS server are automatically deleted.
- Regardless of the settings of these registry entries, query responses sent to DNS clients from the authoritative DNS server will indicate that the responses are from an authoritative DNS server.
- The registry key entry described here does not exist by default and must be created and configured according to this procedure.

**Using a command line**

1. Open Command Prompt.

   **Caution**

   - In this procedure you will be editing the registry. Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

2. Type:

   **dnscmd***ServerName***/Config/DisableNSRecordsAutoCreation 0x1**

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/Config** | Specifies the configuration command. |
| **/DisableNSRecordsAutoCreation** | Determines the local DNS server configuration for registering NS resource records for authoritative zones. |
| **0x1** | Specifies that the DNS server specified in *ServerName* should not add NS resource records for authoritative zones.<br><br>To specify that the DNS server should add NS resource records for all its authoritative zones, type a value of **0x0**. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- This procedure restricts NS resource records registered for Active Directory domain controllers only.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /config /?**

- The DWORD value is a local DNS server setting and applies to authoritative DNS zones hosted on this DNS server.

- Regardless of the settings above, query responses sent to DNS clients from authoritative DNS servers and selected domain controllers will indicate that the responses are from authoritative DNS servers.

- To configure the DNS server to automatically add NS resource records corresponding to itself when loading a zone, you may assign a value of **0x0** or enter no value (default setting). This setting has the same effect as not creating the **DisableNSRecordsAutoCreation** registry entry.

- If you have configured the registry to restrict the DNS server from registering NS resource records for authoritative zones, any existing NS resource records for the authoritative zones located on the DNS server are automatically deleted.

- Regardless of a NS resource record registration setting, query responses sent to DNS clients from the authoritative DNS server will indicate that the responses are authoritative.

- The registry key entries described here do not exist by default and must be created and configured using this procedure.

**Formatting legend**

| **Format** | **Meaning** |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Allow NS record creation for specific domain controllers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To allow NS resource record creation for specific domain controllers**

1. Open Command Prompt.

   **Important**

   - This procedure applies to domain controller name server (NS) resource records in Active Directory-integrated DNS zones that are hosted on DNS servers configured to not add these resource records for their authoritative zones. For more information, see Related Topics.

2. Type:

   **dnscmd***ServerName* **/Config** *ZoneName* **/AllowNSRecordsAutoCreation** *IpAddresses...*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/Config** | Required. Specifies the configuration command. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| **/AllowNSRecordsAutoCreation** | Required. Specifies that domain controllers entered for *Value* will add their names to NS resource records for the zone specified in *ZoneName*. NS resource records that were previously registered for this zone are not affected. Therefore, you must remove them manually if you do not want them. |
| *IpAddresses...* | Required. Specifies the IP addresses of the domain controllers that will add their names in NS resource records for the zone specified in *ZoneName*. Type a space-separated list of the IP addresses of the DNS servers. For example, 10.0.0.0 172.16.0.0 192.168.0.0. |

**Additional considerations**

- To perform this procedure, you must be a member of the DnsAdmins or the Domain Admins group in Active Directory. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /Config /?**

- If any domain controllers in the specified zone are not listed for *IpAddresses...*, their names will be deleted from the NS resource records for the zone specified in *ZoneName*.

  To specify that all domain controllers are allowed to add their names to NS resource records for the zone, or to clear the list of allowed DNS server IP addresses, type the command and omit *IpAddresses...*:

  **dnscmd***ServerName***/Config***ZoneName***/AllowNSRecordsAutoCreation**

- Regardless of the settings above, query responses sent to DNS clients from authoritative DNS servers and selected domain controllers will indicate that the responses are from authoritative DNS servers.

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Restrict NS resource record registration

# Restrict DNS resource records updated by Netlogon

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restrict the DNS resource records updated by the Net Logon service**

1. Open Registry Editor.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

2. In Registry Editor, navigate to the following registry key:

   **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters**

3. Add the following multi-string value (REG_MULTI_SZ) value:

   **DnsAvoidRegisterRecords**

4. In this value, specify the list of data corresponding to the DNS resource records that *should not* be registered for this domain controller by the Net Logon service. The list of data include:

| Data Value | Resource Record Type | DNS Resource Record |
|---|---|---|
| LdapIpAddress | A | <*DnsDomainName*> |
| Ldap | SRV | _ldap._tcp.<*DnsDomainName*> |
| LdapAtSite | SRV | _ldap._tcp.<*SiteName*>._sites.<*DnsDomainName*> |
| Pdc | SRV | _ldap._tcp.pdc._msdcs.<*DnsDomainName*> |
| Gc | SRV | _ldap._tcp.gc._msdcs.<*DnsForestName*> |
| GcAtSite | SRV | _ldap._tcp.<*SiteName*>._sites.gc._msdcs.<*DnsForestName*> |
| DcByGuid | SRV | _ldap._tcp.<*DomainGuid*>.domains._msdcs.<*DnsForestName*> |
| GcIpAddress | A | gc._msdcs.<*DnsForestName*> |
| DsaCname | CNAME | <*DsaGuid*>._msdcs.<*DnsForestName*> |
| Kdc | SRV | _kerberos._tcp.dc._msdcs.<*DnsDomainName*> |
| KdcAtSite | SRV | _kerberos._tcp.<*SiteName*>._sites.dc._msdcs.<*DnsDomainName*> |
| Dc | SRV | _ldap._tcp.dc._msdcs.<*DnsDomainName*> |
| DcAtSite | SRV | _ldap._tcp.<*SiteName*>._sites.dc._msdcs.<*DnsDomainName*> |
| Rfc1510Kdc | SRV | _kerberos._tcp.<*DnsDomainName*> |
| Rfc1510KdcAtSite | SRV | _kerberos._tcp.<*SiteName*>._sites.<*DnsDomainName*> |
| GenericGc | SRV | _gc._tcp.<*DnsForestName*> |

| | | |
|---|---|---|
| GenericGcAtSite | SRV | _gc._tcp.<*SiteName*>._sites.<*DnsForestName*> |
| Rfc1510UdpKdc | SRV | _kerberos._udp.<*DnsDomainName*> |
| Rfc1510Kpwd | SRV | _kpasswd._tcp.<*DnsDomainName*> |
| Rfc1510UdpKpwd | SRV | _kpasswd._udp.<*DnsDomainName*> |

**Important**

- This procedure restricts DNS resource records registered by the Net Logon service for Active Directory domain controllers only.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Registry Editor, click **Start**, click **Run**, type **regedit**, and then click **OK**.

- Restart of the Net Logon service is *not* required to make the changes to this value effective. If the **DnsAvoidRegisterRecords** registry key is created or modified while the Net Logon service is stopped or within the first 15 minutes after it is started, then appropriate DNS updates may take place with a short delay; however, the delay is no later than 15 minutes after the Net Logon service starts.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Optimize Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Optimize servers**

- Enable or disable fast transfer format during zone transfers
- Prevent loading of a zone when bad data is found
- Disable round-robin rotation for multihomed names
- Disable local subnet prioritization for multihomed names
- Restore server default preferences
- Disable recursion on the DNS server
- Update root hints on the DNS server
- Secure server cache against names pollution
- Clear the server names cache
- Modify DNSSEC configuration
- Modify EDNS0 configuration
- Modify UDP message size

# Enable or disable fast transfer format during zone transfers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable fast transfer format during zone transfers**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

You can enable or disable fast transfer format during zone transfers using the Windows interface.

### To enable or disable fast transfer format during zone transfers using the Windows interface

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. Do one of the following:
   - To enable the fast transfer format (the default), in the **Server options** list, clear the **BIND secondaries** check box, and then click **OK**.
   - To disable the fast transfer format, in the **Server options** list, select the **BIND secondaries** check box, and then click **OK**.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The fast transfer format optimizes zone transfers between Windows-based DNS servers and other DNS server implementations, and it is enabled by default. Zone transfers between Windows-based DNS servers always use the fast transfer format.
- DNS servers running versions of the Berkeley Internet Name Domain (BIND) server implementation prior to version 4.9.4 do not support the fast transfer format. You should enable the **Bind secondaries** option if you are transferring zones to BIND servers running versions earlier than 4.9.4.

**Using a command line**

You can enable or disable fast transfer format during zone transfers using a command line.

### The procedure title

1. Open Command Prompt.

2. Type:

   **dnscmd** *ServerName* **/Config /BindSecondaries** {**1**|**0**}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/Config** | Specifies the configuration command. |
| **/BindSecondaries** | Specifies use of fast transfer format used by legacy Berkeley Internet Name Domain (BIND) servers. |
| {**1**\|**0**} | To disable fast transfer format when transferring a zone to legacy BIND DNS servers, type **1** (on). To enable fast transfer format, type **0** (off). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd***ServerName***/Config/help**

- The fast transfer format optimizes zone transfers between Windows-based DNS servers and other DNS server implementations, and it is enabled by default. Zone transfers between Windows-based DNS servers always use the fast transfer format.

- DNS servers running versions of the BIND server implementation earlier than version 4.9.4 do not support the fast transfer format. You should set **BindSecondaries** to 1 if you are transferring zones to BIND servers running versions earlier than 4.9.4.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

# Prevent loading of a zone when bad data is found

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To prevent loading of a zone when bad data is found**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. In **Server options**, select the **Fail on load if bad zone data** check box, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disable round-robin rotation for multihomed names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable round-robin rotation for multihomed names**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. In **Server options**, clear the **Enable round robin** check box, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure..
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/Config/RoundRobin** {**1**|**0**}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/Config** | Specifies the configuration command. |
| **/RoundRobin** | Configures round robin rotation. |

| | |
|---|---|
| {**1**\|**0**} | To enable round robin, type **1** (on). To disable round robin, type **0** (off). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

# Disable local subnet prioritization for multihomed names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable local subnet prioritization for multihomed names**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. In **Server options**, clear the **Enable netmask ordering** check box, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/Config/LocalNetPriority** {**1**|**0**}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/Config** | Specifies the configuration command. |
| **/LocalNetPriority** | Configures netmask ordering. |

| | |
|---|---|
| {**1**\|**0**} | To enable netmask ordering, type **1** (on). To disable netmask ordering, type **0** (off). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

# Restore server default preferences

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restore server default preferences**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, and then click **Properties**.
3. Click the **Advanced** tab.
4. Click **Reset to Default**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Clicking **Reset to Default** configures the DNS server with the initial configuration it had following installation. These setting are displayed in the table below.

| Property | Setting |
|---|---|
| Disable recursion | Off |
| BIND secondaries | On |
| Fail on load if bad zone data | Off |
| Enable round robin | On |
| Enable netmask ordering | On |
| Secure cache against pollution | On |
| Name checking | Multibyte (UTF8) |
| Load zone data on startup | From Active Directory and registry |
| Enable automatic scavenging of stale records | Off |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disable recursion on the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable recursion on the DNS server**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, then click **Properties**.
3. Click the **Advanced** tab.
4. In **Server options**, select the **Disable recursion** check box, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- If you disable recursion on the DNS server, you will not be able to use forwarders on the same server.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/Config/NoRecursion** {**1**|**0**}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/Config** | Required. Specifies the configuration command. |
| **/NoRecursion** | Required. Specifies the command to disable recursion. |
| {**1**\|**0**} | Required. To disable recursion, type **1** (off). To enable recursion, type **0** (on). By default, recursion is enabled. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/Config/help**

- If you disable recursion on the DNS server, you will not be able to use forwarders on the same server.

**Formatting legend**

| Format | Meaning |
|---|---|

# Update root hints on the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To update root hints on the DNS server**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Root Hints** tab.
5. Modify server root hints as follows:

   - To add a root server to the list, click **Add**, and then specify the name and IP address of the server to be added to the list.
   - To modify a root server in the list, click **Edit**, and then specify the name and IP address of the server to be modified in the list.
   - To remove a root server from the list, select it in the list, and then click **Remove**.
   - To copy root hints from a DNS server, click **Copy from server**, and then specify the IP address of the DNS server from which you want to copy a list of root servers to use in resolving queries. These root hints will not overwrite any existing root hints.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

# Secure server cache against names pollution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To secure server cache against names pollution**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Advanced** tab.
5. In **Server options**, select the **Secure cache against pollution** check box, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The **Secure cache against pollution** option is enabled by default.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Clear the server names cache

Published: January 21, 2005

Updated: November 4, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To clear the server names cache**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Clear Cache**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type the following command and then press ENTER:

   **Dnscmd** *ServerName* **/clearcache**

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/clearcache** | Required. Specifies the command to clear the DNS server cache. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify DNSSEC configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify DNSSEC configuration**

1. Open Registry Editor.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

2. In Registry Editor, navigate to the following registry subkey:

   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Parameters

3. Add the following DWORD entry:

   **EnableDnsSec**

4. Do one of the following:

   - To exclude DNSSEC resource records in query responses other than responses to requests for SIG, KEY or NXT resource records, assign a value of **0x0**. Appropriate resource records will be included in responses to requests for SIG, KEY, or NXT resource records only.

   - To include the DNSSEC resource records in all query responses (according to RFC 2535), assign a value of **0x2**.

   - To include DNSSEC resource records only in cases where the original client query contained the OPT resource record (according to RFC 2671), assign a value of **0x1** or do not create the value at all. The DNS server behaves the same if the value is **0x1** or if the entry does not appear in the registry.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Registry Editor, click **Start**, click **Run**, type **regedit**, and then click **OK**.

- The value of the registry entry **EnableDnsSec** determines whether the DNS server will include or exclude DNSSEC resource records when it receives queries.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify EDNS0 configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify EDNS0 configuration**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Registry Editor.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

2. In Registry Editor, navigate to the following registry subkey:

   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Parameters

3. Add the following DWORD entry:

   **EDNSCacheTimeout**

4. To change the cache timeout, type a value in seconds between 3600 (1 hour) and 15724800 (182 days).

5. In the same registry subkey (Parameters), add the following DWORD entry:

   **EnableEDNSProbes**

6. To configure the DNS server to include an OPT resource record only in response to EDNS0 requests containing OPT resource records, type **0x1** (DWORD).

7. Restart DNS server.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Registry Editor, click **Start**, click **Run**, type **regedit**, and then click **OK**.
- The value of the registry key **EDNSCacheTimeout** determines how long the DNS server will keep information about the EDNS versions supported by other DNS servers that have responded to a query with a OPT resource record.

**Using a command line**

- Open Command Prompt.

- Type one of the following:
    - **dnscmd***ServerName***/Config/EDNSCacheTimeout***Value***
    - **dnscmd***ServerName***/Config/EnableEDNSProbes***Value***

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/Config** | Required. Specifies the command to configure the DNS server. |
| **/EDNSCacheTimeout** | Required. Specifies the length of time the DNS server remembers the EDNS parameters remote servers report. |
| **/EnableEdnsProbes** | Required. Specifies whether or not the DNS server probes other DNS servers to determine if they support EDNS. |
| Value | Required. For **/EDNSCacheTimeout**, type a value in between 3600 (1 hour) and 15724800 (182 days). For **/EnableEDNSProbes**, type 1 to configure the DNS server to probe other DNS servers and determine if they support EDNS. Type 0 to configure the DNS server to not probe remote servers for EDNS support. If you type 0, the DNS server will continue to use EDNS if other servers request it. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /Config help**
- For information about the current registry setting, type one of the following:
    - **dnscmd /Info /EDNSCacheTimeout**
    - **dnscmd /Info /EnableEDNSProbes**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |

| | |
|---|---|
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Using Extension Mechanisms for DNS (EDNS0)
Modify UDP message size

# Modify UDP message size

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To modify UDP message size

1. Open Registry Editor.

   **Caution**

   - Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. You can also use the Last Known Good Configuration startup option if you encounter problems after manual changes have been applied.

2. In Registry Editor, navigate to the following registry key:

   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DNS\Parameters

3. Add the following DWORD entry:

   **MaximumUdpPacketSize**

4. Type a maximum UDP packet size value in bytes.

   The default value is 1280 bytes. The value must be between 512 and 16384 in decimal format (200 and 4000 in hexadecimal format).

5. Restart DNS server.

### Caution

- When configuring the UDP packet size to be larger than 512 bytes, remember UDP packets must travel through devices other than UDP hosts, such as routers, and these devices may not support UDP packets larger than 512 bytes. It is recommended that you establish the maximum UDP packet length support for all devices, and the path's MTU, if possible, and configure your UDP hosts according to this maximum.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Registry Editor, click **Start**, click **Run**, type **regedit**, and then click **OK**.

- For information on discovering the maximum transmission unit (MTU) of an arbitrary Internet path, see Request for Comment (RFC) 1191, "Path MTU Discovery."

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Monitor Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitor servers**

- Select and enable debug logging options on the DNS server
- Disable debug logging options on the DNS server
- Test a simple query on the DNS server
- Test a recursive query on the DNS server
- Enable automatic query testing on the DNS server
- View the DNS server system event log
- View a DNS server debug log file
- Verify DNS server responsiveness using the nslookup command

# Select and enable debug logging options on the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To select and enable debug logging options on the DNS server**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, then click **Properties**.
3. Click the **Debug Logging** tab.
4. Select **Log packets for debugging**, and then select the events that you want the DNS server to record for debug logging.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- To set the debug logging options, you must first select **Log packets for debugging**.
- To get useful debug logging output you need to select a **Packet direction**, a **Transport protocol** and at least one more option.
- In addition to selecting events for the DNS debug log file, you can specify the file name, location, and maximum file size for the file.
- Using debug logging options slows DNS server performance. For this reason, all debug logging options are disabled by default.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disable debug logging options on the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable debug logging options on the DNS server**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Debug Logging** tab.
5. Clear the **Log packets for debugging** check box, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test a simple query on the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test a simple query on the DNS server**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Monitoring** tab.
5. Select the **A simple query against this DNS server** check box.
6. Click **Test Now**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Results of the query test appear in **Test results**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test a recursive query on the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test a recursive query on the DNS server**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Monitoring** tab.
5. Select the **A recursive query to other DNS servers** check box.
6. Click **Test Now**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Results of the query test appear in the **Test results** list box.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

How DNS query works

# Enable automatic query testing on the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable automatic query testing on the DNS server**

1. Open DNS.
2. In the console tree, click the applicable DNS server.

   **Where?**

   - DNS/*applicable DNS server*

3. On the **Action** menu, click **Properties**.
4. Click the **Monitoring** tab.
5. Select the type of testing to be used during automatic query testing. You can select one of both of the following:

   - **A simple query against this DNS server**
   - **A recursive query to other DNS servers**

6. Select the **Perform automatic testing at the following interval** check box.
7. Set the **Test interval** to be used.

   The query tests that you select are performed at regular intervals based on the value of the interval you specify. The default polling interval is 1 minute.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Results of automated query tests appear in **Test results** and are updated after each test interval.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View the DNS server system event log

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the DNS server system event log**

1. Open DNS.
2. In the console tree, click **DNS Events**.

   **Where?**

   - DNS/*applicable DNS server*/Event Viewer/DNS Events

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- If the DNS server for which you want to view the log is located on another computer, in the console tree, click **DNS**, and then on the **Action** menu, click **Connect to DNS Server**. Click **The following computer**, and then specify the name or IP address of the remote computer.

# View a DNS server debug log file

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view a DNS server debug log file**

1. Stop the DNS Server service.
2. Open WordPad.
3. On the **File** menu, click **Open**.
4. In **Open**, for **File name**, specify the path to the DNS server debug log file.

   By default, if the applicable DNS server is running locally, the file and path are as follows:

   systemroot\System32\Dns\Dns.log
5. After you specify the correct path and file, click **Open** to view the log file.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open WordPad, click **Start**, point to **All programs**, point to **Accessories**, and then click **WordPad**.
- To stop the DNS Server service, see Related Topics.
- The location of the DNS.log file is managed using the DNS console. To specify the name and location of the DNS.log file, see Related Topics.
- By default, the Dns.log file is empty if you have not previously enabled debug logging options.
- Debug logging slows DNS server performance and should only be enabled for temporary use.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Verify DNS server responsiveness using the nslookup command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Verify DNS server responsiveness**
**To verify DNS server responsiveness**

1. Open a command prompt, type the following command, and then press ENTER:

   **nslookup 127.0.0.1** *server_ip_address*

2. If the server is responding, the name "localhost" is returned.

| Value | Description |
|---|---|
| *server_ip_address* | The Internet Protocol (IP) address of the DNS server. For example, if the IP address of your DNS server is 10.0.0.1, type:<br><br>**nslookup 127.0.0.1 10.0.0.1** |

**Note**

In the previous procedure, the syntax for the nslookup command is: **nslookup***[-option] host server* . This command can be entered from any computer that is running a Microsoft Windows operating system and has network connectivity to the DNS server you wish to query. Only the host entry is required for the command. However, if an IP address or hostname for the server is not supplied, then the default DNS server specified in TCP/IP properties will be queried.

When you enter 127.0.0.1 as the host, this IP address will automatically resolve to the name **localhost** if the DNS Server service is running at the IP address that you specify as the *server*.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add and Remove Zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Add and remove zones**

- Add a forward lookup zone
- Add a reverse lookup zone
- Add a stub zone
- Delete a zone
- Pause a zone
- Start a zone

# Add a forward lookup zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a forward lookup zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click a DNS server, and then click **New Zone** to open the New Zone Wizard.
3. Follow the instructions to create a new primary, secondary, or stub zone.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneAdd***ZoneName* {**/Primary**|**/DsPrimary**|**/Secondary**|**/Stub**|**/DsStub**} [**/file** *FileName*] [**/load**] [**/a** *AdminEmail*] [**/DP** *FQDN*]

| Value | Description |
|---|---|
| **dsncmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneAdd** | Required. Adds a zone. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| **/Primary**\|**/DsPrimary**\|**/Secondary**\|**/Stub**\|**/DsStub** | Required. Specifies the type of zone. **/DsPrimary** and **/DsStub** specify an Active Directory-integrated zone type. |
| **/file** | Required for **/Primary**. Specifies a file for the new zone. This parameter is invalid for the **/DsPrimary** zone type. |
| *FileName* | Required for **/Primary**. Specifies the name of the zone file. This parameter is invalid for the **/DsPrimary** zone type. |

| | |
|---|---|
| **/load** | Loads an existing file for the zone. Loads an existing file for the zone. If this parameter is not specified, default zone records are created automatically. This parameter does not apply to **/DsPrimary**. |
| **/a** | Adds an administrator e-mail address for the zone. |
| *AdminEmail* | Specifies the administrator email name for the zone. |
| **/DP** | Adds the zone to an application directory partition. You may also use one of the following:<br>• **/DP /domain** For domain directory partition (replicates to all DNS servers in the domain).<br>• **/DP /forest** For forest directory partition (replicates to all DNS server in the forest).<br>• **/DP /legacy** For legacy directory partition (replicates to all domain controllers in the domain). This setting supports domains using legacy Windows 2000 Server domain controllers. |
| *FQDN* | Specifies the fully qualified domain name of the directory partition. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/ZoneAdd/help**

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a reverse lookup zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a reverse lookup zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click a DNS server, and then click **New Zone** to open the New Zone Wizard.
3. Follow the instructions to create a new reverse lookup zone.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd** *ServerName* **/ZoneAdd** *ZoneName* {**/Primary**|**/DsPrimary**} [**/file** *FileName*] [**/load**] [**/a** *AdminEmail*] [**/DP** *FQDN*]

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneAdd** | Required. Adds a zone. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the in-addr.arpa domain for the zone. For example, **20.1.168.192.in-addr.arpa.**. |
| **/Primary**\|**/DsPrimary** | Required. Specifies the type of zone. To specify an Active Directory-integrated zone, type **/DsPrimary**. |
| **/file** | Required for **/Primary**. Specifies a file for the new zone. This parameter is invalid for the **/DsPrimary** zone type. |
| *FileName* | Required for **/Primary**. Specifies the name of the zone file. This parameter is invalid for the **/DsPrimary** zone type. |

| | |
|---|---|
| **/load** | Loads an existing file for the zone. Loads an existing file for the zone. If this parameter is not specified, default zone records are created automatically. This parameter does not apply to **/DsPrimary**. |
| **/a** | Adds an administrator e-mail address for the zone. |
| *AdminEmail* | Specifies the administrator e-mail name for the zone. |
| **/DP** | Adds the zone to an application directory partition. You may also use one of the following:<br>• **/DP /domain** For domain directory partition (replicates to all DNS servers in the domain).<br>• **/DP /forest** For forest directory partition (replicates to all DNS server in the forest).<br>• **/DP /legacy** For legacy directory partition (replicates to all domain controllers in the domain). This setting supports domains using legacy Windows 2000 Server domain controllers. |
| *FQDN* | Specifies the fully qualified domain name of the directory partition. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneAdd /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a stub zone

Published: January 21, 2005

Updated: August 25, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a stub zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click a DNS server, and then click **New Zone** to open the New Zone Wizard.
3. Follow the instructions to create a new stub zone.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The stub zone cannot be hosted on a DNS server that is authoritative for the same zone.
- If you choose to integrate the stub zone into Active Directory (using Active Directory as the stub zone's storage method), you have the option to specify that the DNS server hosting the stub zone use a local list of master servers when updating the stub zone's resource records, rather than have the DNS server use the master servers list stored in Active Directory. If you want to use a local master servers list, you will need the IP addresses of the local master servers.
- If you want the DNS server hosting a stub zone to use a local list of master servers, see Related Topics.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName* **/ZoneAdd** *ZoneName* {**/Stub**|**/DsStub**} *MasterIPaddress...* [**/file** *FileName*] [**/load**] [**/DP** *FQDN*]

ValueDescription

**dnscmd** Specifies the name of the command-line tool.

*ServerName* Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.)

**/ZoneAdd** Required. Adds a zone.

*ZoneName* Required. Specifies the fully qualified domain name (FQDN) of the zone.

**/Stub**|**/DsStub**Required. Specifies the type of zone. To specify an Active Directory-integrated stub zone, type **/DsStub**.

*MasterIPaddress...* Required. Specifies one or more IP addresses for the master servers of the stub zone, from which it copies zone data.

**/file** Adds a file for the new zone.

*FileName* Specifies the name of the zone file.

**/load** Loads an existing file for the zone. If this parameter is not specified, default zone records are created automatically.

**/DP** Adds the zone to an application directory partition. You may also use one of the following:

- **/DP /domain** For domain directory partition (replicates to all DNS servers in the domain).
- **/DP /forest** For forest directory partition (replicates to all DNS server in the forest).
- **/DP /legacy** For legacy directory partition (replicates to all domain controllers in the domain). This setting supports domains using legacy domain controllers running Windows 2000 Server.

*FQDN* Specifies the fully qualified domain name of the directory partition.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/ZoneAdd /help**

- The stub zone cannot be hosted on a DNS server that is authoritative for the same zone.
- If you choose to integrate the stub zone into Active Directory (using Active Directory as the stub zone's storage method), you have the option to specify that the DNS server hosting the stub zone use a local list of master servers when updating the stub zone's resource records, rather than have the DNS server use the master servers list stored in Active Directory. If you want to use a local master servers list, you will need the IP addresses of the local master servers.
- If you want the DNS server hosting a stub zone to use a local list of master servers, see Related Topics.

# Delete a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To delete a zone

- Using the Windows interface
- Using a command line

#### Using the Windows interface

1. Open DNS.
2. In the console tree, click the applicable zone.

   **Where?**

   - DNS/*applicable DNS server*/Forward Lookup Zones (*or* Reverse Lookup Zones)/*applicable zone*

3. On the **Action** menu, click **Delete**.
4. When asked to confirm that you want to delete the zone, click **OK**.

### Caution

- Deleting an Active Directory-integrated zone effectively deletes the zone and eliminates its use at all other DNS servers using the same directory store of zone data.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- This procedure is most often used to delete a secondary copy of a zone, although it can also be used to delete a primary zone.
- Deleting a standard primary zone is usually unnecessary, unless you are redesigning your DNS namespace and the zone is no longer needed or used. In most cases, you can change the zone type if you only want to modify the zone. For more information, see Related Topics.

#### Using a command line

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneDelete***ZoneName* [**/DsDel**] [**/f**]

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneDelete** | Required. Specifies the command to delete the zone specified by *ZoneName*. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone you are deleting. |
| **/DsDel** | Deletes a the zone from Active Directory. |
| **/f** | Performs the command without asking for confirmation. If you omit this parameter, you are prompted to confirm the deletion of the resource record. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneDelete /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Pause a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To pause a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable zone.

   **Where?**

   - DNS/*applicable DNS server*/Forward Lookup Zones (*or* Reverse Lookup Zones)/*applicable zone*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, click **Pause**, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, zones are started when created or loaded at the server. Once you use this procedure to pause a zone, you must restart the zone before it is available for servicing clients or zone updates.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZonePause***ZoneName*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZonePause** | Required. Pauses the zone. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

**Formatting legend**

| **Format** | **Meaning** |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable zone.

   **Where?**

   - DNS/*applicable DNS server*/Forward Lookup Zones (*or* Reverse Lookup Zones)/*applicable zone*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, click **Start**, and then click **OK**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, zones are started when created or loaded at the server. Only zones that have previously been paused need to be restarted.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneResume***ZoneName*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneResume** | Required. Resumes the hosting of the zone by the DNS server. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone resuming operation. |

**Notes**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- By default, zones are started when created or loaded at the server. Only zones that have previously been paused need to be restarted.

**Formatting legend**

# Configure Zone Properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure zone properties**

- Change the zone type
- Change a zone file name
- Change zone replication scope
- Modify the start of authority (SOA) record for a zone
- Modify zone transfer settings
- Create and manage a notify list for a zone
- Create a zone delegation
- Verify a zone delegation using the nslookup command
- Configure a stub zone for local master servers
- Specify other DNS servers as authoritative for a zone
- Update the master server for a secondary zone
- Enable DNS to use WINS resolution
- Verify WINS as the source for answering a DNS query

# Change the zone type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the zone type**

- Using the Windows interface
- Using a command line

### To change the zone type using the Windows interface

1. Open DNS.
2. In the console tree, right-click the applicable zone, and then click **Properties**.
3. On the **General** tab, note the current zone type, and then click **Change**.
4. In **Change Zone Type**, select a zone type other than the current one, and then click **OK**.

**Additional considerations**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- You can select from **Primary zone**, **Secondary zone**, or **Stub zone**. When selecting the secondary or stub zone types, you must specify the IP address of another DNS server to be used as the source for obtaining updated information for the zone.
- If the DNS server computer is operating as a domain controller, the option to change the zone type to **Active Directory-integrated** is available. This option is not otherwise available. When this zone type is selected for use, zone data is stored and replicated as part of the Active Directory database.

| **Note** |
| --- |
| You cannot change the zone type (primary, secondary, or stub) and the method for storing the zone at the same time. You must perform the two operations separately. |

- Changing a zone from secondary to primary type can affect other zone activities, including management of dynamic updates and zone transfers and the use of DNS notify lists to notify other servers about changes in the zone. For more information, see Related Topics.
- Changing a zone from stub to primary type or vice versa is not recommended due to the purpose of stub zones.
- Changing DNS zone type or storage can be time-consuming for large zones.

### To change the zone type using a command line

1. Open Command Prompt.
2. Type the following command, and then press ENTER:

   **dnscmd** *ServerName* **/ZoneResetType** *ZoneName Property* [*MasterIPaddress...*] [**/file** *FileName*] {**/OverWrite_Mem**|**/OverWrite_Ds**|**/DirectoryPartition** *FQDN*}

| Value | Description |
| --- | --- |
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the Domain Name System (DNS) host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of zone. |
| *Property* | Required. One of the following zone types:<br>• **/Primary**<br>Standard primary zone. The **/file***FileName* option is required.<br>• **/DsPrimary**<br>Active Directory Domain Services (AD DS)–integrated primary zone. If the zone is not already a primary zone, you must convert it to a primary zone (using **/Primary**) before you use this option to integrate the zone with AD DS.<br>• **/Secondary**<br>Secondary zone. You must specify at least one *MasterIPaddress*.<br>• **/Stub**<br>Stub zone. You must specify at least one *MasterIPaddress*. If the zone is an AD DS–integrated primary zone, you must use **/DsStub** to convert it to an AD DS–integrated stub zone before using this option.<br>• **/DsStub**<br>Active Directory-integrated stub zone. You must specify at least one *MasterIPaddress*. If the zone is not already a stub zone, you must convert it to a stub zone (using **/Stub**) before using this option to integrate the zone with AD DS. |
| **/file** *FileName* | Required for **/Primary**. Specifies the name of a file for the new zone. This parameter is not valid for the **/DsPrimary** zone type. |
| *MasterIPaddress...* | Required for **/Secondary**, **/Stub** and **/DsStub**. Specifies one or more IP addresses for the master servers of the secondary or stub zone, from which it copies zone data. |
| **/OverWrite_Mem\|/OverWrite_Ds\|**<br>**/DirectoryPartition** *FQDN* | **/OverWrite_Mem** overwrites exisiting DNS data using the data in Active Directory. **/OverWrite_Ds** overwrites Active Directory data with data in DNS. **/DirectoryPartition** stores the new zone in the application directory partition specified by *FQDN*, such as DomainDnsZones.corp.example.microsoft.com. |

| Format | Meaning |
| --- | --- |
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |

| | |
|---|---|
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Additional considerations**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/ZoneResetType/help**

- You can select from primary, secondary or stub zone. When selecting the secondary or stub zone type, you need to specify the IP address of another DNS server to be used as the source for obtaining updated information for the zone.
- If the DNS server computer is operating as a domain controller, the option to change the zone type to **Active Directory-integrated** is available. This option is not otherwise available. When this zone type is selected for use, zone data is stored and replicated as part of the Active Directory database.
- Changing a zone from secondary to primary type can affect other zone activities, including management of dynamic updates and zone transfers, and the use of DNS notify lists to notify other servers about changes in the zone.
- Changing a zone from stub to primary type or vice versa is not recommended due to the purpose of stub zones.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change a zone file name

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change a zone file name**

1. Open DNS.
2. In the console tree, click the applicable zone.

   **Where?**

   - DNS/*applicable DNS server*/Forward Lookup Zones (*or* Reverse Lookup Zones)/*applicable zone*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, in the **Zone file name** text box, type the new file name for this zone.
5. Click **OK** when you have finished entering the new zone file name.

### Caution

- If the zone file name is changed, be sure to update **Zone file name** on other DNS servers that maintain this zone. Otherwise, subsequent zone transfers and updates might fail. This can occur in the following situations:
  - The zone type is primary on this server.
  - The zone type is secondary on this server and this server acts as a source or master server for this zone to other DNS servers that host secondary copies of this zone.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The name of the zone file changes, not the name of the zone. You can use Windows Explorer to view or verify the new zone file name.
- The zone file name is not used for Active Directory-integrated zones because these zones store zone data in the Active Directory database and not a text file on the DNS server computer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change zone replication scope

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change zone replication scope**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone, and then click **Properties**.
3. On the **General** tab, note the current zone replication type, and then click **Change**.
4. Select a replication scope for the zone.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Only Active Directory-integrated primary and stub forward lookup zones can change their replication scope. Secondary forward lookup zones cannot change their replication scope.
- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneChangeDirectoryPartition***ZoneNameNewPartitionName***

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneChangeDirectoryPartition** | Required. Changes a zone's replication scope. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

| | |
|---|---|
| *NewPartitionName* | Required. The FQDN of the DNS application directory partition where the zone will be stored. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneChangeDirectoryPartition /?**
- Only Active Directory-integrated primary forward lookup zones and Active Directory-integrated stub zones can change their replication scope. Secondary forward lookup zones cannot change their replication scope.
- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify the start of authority (SOA) record for a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify the start of authority (SOA) record for a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone, and then click **Properties**.
3. Click the **Start of Authority (SOA)** tab.
4. As needed, modify properties for the start of authority (SOA) record.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The settings applied for the start of authority (SOA) record affect how zone transfers are made between servers. For more information, see Related Topics.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/RecordAdd***ZoneNameNodeName* [**/Aging**] [*Ttl*] **SOA** *PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/RecordAdd** | Required. Adds or modifies a resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace for which the SOA record is added. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |

| | |
|---|---|
| **/Aging** | Specifies that this resource record is able to be aged and scavenged. If this parameter is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time to Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **SOA** | Required. Specifies the type of resource record you are modifying. |
| *PrimSvr* | Required. Specifies the FQDN name of the server that is the primary source for information about the zone. For example, *nameserver.place.example.microsoft.com*. |
| *Admin* | Required. Specifies the name of the DNS administrator for the zone. For example, *postmaster.nameserver.place.example.microsoft.com*. |
| *Serial#* | Required. Specifies the version information for the zone. |
| *Refresh* | Required. Specifies the refresh interval for the zone. The standard setting is 3600 (one hour). |
| *Retry* | Required. Specifies the retry interval for the zone. The standard setting is 600 (ten minutes). |
| *Expire* | Required. Specifies the expire interval for the zone. The standard setting is 86400 (one day). |
| *MinTTL* | Required. Specifies the minimum Time to Live (TTL) value. This is the length of time used by other DNS servers to determine how long to cache information for a record in the zone before expiring and discarding it. The standard setting is 3600 (one hour). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

- To modify any specific SOA resource record's values using dnscmd, you must specify all of the SOA values (*PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*).

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |

| | |
|---|---|
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

# Modify zone transfer settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify DNS zone transfer settings**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. Right-click a DNS zone, and then click **Properties**.
3. On the **Zone Transfers** tab, do one of the following:
   - To disable zone transfers, clear the **Allow zone transfers** check box.
   - To allow zone transfers, select the **Allow zone transfers** check box.
4. If you allowed zone transfers, do one of the following:
   - To allow zone transfers to any server, click **To any server**.
   - To allow zone transfers only to the DNS servers listed on the **Name Servers** tab, click **Only to servers listed on the Name Servers tab**.
   - To allow zone transfers only to specific DNS servers, click **Only to the following servers**, and then add the IP address of one or more DNS servers.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- To improve the security of your DNS infrastructure, zone transfers should only be allowed for either the DNS servers in the name server (NS) resource records for a zone or for specified DNS servers. If you allow any DNS server to perform a zone transfer, you are allowing internal network information to be transferred to any host that can contact your DNS server.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneResetSecondaries***ZoneName* {**/NoXfr** | **/NonSecure** | **/SecureNs** | **/SecureList** [*SecondaryIPAddress*...]}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of zone. |
| **/NoXfr** | Disables zone transfers for the zone. |
| **/NonSecure** | Permits zone transfers to any DNS server. |
| **/SecureNs** | Permits zone transfers only to DNS servers listed in the zone using name server (NS) resource records. |
| **/SecureList** | Permits zone transfers only to DNS servers specified by *SecondaryIPAddress*. |
| *SecondaryIPAddress* | Required, if **/SecureList** is specified. A list of one or more IP addresses for DNS servers that are permitted to obtain zone transfers. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneResetSecondaries /?**

- To improve the security of your DNS infrastructure, zone transfers should only be allowed for either the DNS servers in the NS resource records for a zone or for specified DNS servers. If you allow any DNS server to perform a zone transfer, you are allowing internal network information to be transferred to any host that can contact your DNS server.

**Formatting legend**

# Create and manage a notify list for a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create and manage a notify list for a zone**

1. Open DNS.
2. In the console tree, click the applicable zone.

   **Where?**

   - DNS/*applicable DNS server*/Forward Lookup Zones (*or* Reverse Lookup Zones)/*applicable zone*

3. On the **Action** menu, click **Properties**.
4. Click the **Zone Transfers** tab.
5. Click **Notify**.
6. Verify that the **Automatically notify** check box is checked.
7. Select the method to be used for creating a list for notifying other DNS servers when changes to the zone occur. Your options are:

   - Use the default, **Servers listed on the Name Servers tab**, to permit only those servers that appear by IP address on the **Name Servers** tab to be included in the notify list.
   - Select **The following servers** if you want to specify a different notify list to be used instead.

8. If you selected **The following servers** in the previous step, add or remove server IP addresses to form the notify list as needed:

   - To add a server to the notify list, type its IP address in the **IP address** field and click **Add**.
   - To remove a server from the notify list, click the server IP address in the list box and click **Remove**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Changes to the notify list properties are only available on primary zones. For secondary zones, these properties are read-only. DNS Notify is an RFC-compliant extension of the DNS standard defined in RFC 1996, "A Mechanism for Prompt Notification of Zone Changes."
- By default, the DNS server will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a zone delegation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a zone delegation**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open the DNS console.
2. In the console tree, right-click the applicable subdomain, and then click **New Delegation**.
3. Follow the instructions provided in the **New Delegation Wizard** to finish creating the new delegated domain.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- All domains (or subdomains) that appear as part of the applicable zone delegation must be created in the current zone prior to performing delegation as described here. As necessary, use the DNS console to first add domains to the zone before completing this procedure. For more information, see Related Topics.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/RecordAdd***ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] **NS** {*HostName*|*FQDN*}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/RecordAdd** | Required. Specifies the command to add a resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace for which the SOA record is added. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | If this command is used, this resource record is able to be aged and scavenged. If this command is not used, the resource record remains in the DNS database unless it is manually updated or removed. |

| | |
|---|---|
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time-To-Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **NS** | Required. Specifies that you are adding a name server (NS) resource record to the zone specified in *ZoneName*. |
| *HostName\|FQDN* | Required. Specifies the host name or FQDN of the new authoritative server. |

See the following examples:

**dnscmd dnssvr1.contoso.com /recordadd test A 10.0.0.5**

**dnscmd /recordadd test.contoso.com test MX 10 mailserver.test.contoso.com**

For more information, see Dnscmd Syntax.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Verify a zone delegation using the nslookup command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To verify a zone delegation using the nslookup command**

1. Open Command Prompt.

2. Type:

   **nslookup***RootServerIpAddress*

3. Then type:

   **nslookup**

4. At the next prompt, type:

   **set norecurse**

5. At the next prompt, type:

   **set q=NS**

6. Type the fully qualified domain name (FQDN) for the failed name.

   Use the trailing period (**.**) when entering the name. If zone delegations are set correctly, a list of name server (NS) resource records for delegated servers should be returned in the response.

7. If the NS query response contains no names or IP addresses for delegated servers, type **q=ns** and query again using the FQDN for the parent zone of the failed name.

   For example, if the failed name you used in the previous step was example.microsoft.com, query for microsoft.com.

8. If the response contains NS resource records, but no host (A) resource records, type **set recurse** and query individually for any of the A resource records of servers listed in the NS resource records.

   If, for each NS resource record you encounter in a zone, you do not find at least one valid IP address in an A resource record, you have a broken delegation.

9. Either fix the broken delegation or retry the delegation test described in the previous step using a different IP address.

   If more than one A resource record or IP address is found, use it to repeat the delegation test described in the previous step. To fix a delegation, add or update an A resource record in the parent zone with a valid IP address for a correct DNS server for the delegated zone.

| Value | Description |
|---|---|
| **nslookup** | The name of the command-line tool. |
| *root_server_ip_address* | The IP address of a valid root server for your network. |
| **set norecursion** | A command to instruct the root server to not perform recursion on your query. |
| **set q=NS** | The command to send the query for NS resource records to the root server. |

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **nslookup**, press **Enter** and then type **help**

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Understanding zones and zone transfer

# Configure a stub zone for local master servers

Published: January 21, 2005

Updated: February 17, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default, the list of master servers is stored in Active Directory. You can also specify a **local list of master servers**, which is a list of master DNS servers stored in the Windows Registry on the local server. If it exists, this list overrides the list of master servers stored in Active Directory.

By specifying a local list of master servers, an administrator can allow a server to have a different list of master servers than other servers that are hosting the same Active Directory integrated zone.

**To configure a stub zone to use local master servers**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the stub zone, and then click **Properties**.
3. On the **General** tab, under **IP address**, modify the list to display the IP addresses of the local master servers that you want the DNS server to use when loading and updating the stub zone.

   Ensure that the IP addresses of the local master servers are for only those authoritative DNS servers that should be queried to update the records of the stub zone on this server.
4. Select the **Use the list above as a local list of masters** check box, and then click **OK**.

### Notes

- To perform this procedure, you must be a member of the DnsAdmins or the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- If the local list of master servers is cleared at a later date, the master servers list from Active Directory is applied and the local list of master servers is deleted.
- When modifications to the master servers list are made and applied on a domain controller hosting the stub zone, the list of master servers for the stub zone is updated in Active Directory.
- The DNS server will keep the master servers list from Active Directory stored in memory.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneResetMasters***ZoneName* [**/Local**] [*MasterIPaddress*...]

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| **/Local** | Configures the local master list for Active Directory-integrated zones. |
| *MasterIPaddress...* | List of one or more IP addresses of master servers for this zone. Master servers may include the server hosting the primary zone or servers hosting other secondary copies for the zone. To clear the local list of masters, type the command without entering any IP addresses. Ensure that the IP addresses of the local master servers are for only those authoritative DNS servers that should be queried to update the records of the stub zone on this server. |

**Notes**

- To perform this procedure, you must be a member of the DnsAdmins or the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/ZoneResetMasters/help**
- If the local list of master servers is cleared at a later date, the master servers list from Active Directory is applied and the local list of master servers is deleted.
- When modifications to the master servers list are made and applied on a domain controller hosting the stub zone, the list of master servers for the stub zone is updated in Active Directory.
- The DNS server will keep the master servers list from Active Directory stored in memory.

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Specify other DNS servers as authoritative for a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify other DNS servers as authoritative for a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone, and then click **Properties**.
3. Click the **Name Servers** tab.
4. Click **Add**.
5. Specify additional DNS servers by their names and IP addresses, and then click **Add** to add them to the list.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- To add a name server to the list of authoritative servers for the zone, you must specify both the server's IP address and its DNS name. When entering names, click **Resolve** to resolve the name to its IP address prior to adding it to the list.
- DNS servers specified using this procedure are added to those server IP addresses already present for the existing name server (NS) resource record for the zone. Typically, you might only need to perform this procedure at the primary zone when adding DNS servers to act as secondary servers and also to specify that these servers are known to be authoritative when answering queries for zone data.
- DNS servers automatically add and perform initial configuration of the NS resource record for each new primary zone added to the server.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] **NS** {*HostName*|*DomainName*}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |

| | |
|---|---|
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/RecordAdd** | Required. Specifies the command to add a resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace for which the SOA record is added. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | If this command is used, this resource record is able to be aged and scavenged. If this command is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time-To-Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **NS** | Required. Specifies that you are adding a name server (NS) resource record to the zone specified in *ZoneName*. |
| *HostName\|FQDN* | Required. Specifies the host name or FQDN of the new authoritative server. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd/RecordAdd/help**

- DNS servers specified using this procedure are added to those server IP addresses already present for the existing name server (NS) resource record for the zone. Typically, you might only need to perform this procedure at the primary zone when adding DNS servers to act as secondary servers and also to specify that these servers are known to be authoritative when answering queries for zone data.

- DNS servers automatically add and perform initial configuration of the NS resource record for each new primary type added to the server.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |

| | |
|---|---|
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Install Windows Support Tools

# Update the master server for a secondary zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To update the master server for a secondary zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable secondary zone, and then click **Properties**.
3. On the **General** tab, in **IP address**, specify the IP address for a new master server, and then click **Add** to update the list.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneResetMasters***ZoneName* [**/Local**] *MasterIPaddress...*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneResetMasters** | Required. Updates the master servers for a secondary zone. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone you are updating. |
| **/Local** | Specifies the local master list for Active Directory-integrated zones. |
| *MasterIPaddress...* | Required. Specifies the IP addresses of the master servers to be used by the DNS server when updating the specified secondary zones. If you do not specify *ServerIPs*, you are requesting the DNS server to reset the value to an empty list. The request may be denied because a zone must always have at least one master server. *MasterIPaddress...* is required to clear the local master list for a zone. |

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group

might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneResetMasters /help**

**Formatting legend**

| Format | Meaning |

# Enable DNS to use WINS resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable DNS to use WINS resolution**

1. Open DNS.
2. In the console tree, right-click the applicable zone, then click **Properties**.
3. Do one of the following:
   - If the applicable zone is a forward lookup zone, on the **WINS** tab, select the **Use WINS forward lookup** check box. In **IP address**, type the IP address of a WINS server to be used for resolution of names not found in DNS, and then click **Add**.
   - If the applicable zone is a reverse lookup zone, on the **WINS-R** tab, select the **Use WINS-R lookup** check box. In **Domain to append to returned name**, type a name.
4. Select the **Do not replicate this record** check box for this WINS record, if applicable.

   If you are replicating this zone between DNS servers that do not recognize the WINS or WINS-R resource records, click this check box. This prevents these records from being replicated to these other servers during zone transfers. If this zone will be used in performing zone transfers to BIND servers, this is a critical option as BIND will not recognize WINS records.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- When this option is used, specified WINS servers configured in this procedure are used for final referral of names not found in the applicable zone.
- Optionally, click **Advanced** to adjust advanced WINS lookup parameters.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Verify WINS as the source for answering a DNS query

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To verify WINS as the source for answering a DNS query**

1. Open Command Prompt.

2. Type:

   **nslookup**

3. After the previous command completes, at the nslookup ("") prompt type:

   **set debug**

4. Next, either type:

   **set querytype=a**

   if you are testing for a WINS forward lookup, or:

   **set querytype=ptr**

   if you are testing for a WINS-R reverse lookup.

   Respectively, these two commands can be used to set the query type to filter either by host (A) or pointer (PTR) resource records as appropriate for researching either a forward or reverse lookup.

5. Based on whether you are verifying possible WINS sourcing for either a forward or reverse lookup, type the appropriate fully qualified domain name (FQDN).

   For example, if the forward lookup you are tracing is for a domain name host-a.example.microsoft.com, type:

   **host-a.example.microsoft.com.**

   If the reverse lookup you are tracing is for an IP address 10.0.0.1, type:

   **1.0.0.10.in-addr.arpa.**

6. In the response, note whether the server answered authoritatively or non-authoritatively, and note the Time-To-Live (TTL) value.

7. If the server answered authoritatively, repeat the same query you performed in step 4.

8. In the response, note whether the TTL value decreased with the second query answer or if it remained consistent with the TTL value specified in the first query answer.

   If the TTL value decreased for an authoritatively answered query, the source of the query answer is a WINS server.

9. To leave debug mode and return to the command prompt, type **exit**.

| Value | Description |
|---|---|

| | |
|---|---|
| **nslookup** | The name of the command-line program. |
| **set debug** | Enables the **nslookup** command to operate in debug mode, providing extended information in the command output.<br><br>This mode is required to view query response information about whether the source for a query answer is:<br><br>• *authoritative* (from a DNS zone or WINS server database)<br><br>• *non-authoritative* (cached data from previous queries made by the DNS server or loaded from root hints) |
| **set querytype** | Changes the type of information query. More information about types can be found in Request For Comment (RFC) 1035. |

**Notes**

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **nslookup**, press **Enter** and then type **help**

- Normally, when a DNS server answers a query from its authoritative zone data, it uses the set minimum or default TTL for the zone or the record-specific TTL value (if one is configured). In so doing, TTLs are decreased in answers the server returns if based on non-authoritative data, such as a cached record at the server.

  WINS lookups present an exceptional case, where an answer received back from a WINS server is cached by the DNS server but is also considered to be authoritative data. In this case, the WINS sourced data is returned to clients as authoritative but ages while in the DNS server names cache, causing the TTL used by the server to decrease over time.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage zones**

- Allow dynamic updates
- Allow only secure dynamic updates
- Initiate a zone transfer at a secondary server
- Reload or transfer a stub zone
- Adjust the refresh interval for a zone
- Adjust the retry interval for a zone
- Adjust the expire interval for a zone
- Modify security for a directory-integrated zone

# Allow dynamic updates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To allow dynamic updates**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone, and then click **Properties**.
3. On the **General** tab, verify that the zone type is either **Primary** or **Active Directory-integrated**.
4. In **Dynamic Updates**, click **Nonsecure and secure**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Dynamic update is an RFC-compliant extension to the DNS standard. The DNS update process is defined in RFC 2136, "Dynamic Updates in the Domain Name System (DNS UPDATES)."

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd** *ServerName* **/Config** {*ZoneName*|**..AllZones**} **/AllowUpdate** {**1**|**0**}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/Config** | Required. Specifies the configuration command. |
| *ZoneName*\|**..AllZones** | Required. Specifies the fully qualified domain name (FQDN) of the zone. To configure all zones hosted on the specified DNS server to allow dynamic updates, type **..AllZones**. |
| **/AllowUpdate** | Required. Specifies the allow update command. |
| **1**\|**0** | Configures dynamic update. To allow dynamic updates, enter a value of 1. To not allow dynamic updates, enter a value of 0. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /Config /help**

- Dynamic update is an RFC-compliant extension to the DNS standard. The DNS update process is defined in RFC 2136, "Dynamic Updates in the Domain Name System (DNS UPDATES)."

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |

# Allow only secure dynamic updates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To allow only secure dynamic updates**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone and click **Properties**.
3. On the **General** tab, verify that the zone type is **Active Directory-integrated**.
4. In **Dynamic Updates**, click **secure only**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Secure dynamic update is supported only for Active Directory-integrated zones. If the zone type is configured differently, you must change the zone type and directory integrate the zone prior to securing it for DNS dynamic updates.
- Dynamic update is an RFC-compliant extension to the DNS standard. The DNS update process is defined in RFC 2136, "Dynamic Updates in the Domain Name System (DNS UPDATE)."
- By default, the DNS server will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.
- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/Config** {*ZoneName*|**..AllZones**} **/AllowUpdate 2**

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |

| | |
|---|---|
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/Config** | Required. Specifies the configuration command. |
| *ZoneName*\|**..AllZones** | Required. Specifies the fully qualified domain name (FQDN) of the zone. To configure all zones hosted on the specified DNS server to allow dynamic updates, type **..AllZones**. |
| **/AllowUpdate** | Required. Specifies the allow update command. |
| **2** | Required. Configures server to allow secure update. If you exclude the **2**, the zone will be set to perform standard dynamic updates only. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /Config /help**
- Dynamic update is an RFC-compliant extension to the DNS standard. The DNS update process is defined in RFC 2136, "Dynamic Updates in the Domain Name System (DNS UPDATE)."
- By default, the DNS server will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.
- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

# Initiate a zone transfer at a secondary server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To initiate a zone transfer at a secondary server**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone and click **Transfer from master**.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- This procedure checks to see if the start of authority (SOA) resource record in the secondary zone is the most recent version of the SOA resoure record in the primary zone. If the SOA resource records are synchronized, then there is no zone transfer. If the SOA resource records are not synchronized, then there is a zone transfer.
- By default, the DNS server will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/ZoneRefresh***ZoneName*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneRefresh** | Required. Updates the secondary zone. |
| *ZoneName* | Required. Specifies the name of the secondary zone to update. |

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneRefresh /help**

- This procedure checks to see if the start of authority (SOA) resource record in the secondary zone is the most recent version of the SOA resoure record in the primary zone. If the SOA resource records are synchronized, then there is no zone transfer. If the SOA resource records are not synchronized, then there is a zone transfer.

- By default, the DNS server will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Reload or transfer a stub zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To reload or transfer a stub zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable stub zone, and do one of the following:
   - To reload the stub zone from storage, click **Reload**.
   - To have the DNS server determine if the serial number in the stub zone's SOA resource record has expired and then perform a zone transfer from the stub zone's master server, click **Transfer from Master**.
   - To perform a zone transfer from the stub zone's master server regardless of the serial number in the stub zone's SOA resource record, click **Reload from Master**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName* {**/ZoneReload**|**/ZoneUpdateFromDs**|**/ZoneRefresh**} *ZoneName*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneReload** | Reloads the stub zone. |
| **/ZoneUpdateFromDs** | Reloads the stub zone from Active Directory. |
| **/ZoneRefresh** | Refreshes the stub zone. The DNS server will determine if the serial number in the stub zone's SOA resource record has expired. If the serial number has expired, the DNS server will perform a zone transfer from the stub zone's master server. |

| | |
|---|---|
| *ZoneName* | Required. Specifies the name of the stub zone you want to reload or refresh. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneReload /help** or **dnscmd /ZoneUpdateFromDs /help** or **dnscmd /ZoneRefresh /help**.
- There is no **dnscmd** command to perform a zone transfer regardless of the SOA resource record's expiration date. To perform this operation, use the Windows interface procedure.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Adjust the refresh interval for a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To adjust the refresh interval for a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone and click **Properties**.
3. On the **General** tab, verify that the zone type is either **Primary** or **Active Directory-integrated**.
4. Click the **Start of Authority (SOA)** tab.
5. In **Refresh interval**, click a time period in minutes, hours, or days, and type a number in the text box.
6. Click **OK** to save the adjusted interval.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, the refresh interval for each zone is set to 15 minutes. The refresh interval is used to determine how often other DNS servers that load and host the zone must attempt to renew the zone.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneName NodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] **SOA** *PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/RecordAdd** | Required. Adds or modifies a resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

| | |
|---|---|
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace for which the SOA record is added. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | Specifies that this resource record is able to be aged and scavenged. If this parameter is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time-To-Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **SOA** | Required. Specifies the type of resource record you are modifying. |
| *PrimSvr* | Required. Specifies the FQDN name of the server that is the primary source for information about the zone. For example, *nameserver.place.example.microsoft.com*. |
| *Admin* | Required. Specifies the name of the DNS administrator for the zone. For example, *postmaster.nameserver.place.example.microsoft.com*. |
| *Serial#* | Required. Specifies the version information for the zone. |
| *Refresh* | Required. Specifies the refresh interval for the zone. The standard setting is 900 (15 minutes). |
| *Retry* | Required. Specifies the retry interval for the zone. The standard setting is 600 (ten minutes). |
| *Expire* | Required. Specifies the expire interval for the zone. The standard setting is 86400 (one day). |
| *MinTTL* | Required. Specifies the minimum Time-To-Live value. This is the length of time used by other DNS servers to determine how long to cache information for a record in the zone before expiring and discarding it. The standard setting is 3600 (one hour). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

- To modify any specific SOA resource record's values using dnscmd, you must specify all of the SOA values (*PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*).

- By default, the refresh interval for each zone is set to 15 minutes. The refresh interval is used to determine how often other DNS servers that load and host the zone must attempt to renew the zone.

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |

| | |
|---|---|
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Adjust the retry interval for a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To adjust the retry interval for a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone and click **Properties**.
3. On the **General** tab, verify that the zone type is either **Primary** or **Active Directory-integrated**.
4. Click the **Start of Authority (SOA)** tab.
5. In **Retry interval**, click an interval in minutes, hours, or days, and type a number in the text box.
6. Click **OK** to save the adjusted interval.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, the retry interval for each zone is set at 10 minutes. The retry interval is used to determine how often other DNS servers that load and host the zone are to retry a request for update of the zone each time the refresh interval occurs.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneName NodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] **SOA** *PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/RecordAdd** | Required. Adds or modifies a resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

| | |
|---|---|
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace for which the SOA record is added. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | Specifies that this resource record is able to be aged and scavenged. If this parameter is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time-To-Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **SOA** | Required. Specifies the type of resource record you are modifying. |
| *PrimSvr* | Required. Specifies the FQDN name of the server that is the primary source for information about the zone. For example, *nameserver.place.example.microsoft.com*. |
| *Admin* | Required. Specifies the name of the DNS administrator for the zone. For example, *postmaster.nameserver.place.example.microsoft.com*. |
| *Serial#* | Required. Specifies the version information for the zone. |
| *Refresh* | Required. Specifies the refresh interval for the zone. The standard setting is 3600 (one hour). |
| *Retry* | Required. Specifies the retry interval for the zone. The standard setting is 600 (ten minutes). |
| *Expire* | Required. Specifies the expire interval for the zone. The standard setting is 86400 (one day). |
| *MinTTL* | Required. Specifies the minimum Time-To-Live value. This is the length of time used by other DNS servers to determine how long to cache information for a record in the zone before expiring and discarding it. The standard setting is 3600 (one hour). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

- To modify any specific SOA resource record's values using dnscmd, you must specify all of the SOA values (*PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*).

- By default, the retry interval for each zone is set at 10 minutes. The retry interval is used to determine how often other DNS servers that load and host the zone are to retry a request for update of the zone each time the refresh interval occurs.

**Formatting legend**

# Adjust the expire interval for a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To adjust the expire interval for a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone and click **Properties**.
3. On the **General** tab, verify that the zone type is either **Primary** or **Active Directory-integrated**.
4. Click the **Start of Authority (SOA)** tab.
5. In **Expires after**, click an interval in either minutes, hours, or days, and then type a number in the text box.
6. Click **OK** to save the adjusted interval.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- By default, the expire interval for each zone is set to 1 day. The expire interval is used by other DNS servers configured to load and host the zone to determine when zone data expires if not renewed.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] **SOA** *PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/RecordAdd** | Required. Adds or modifies a resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

| | |
|---|---|
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace for which the SOA record is added. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | Specifies that this resource record is able to be aged and scavenged. If this parameter is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time-To-Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **SOA** | Required. Specifies the type of resource record you are modifying. |
| *PrimSvr* | Required. Specifies the FQDN name of the server that is the primary source for information about the zone. For example, *nameserver.place.example.microsoft.com*. |
| *Admin* | Required. Specifies the name of the DNS administrator for the zone. For example, *postmaster.nameserver.place.example.microsoft.com*. |
| *Serial#* | Required. Specifies the version information for the zone. |
| *Refresh* | Required. Specifies the refresh interval for the zone. The standard setting is 3600 (one hour). |
| *Retry* | Required. Specifies the retry interval for the zone. The standard setting is 600 (ten minutes). |
| *Expire* | Required. Specifies the expire interval for the zone. The standard setting is 86400 (one day). |
| *MinTTL* | Required. Specifies the minimum Time-To-Live value. This is the length of time used by other DNS servers to determine how long to cache information for a record in the zone before expiring and discarding it. The standard setting is 3600 (one hour). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

- To modify any specific SOA resource record's values using dnscmd, you must specify all of the SOA values (*PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL*).

# Modify security for a directory-integrated zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify security for a directory-integrated zone**

1. Open DNS.
2. In the console tree, click the applicable zone.

   **Where?**

   - DNS/*applicable DNS server*/Forward Lookup Zones (*or* Reverse Lookup Zones)/*applicable zone*

3. On the **Action** menu, click **Properties**.
4. On the **General** tab, verify that the zone type is **Active Directory-integrated**.
5. On the **Security** tab, modify the list of member users or groups that are allowed to securely update the applicable zone and reset their permissions as needed.

## Notes

- To perform this procedure, you must be a member of the DnsAdmins or the Domain Admins group in Active Directory. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups and Using Run as.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Secure dynamic updates are only supported for zones stored in Active Directory.
- The security settings determine who can administer the zone, but do not affect dynamic updates to the zone. To apply security settings for dynamic updates, see Related Topics.
- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Resource Records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage resource records**

- Add a host (A) resource record to a zone
- Add a mail exchanger (MX) resource record to a zone
- Add an alias (CNAME) resource record to a zone
- Add a new domain to a zone
- Add a pointer (PTR) resource record to a reverse zone
- Add a resource record to a zone
- Modify an existing resource record in a zone
- Delete a resource record from a zone
- View unsupported resource records in a zone
- Modify security for a resource record

# Add a host (A) resource record to a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a host (A) resource record to a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable forward lookup zone and click **New Host**.
3. In the **Name** text box, type the DNS computer name for the new host.
4. In the **IP address** text box, type the IP address for the new host.
5. As an option, select the **Create associated pointer (PTR) record** check box to create an additional pointer record in a reverse zone for this host, based on the information you entered in **Name** and **IP address**.
6. Click **Add Host** to add the new host record to the zone.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- PTR resource records created automatically when adding an A resource record to a zone will be deleted automatically if the corresponding A resource record is deleted.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] **A** *IPAddress*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/RecordAdd** | Required. Adds a new resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

| | |
|---|---|
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | Specifies that this resource record is able to be aged and scavenged. If this command is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time-To-Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **A** | Required. Specifies the resource record type of the record you are adding. |
| *IPAddress* | Required. The IP address for the host. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

- PTR resource records are deleted automatically if the corresponding A resource record is deleted.

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a mail exchanger (MX) resource record to a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a mail exchanger (MX) resource record to a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable forward lookup zone and click **New Mail Exchanger**.
3. In the **Host or domain** text box, type the domain name for which this record is to be used to deliver mail.
4. In the **Mail server** text box, type the DNS host computer name of the mail exchanger or mail server host that delivers mail for the specified domain name.

   As an option, you can click **Browse** to view the DNS namespace for mail exchanger hosts in this domain that have host (A) records already defined.
5. Adjust the **Mail server priority** as needed for this zone.
6. Click **OK** to add the new record to the zone.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [*Ttl*] **MX** *PreferenceMXServerName*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/RecordAdd** | Adds a new resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone in which you will add the new MX resource record. |

| | |
|---|---|
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | Specifies that this resource record is able to be aged and scavenged. If this command is used, this resource record is able to be aged and scavenged. If this command is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| **Ttl** | Specifies the Time-To-Live setting for the resource record. |
| **MX** | Required. Specifies the MX resource record type for the record you are adding. |
| *Preference* | Required. Specifies a numeric value (between 0 and 65535) that indicates the mail exchange server's priority with respect to the other mail exchange servers. Lower numbers are given greater preference. |
| *MXServerName* | Required. Specifies the fully qualified domain name (FQDN) for a mail exchanger. The value entered here must resolve to a corresponding host (A) resource record in this zone. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |

# Add an alias (CNAME) resource record to a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an alias (CNAME) resource record to a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable forward lookup zone, and then click **New Alias**.
3. In the **Alias name** text box, type the alias name.
4. In the **Fully qualified domain name (FQDN) for target host** text box, type the fully qualified domain name of the DNS host computer for which this alias is to be used.

   As an option, you can click **Browse** to search the DNS namespace for hosts in this domain that have host (A) records already defined.
5. Click **OK** to add the new record to the zone.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] **CNAME** *HostName*|*DomainName*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/RecordAdd** | Required. Specifies the command to add a new resource record. |
| *ZoneName* | Required. Specifies the name of the zone where this CNAME resource record will be added. |
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |

| | |
|---|---|
| **/Aging** | Specifies that this resource record is aged and scavenged. If this parameter is not used, the resource record remains in the DNS database unless it is manually updated or removed. |
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| *Ttl* | Specifies the Time-To-Live (TTL) setting for the resource record. (The default TTL is defined in SOA resource record). |
| **CNAME** | Required. Specifies the resource record type of the record you are adding. |
| *HostName\|DomainName* | Required. Specifies the FQDN of any valid DNS host or domain name in the namespace. For FQDN's, a trailing period (.) is used to fully qualify the name. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

# Add a new domain to a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a new domain to a zone**

1. Open DNS.
2. In the console tree, click the applicable zone.

   **Where?**

   - DNS/*applicable DNS server*/Forward Lookup Zones (*or* Reverse Lookup Zones)/*applicable zone*

3. On the **Action** menu, click **New Domain**, and then type the name of the new domain without using periods.
4. Click **OK** to add the new domain to the zone.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a pointer (PTR) resource record to a reverse zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a pointer (PTR) resource record to a reverse zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable reverse lookup zone.
3. On the **Action** menu, click **New Pointer**.
4. In the **Host IP number** text box, type the host IP address octet number.
5. In the **Host name** text box, type the fully qualified domain name for the DNS host computer for which this pointer record is to be used to provide reverse lookup (address-to-name resolution).

   As an option, you can click **Browse** to search the DNS namespace for hosts in this domain that have host (A) records already defined.
6. Click **OK** to add the new record to the zone.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- When creating a new A resource record, there is an option to create an associated PTR resource record automatically. PTR resource records created automatically when adding an A resource record to a zone will be deleted automatically if the corresponding A resource record is deleted.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [**Ttl**] **PTR** *HostName*|*DomainName*

ValueDescription

**dnscmd** Specifies the name of the command-line tool.

*ServerName* Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.).

**/RecordAdd** Required. Adds a new resource record.

*ZoneName* Required. Specifies the fully qualified domain name (FQDN) of the zone.

*NodeName* Required. Specifies the FQDN of the node in the DNS namespace. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node.

**/Aging** Specifies that this resource record is able to be aged and scavenged. If this command is used, this resource record is able to be aged and scavenged. If this command is not used, the resource record remains in the DNS database unless it is manually updated or removed.

**/OpenAcl** Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record.

**Ttl** Specifies the Time-To-Live setting for the resource record.

**PTR** Required. Specifies the resource record type.

*HostName|DomainName* Required. Specifies the FQDN of a resource record located in the DNS namespace. The host you specify is used as the data for answering reverse lookups based on the address information specified by this pointer (PTR) resource record.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

- PTR resource records are deleted automatically if the corresponding A resource record is deleted.

# Add a resource record to a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a resource record to a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone and click **Other New Records**.
3. In **Select a resource record type** list box, select the type of resource record you want to add.
4. Click **Create Record**.
5. In **New Resource Record**, enter the information needed to complete the resource record.
6. After you specify all of the necessary information for the resource record, click **OK** to add the new record to the zone.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [**Ttl**] *RRType RRData*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/RecordAdd** | Required. Adds a new resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| **/Aging** | Specifies that this resource record is able to be aged and scavenged. If this command is used, this resource record is able to be aged and scavenged. If this command is not used, the resource record remains in the DNS database unless it is manually updated or removed. |

| | |
|---|---|
| **/OpenAcl** | Specifies that new records are open to modification by any user. Without this parameter, only administrators may modify the new record. |
| **Ttl** | Specifies the Time-To-Live setting for the resource record. |
| *RRType RRData* | Required. Specifies the type of resource record to add, followed by the data to be contained in the resource record. For information about each resource record type see the Resource records reference. |

| Resource record type | Resource record data |
|---|---|
| A | *IPAddress* |
| NS,CNAME,MB,MD,PTR,MF,MG,MR | *HostName\|DomainName* |
| MX,RT,AFSDB | *Preference ServerName* |
| SRV | *Priority Weight Port HostName* |
| SOA | *PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL* |
| AAAA | *Ipv6Address* |
| TXT,X25,HINFO,ISDN | *String [String]* |
| MINFO,RP | *MailboxName ErrMailboxName* |
| WKS | *Protocol IPAddress Service...* |
| WINS | *MapFlag LookupTimeout CacheTimeout IPAddress...* |
| WINSR | *MapFlag LookupTimeout CacheTimeout RstDomainName* |

| Value | Description |
|---|---|
| *IPAddress* | Specifies a standard IP address. For example, 255.255.255.255. |
| *ipv6Address* | Specifies a standard IPv6 address. For example, 1:2:3:4:5:6:7:8. |
| *Protocol* | Specifies the transmission protocol: UDP or TCP. |
| *Service* | Specifies a standard service. For example, domain, smtp. |
| *HostName\|DomainName* | Specifies the FQDN of a resource record located in the DNS namespace. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

**Formatting legend**

# Modify an existing resource record in a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify an existing resource record in a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable zone.
3. In the details pane, right-click the resource record you want to modify, and then click **Properties**.
4. In **Properties**, edit the properties that can be modified.

   If necessary, you can view and modify advanced resource record properties for the DNS console. To display advanced properties, on the **View** menu, click **Advanced**.
5. Click **OK** when you have finished modifying the record.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- When **Advanced** view options are enabled, you can modify additional settings for an existing resource record, such as its record-specific Time to Live (TTL).

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/RecordAdd** *ZoneNameNodeName* [**/Aging**] [**/OpenAcl**] [*Ttl*] *RRType RRData*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/RecordAdd** | Required. Adds a new resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

| | |
|---|---|
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| *RRType RRData* | Required. Specifies the type of resource record to add, followed by the data to be contained in the resource record. For information about each resource record type see the Resource records reference. |

| Resource record type | Resource record data |
|---|---|
| A | *IPAddress* |
| NS,CNAME,MB,MD,PTR,MF,MG,MR | *HostName\|DomainName* |
| MX,RT,AFSDB | *Preference ServerName* |
| SRV | *Priority Weight Port HostName* |
| SOA | *PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL* |
| AAAA | *Ipv6Address* |
| TXT,X25,HINFO,ISDN | *String [String]* |
| MINFO,RP | *MailboxName ErrMailboxName* |
| WKS | *Protocol IPAddress Service...* |
| WINS | *MapFlag LookupTimeout CacheTimeout IPAddress...* |
| WINSR | *MapFlag LookupTimeout CacheTimeout RstDomainName* |

| Value | Description |
|---|---|
| *IPAddress* | Specifies a standard IP address. For example, 255.255.255.255. |
| *ipv6Address* | Specifies a standard IPv6 address. For example, 1:2:3:4:5:6:7:8. |
| *Protocol* | Specifies the transmission protocol: UDP or TCP. |
| *Service* | Specifies a standard service. For example, domain, smtp. |
| *HostName\|DomainName* | Specifies the FQDN of a resource record located in the DNS namespace. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordAdd /help**

**Formatting legend**

| Format | Meaning |

# Delete a resource record from a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a resource record from a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable zone.
3. In the details pane, right-click the resource record you want to delete, and then click **Delete**.
4. When you are asked to confirm that you want to delete the selected resource record, click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- PTR resource records are deleted automatically if the corresponding A resource record is deleted.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/RecordDelete***ZoneNameNodeNameRRTypeRRData* [**/f**]

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.). |
| **/RecordDelete** | Required. Deletes a resource record. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |
| *NodeName* | Required. Specifies the FQDN of the node in the DNS namespace. You can also type the node name relative to the *ZoneName* or @, which specifies the zone's root node. |
| *RRType RRData* | Required. Specifies the type of resource record (RR) to add, followed by the data to be contained in the resource record. For information about each resource record type see the Resource records reference. |

| Resource record type | Resource record data |
|---|---|
| A | *IPAddress* |
| NS,CNAME,MB,MD,PTR,MF,MG,MR | *HostName\|DomainName* |
| MX,RT,AFSDB | *Preference ServerName* |
| SRV | *Priority Weight Port HostName* |
| SOA | *PrimSvr Admin Serial#\ Refresh Retry Expire MinTTL* |
| AAAA | *Ipv6Address* |
| TXT,X25,HINFO,ISDN | *String [String]* |
| MINFO,RP | *MailboxName ErrMailboxName* |
| WKS | *Protocol IPAddress Service...* |
| WINS | *MapFlag LookupTimeout CacheTimeout IPAddress...* |
| WINSR | *MapFlag LookupTimeout CacheTimeout RstDomainName* |

| Value | Description |
|---|---|
| *IPAddress* | Specifies a standard IP address. For example, 255.255.255.255. |
| *ipv6Address* | Specifies a standard IPv6 address. For example, 1:2:3:4:5:6:7:8. |
| *Protocol* | Specifies the transmission protocol: UDP or TCP. |
| *Service* | Specifies a standard service. For example, domain, smtp. |
| *HostName\|DomainName* | Specifies the FQDN of a resource record located in the DNS namespace. |
| **/f** | Specifies that the command is executed without asking for confirmation. If you omit this parameter, you are prompted to confirm the deletion of the resource record. |

**Important**

- If the parameter *RRData* is not specified, all resource records of the same type are deleted.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /RecordDelete /help**

- If the variable *RRData* is not specified, all resource record types matching the previous criteria are deleted.

- PTR resource records are deleted automatically if the corresponding A resource record is deleted.

**Formatting legend**

| Format | Meaning |
| --- | --- |
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |

# View unsupported resource records in a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view unsupported resource records in a zone**

1. Open DNS.
2. In the console tree, click the applicable zone.
3. In the details pane, right-click the record you want to view, then click **Properties**.
4. In **Properties**, view properties specific to this record.
5. When you have finished viewing the record, click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The DNS console allows you to view unsupported resource records (RRs) in secondary zones that are obtained from other DNS server implementations, such as DNS servers running versions of BIND. These records are not used by DNS servers running Windows Server 2003 and cannot be managed through the DNS console. These types of records include legacy records, such as mail forwarder (MF) and mail domain (MD) resource records (RRs).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Modify security for a resource record

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To modify security for a resource record**

1. Open DNS.
2. In the console tree, click the applicable zone.
3. In the details pane, click the record you want to view.
4. On the **Action** menu, click **Properties**.
5. On the **Security** tab, modify the list of member users or groups that are allowed to securely update the applicable record and reset their permissions as needed.

## Notes

- To perform this procedure, you must be a member of the DnsAdmins or the Domain Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Secure dynamic updates are only supported or configurable for resource records in zones stored in Active Directory.
- Security settings applied to resource records only affect dynamic updates. These security settings do not affect who may administer the zone where these resource records are located. For information on the security settings that affect who may administer a zone, see Related Topics.
- Resource records with the same name share the same resource record security settings. The names of resource records are listed in the **Name** column of the DNS console.
- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use Aging and Scavenging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Use aging and scavenging**

- Set aging/scavenging properties for the DNS server
- Set aging/scavenging properties for a zone
- Enable automatic scavenging of stale resource records
- Start immediate scavenging of stale resource records
- View when a zone can start scavenging stale records
- Reset scavenging and aging properties for a specified resource record

# Set aging/scavenging properties for the DNS server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set aging/scavenging properties for the DNS server**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, and then click **Set Aging/Scavenging for all zones**.
3. Select the **Scavenge stale resource records** check box.
4. Modify other aging and scavenging properties as needed.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- Aging and scavenging properties configured by this procedure act as server defaults that apply only toward Active Directory-integrated zones. For standard primary zones, you must set the appropriate properties at the applicable zone.
- Once you apply changes for server aging/scavenging settings, the DNS console prompts you to confirm. You then have the option to apply your changes to new Active Directory-integrated zones only. If needed, you can also apply your changes to existing Active Directory-integrated zones.
- Regardless of whether the **Scavenge stale resource records** check box is selected as described in step 4, for standard primary zones, this feature is disabled unless manually enabled at the applicable zone.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/Config** {**/ScavengingInterval** *Value*|**/DefaultAgingState** *Value*|**/DefaultNoRefreshInterval** *Value*|**/DefaultRefreshInterval** *Value*}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |

| | |
|---|---|
| **/Config** | Required. Specifies the configuration command. |
| **/ScavengingInterval** | Required. Sets the frequency by which the server will perform scavenging for all scavenging-enabled zones. |
| **/DefaultAgingState** | Required. Sets the default aging configuration for all zones on the server. |
| **/DefaultNoRefreshInterval** | Required. Sets the default No-refresh interval for scavenging-enabled zones. |
| **/DefaultRefreshInterval** | Sets the default Refresh interval for scavenging-enabled zones. |
| *Value* | For **/ScavengingInterval**, type a value in hours. The default is 168 (one week). For **/DefaultAgingState**, type 1 to enable aging for new zones when they are created. Type 0 to disable aging for new zones. For **/DefaultNoRefreshInterval**, type a value in hours. The default is 168 (one week). For **/DefaultRefreshInterval**, type a value in hours. The default is 168 (one week). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /Config /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set aging/scavenging properties for a zone

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set aging/scavenging properties for a zone**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable zone, then click **Properties**.
3. On the **General** tab, click **Aging**.
4. Select the **Scavenge stale resource records** check box.
5. Modify other aging and scavenging properties as needed.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/Config** {*ZoneName*|**..AllZones**} {**/Aging***Value*|**/RefreshInterval** *Value*|**/NoRefreshInterval** *Value*}

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/Config** | Required. Specifies the configuration command. |
| *ZoneName*\|**..AllZones** | Required. Specifies the name of the zone to which you want to set aging and scavenging. To apply the operation to all zones, use **..AllZones**. |
| **/Aging** | Required. Enables aging for zones. |
| **/RefreshInterval** | Required. Specifies the Refresh interval for a scavenging-enabled zone. |

| | |
|---|---|
| **/NoRefreshInterval** | Required. Specifies the No-refresh interval for a scavenging-enabled zone. |
| *Value* | Required. For **/Aging**, type 1 to enable aging. Type 0 to disable aging. For **/RefreshInterval**, type a value in hours. The default setting is 168 hours (one week). For **/NoRefreshInterval**, type a value in seconds. The standard setting is 3600 (one hour). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /Config /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

# Enable automatic scavenging of stale resource records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable automatic scavenging of stale resource records**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, then click **Properties**.
3. Click the **Advanced** tab.
4. Select the **Enable automatic scavenging of stale records** check box.
5. To adjust the **Scavenging period**, select from the drop-down list an interval in either hours or days, and then type a number in the text box.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Information about functional differences**

# Start immediate scavenging of stale resource records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start immediate scavenging of stale resource records**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, right-click the applicable DNS server, then click **Scavenge Stale Resource Records**.
3. When asked to confirm that you want to scavenge all stale resource records on the server, click **OK**.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***ServerName***/StartScavenging**

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/StartScavenging** | Required. Initiates resource record scavenging. |

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.

- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /StartScavenging /help**

**Formatting legend**

| Format | Meaning |
| --- | --- |

# View when a zone can start scavenging stale records

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view when a zone can start scavenging stale records**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. On the **View** menu, click **Advanced**.
3. Right-click the applicable zone, then click **Properties**.
4. On the **General** tab, click **Aging**.
5. Under **Refresh interval**, view when the zone is first eligible to be scavenged for stale resource records.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- The start scavenging date and time stamp are used to determine when zone scavenging starts. For more information, see Related Topics.
- After the start scavenging date and time stamp are reached, scavenging can occur only if the **Scavenge stale resource records** check box is selected. If the check box is cleared, scavenging for the zone cannot be performed.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **dnscmd***Server***/ZoneInfo***ZoneName***RefreshInterval**

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line tool. |
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/ZoneInfo** | Required. Displays configuration information. |
| *ZoneName* | Required. Specifies the fully qualified domain name (FQDN) of the zone. |

| | |
|---|---|
| **RefreshInterval** | Required. Specifies the configuration property that displays when the zone is first eligible to be scavenged for stale resource records. The output value is in hours. The default setting is 168 hours (one week). |

**Notes**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /ZoneInfo /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Reset scavenging and aging properties for a specified resource record

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To reset scavenging and aging properties for a specified resource record**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open DNS.
2. In the console tree, click the applicable zone.
3. In the details pane, double-click the resource record for which you want to reset scavenging and aging properties.
4. Depending on the how the resource record was originally added to the zone, do one of the following:
    - If the record was added dynamically using dynamic update, you can clear the **Delete this record when it becomes stale** check box to prevent its aging or potential removal during the scavenging process. If dynamic updates to this record continue to occur, the DNS server will always reset this check box so that the dynamically updated record can be deleted.
    - If you added the record statically, you can select **Delete this record when it becomes stale** check box to permit its aging or potential removal during the scavenging process.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open DNS, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **DNS**.
- This procedure is only necessary for resource records that are dynamically registered. For records that you manually add to a zone, a time stamp value of zero always applies to the record, excluding it from the scavenging process.
- Scavenging and aging properties for NS and SOA resource records are reset in the properties for the zone, not the properties for the resource record.

**Using a command line**

1. Open Command Prompt.
2. Type: **dnscmd** *ServerName* **/Config** {*ZoneName*|**..AllZones**} **/ScavengingInterval** *Value*

| Value | Description |
|---|---|
| **dnscmd** | Specifies the name of the command-line program. |

| | |
|---|---|
| *ServerName* | Required. Specifies the DNS host name of the DNS server. You can also type the IP address of the DNS server. To specify the DNS server on the local computer, you can also type a period (.) |
| **/Config** | Required. Specifies the configuration command. |
| *ZoneName*\|**..AllZones** | Required. Specifies the fully qualified domain name (FQDN) of the zone. To configure all zones hosted on the specified DNS server to allow dynamic updates, type **..AllZones**. |
| **/ScavengingInterval** | Required. Sets the scavenging interval. |
| *Value* | Required. The new value for the scavenging interval, specified in hours. The default is 168 (one week). |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- This procedure requires the Dnscmd Windows support tool. For information about installing Windows support tools, see Related Topics.
- To view the complete syntax for this command, at a command prompt, type:

  **dnscmd /Config /help**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# DNS Concepts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Concepts**

This section provides general background information about Domain Name System (DNS) and the DNS Server service, as well as details about supporting software provided for DNS clients running under Microsoft operating systems.

- DNS Overview
- Understanding DNS
- Deploying DNS
- Administering DNS
- DNS Resources

# DNS Overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS overview**

This section covers:

- DNS defined
- DNS tools
- Server features
- Client features
- Security information for DNS
- New features for DNS

# DNS defined

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS defined**

DNS is an abbreviation for Domain Name System, a system for naming computers and network services that is organized into a hierarchy of domains. DNS naming is used in TCP/IP networks, such as the Internet, to locate computers and services through user-friendly names. When a user enters a DNS name in an application, DNS services can resolve the name to other information associated with the name, such as an IP address.

For example, most users prefer a friendly name such as *example.microsoft.com* to locate a computer such as a mail or Web server on a network. A friendly name can be easier to learn and remember. However, computers communicate over a network by using numeric addresses. To make the use of network resources easier, name systems such as DNS provide a way to map the user-friendly name for a computer or service to its numeric address.

The following figure shows a basic use of DNS, which is finding the IP address of a computer based on its name.

In this example, a client computer queries a DNS server, asking for the IP address of a computer configured to use *host-a.example.microsoft.com* as its DNS domain name. Because the DNS server is able to answer the query based on its local database, it replies with an answer containing the requested information, which is a host (A) resource record that contains the IP address information for *host-a.example.microsoft.com*.

The example shows a simple DNS query between a single client and DNS server. In practice, DNS queries can be more involved than this and include additional steps not shown here. For more information, see How DNS query works.

**Note**

- For additional background information about other DNS concepts, see Understanding DNS.

# DNS tools

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS tools**

There are a number of utilities for administering, monitoring, and troubleshooting both DNS servers and clients. These utilities include:

- The DNS console, which is part of Administrative Tools.
- Command-line utilities, such as Nslookup, which can be used to troubleshoot DNS problems.
- Logging features, such as the DNS server log, which can be viewed using the DNS console or Event Viewer. File-based logs can also be used temporarily as an advanced debugging option to log and trace selected service events.
- Performance monitoring utilities, such as statistical counters to measure and monitor DNS server activity with System Monitor.
- Windows Management Instrumentation (WMI), a standard technology for accessing management information in an enterprise environment.
- Platform Software Developer Kit (SDK).

**The DNS console**

The primary tool that you use to manage DNS servers is the DNS console, which is located in the Administrative Tools folder in the Start menu's Programs folder. The DNS console can be used on its own or as a Microsoft Management Console (MMC) , further integrating DNS administration into your total network management.

The DNS console can only be used after DNS is installed on the server. You can use the DNS console to perform these basic administrative server tasks:

1. Performing initial configuration of a new DNS server.
2. Connecting to and managing a local DNS server on the same computer, or remote DNS servers on other computers.
3. Adding and removing forward and reverse lookup zones as needed.
4. Adding, removing, and updating resource records in zones.
5. Modifying how zones are stored and replicated between servers.
6. Modifying how servers process queries and handle dynamic updates.
7. Modifying security for specific zones or resource records.

In addition, you can also use the DNS console to perform the following tasks:

- Perform maintenance on the server. You can start, stop, pause, or resume the server, or manually update server data files.
- Monitor the contents of the server cache and, as needed, clear it.
- Tune advanced server options.
- Configure and perform aging and scavenging of stale resource records stored by the server.

In addition, you can also operate the DNS console from a workstation to remotely administer DNS servers. For more information, see Windows Server 2003 Administration Tools Pack.

**Important**

- The DNS console can only be used to manage DNS servers running Microsoft® Windows® and cannot be used to manage other DNS servers, such as BIND.

**Notes**

- The DNS console provides new ways to perform familiar DNS administrative tasks previously performed in Microsoft® Windows® NT Server 4.0 using DNS Manager. For more information, see New ways to do familiar DNS tasks.

- To use the DNS console from another non-server computer, such as one running Microsoft® Windows® XP Professional, you must install the Windows Server 2003 Administration Tools Pack

- For information on installing DNS, see Install a DNS server.

**Command-line utilities**

There are several command-line utilities you can use to manage and troubleshoot DNS servers and clients. The following table describes each of these utilities, which can be run either by typing them at a command prompt or by entering them in batch files for scripted use.

| Command | Description |
|---|---|
| Nslookup | Used to perform query testing of the DNS domain namespace. For more information, see Nslookup. |
| Dnscmd | A command-line interface for managing DNS servers. This utility is useful in scripting batch files to help automate routine DNS management tasks, or to perform simple unattended setup and configuration of new DNS servers on your network. For more information, see Server administration using Dnscmd. |
| Ipconfig | This command is used to view and modify IP configuration details used by the computer. Additional command-line options are included with this utility to provide help in troubleshooting and supporting DNS clients. For more information, see Flush and reset a client resolver cache using the ipconfig command or Renew DNS client registration using the ipconfig command. |

For information about other command-line utilities, see Command-line reference A-Z. For more information about manageability, see Management Strategies and Tools.

**Event monitoring utilities**

The Windows Server 2003 family includes two options for monitoring DNS servers:

- **Default logging of DNS server event messages to the DNS server log.**

  DNS server event messages are separated and kept in their own system event log, the DNS server log, which can be viewed using the DNS console or Event Viewer. For more information, see View the DNS server system event log.

  The DNS server log contains events logged by the DNS Server service. For example, when the DNS server starts or stops, a corresponding event message is written to this log. Most additional critical DNS Server service events are also logged here, such as when the server starts but cannot locate initializing data, such as zones or boot information stored in the registry or (in some cases) Active Directory.

  The event types logged by DNS servers can be changed using the DNS console. For more information, see DNS server log reference.

  You can use Event Viewer to view and monitor client-related DNS events. These appear in the System log and are written by the DNS Client service at any computers running Windows (all versions). For more information, see Windows interface administrative tool reference A-Z: Event Viewer.

- **Optional debug options for trace logging to a text file on the DNS server computer.**

You can also use the DNS console to selectively enable additional debug logging options for temporary trace logging to a text-based file of DNS server activity. The file created and used for this feature, Dns.log, is stored in the systemroot\System32\Dns folder.

For more information, see Using server debug logging options.

**Performance monitoring utilities**

Performance monitoring for DNS servers can be done using additional service-specific counters that measure DNS server performance. These counters are accessible through System Monitor, which is provided in the **Performance** console.

When using System Monitor, you can create charts and graphs of server performance trends over time for any of your DNS servers. These can be further studied and analyzed to determine if additional server tuning is needed.

By measuring and reviewing server metrics over a period of time, it is possible to determine performance benchmarks and decide if further adjustments can be made to optimize the system. For more information, see Monitoring DNS server performance.

**Windows Management Instrumentation (WMI)**

WMI is the Microsoft implementation of Web-Based Enterprise Management (WBEM), which is an industry initiative to develop a standard technology for accessing management information in an enterprise environment. WMI uses the Common Information Model (CIM) industry standard to represent systems, applications, networks, devices, and other managed components in an enterprise environment. For more information about Windows Management Instrumentation, see the Microsoft Platform SDK Web site.

**Platform Software Developer Kit (SDK)**

Computers running a product in the Windows Server 2003 family provide functions that enable application programmers to use DNS, such as programmatically making DNS queries, comparing records, and looking up names.

Programmable DNS components are designed for use by C/C++ programmers. Familiarity with networking and with DNS is required. Programmers should be familiar with the IP protocol suite, as well as the DNS protocol and how DNS operates.

### Note

- For more information about manageability, see Management Strategies and Tools.

# Server features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server features**

The Domain Name System (DNS) Server service provides the following:

- **An RFC-compliant DNS server**

  DNS is an open protocol and is standardized by a set of Request for Comments (RFCs). Microsoft supports and complies with these standard specifications.

  For more information, see DNS RFCs.

- **Interoperability with other DNS server implementations**

  Because the DNS Server service is RFC-compliant and can use standard DNS data file and resource record formats, it can successfully work with most other DNS server implementations, such as those that use the Berkeley Internet Name Domain (BIND) software.

  For more information, see Interoperability issues.

- **Support for Active Directory**

  DNS is required for support of the Active Directory® directory service. If you install Active Directory on a server, you can automatically install and configure a DNS server if a DNS server that meets the Active Directory requirements cannot be located.

  First, in the Active Directory Installation Wizard, you specify the DNS name of the Active Directory domain for which you are promoting the server to become a domain controller. Later in the installation process, the wizard tests for the following:

  1. Based on its TCP/IP client configuration, it checks to see whether a preferred DNS server is configured for its use.
  2. If a preferred DNS server is available, it queries to find the primary authoritative server for the DNS name of the Active Directory domain you specified earlier in the wizard.
  3. It then tests to see whether the authoritative primary server can support and accept dynamic updates as described in the dynamic update protocol (RFC 2136).
  4. If, at this point in the process, a supporting DNS server cannot be located to accept updates for the specified DNS domain name you are using with Active Directory, you are provided with the option to install the DNS Server service locally.
  5. If you choose to install the DNS Server service locally, the IP address for the current preferred DNS server is used to configure a forwarder on the local DNS server. This configuration maintains any existing resolution to an Internet Service Provider (ISP).

  In general, the use of the Windows Server 2003 DNS Server service is strongly recommended for the best possible integration and support of Active Directory and enhanced DNS server features. You can, however, use another type of DNS server to support Active Directory deployment.

  When using other types of DNS servers, consider additional issues related to DNS interoperability. For more information, see Interoperability issues.

**Note**

- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

- **Enhancements to DNS zone storage in Active Directory**

  DNS zones can be stored in the domain or application directory partitions of Active Directory. A partition is a data structure within Active Directory used to distinguish data for different replication purposes. You can specify in which Active Directory partition to store the zone and, consequently, the set of domain controllers between which that zone's data will be replicated.

  For more information, see DNS zone replication in Active Directory.

  **Note**

  - This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

- **Conditional forwarders**

  The DNS Server service extends a standard forwarder configuration with conditional forwarders. A conditional forwarder is a DNS server on a network that is used to forward DNS queries according to the DNS domain name in the query. For example, a DNS server can be configured to forward all the queries it receives for names ending with widgets.example.com to the IP address of a specific DNS server or to the IP addresses of multiple DNS servers.

  For more information, see Understanding forwarders.

- **Stub zones**

  DNS supports a new zone type called a stub zone. A stub zone is a copy of a zone that contains only those resource records necessary to identify the authoritative DNS servers for that zone. You can use a stub zone instead of a secondary zone in situations where replicating all the zone data would be undesirable, such as over a slow network link. Note, however, that this replication efficiency is at the expense of resolution efficiency because the server hosting the stub zone is not authoritative for the zone and so must refer all queries for the zone to other servers.

  For more information, see Understanding stub zones.

- **Enhanced DNS security features**

  DNS provides enhanced security administration for the DNS Server service, the DNS Client service, and DNS data. For more information, see Security information for DNS.

- **Integration with other Microsoft networking services**

  The DNS Server service offers integration with other services and contains features beyond those specified in the RFCs. These include integration with Active Directory, WINS, and DHCP services.

  For more information, see Active Directory integration; WINS lookup integration; Dynamic update.

- **Improved ease of administration**

  The DNS console offers an improved graphical user interface for managing the DNS Server service. Also, there are several configuration wizards for performing common server administration tasks. In addition to the DNS console, other tools are provided to help you better manage and support DNS servers and clients on your network.

  For more information, see DNS tools.

- **RFC-compliant dynamic update protocol support**

  The DNS Server service allows clients to dynamically update resource records, based on the dynamic update protocol (RFC 2136). This improves DNS administration by reducing the time needed to manually manage these records. Computers running the DNS Client service can dynamically register their DNS names and IP addresses.

  For more information, see Dynamic update.

- **Support for incremental zone transfer between servers**

  Zone transfers are used between DNS servers to replicate information about a portion of the DNS namespace. Incremental zone transfer is used to replicate only the changed portions of a zone, conserving network bandwidth.

  For more information, see Understanding zones and zone transfer.

- **Support for new resource record types**

  The DNS Server service includes support for several new resource record (RR) types. These types, which include the service location (SRV) and ATM address (ATMA) RRs, expand the possibilities for using DNS as a names database service.

  For more information, see Resource records reference.

# Client features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Client features**

The Domain Name System (DNS) Client service is used to resolve DNS domain names and implements the following features:

- **System-wide caching**

  Resource records (RRs) from query responses are added to the client cache as applications query DNS servers. This information is then cached for a set Time to Live (TTL) and can be used again to answer subsequent queries.

- **RFC-compliant negative caching support**

  In addition to caching positive query responses from DNS servers (which contain resource record information in the answered reply), the DNS Client service also caches negative query responses. A negative response results when a resource record for the queried name does not exist.

  Negative caching prevents the repeating of additional queries for names that do not exist, which can adversely affect client system performance. Any query information negatively cached is kept for a shorter period of time than is used for positive query responses; by default, no more than 5 minutes. This avoids continued negative caching of stale information if the records later become available.

  Negative caching is a new DNS standard specification defined in RFC 2308. For more information, refer to this RFC. For more information on obtaining RFCs, see TCP/IP RFCs.

- **Avoidance of unresponsive DNS servers**

  The DNS Client service uses a server search list, ordered by preference. This list includes all preferred and alternate DNS servers configured for each of the active network connections on the system.

  The list is arranged based on the following criteria:

  1. Preferred DNS servers are given first priority.
  2. If no preferred DNS servers are available, then alternate DNS servers are used.
  3. Unresponsive servers are removed temporarily from these lists.

**Important**

- The DHCP Client service initiates dynamic registration for client DNS names. For more information, see Dynamic update or Using DNS servers with DHCP.

# Security information for DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security information for DNS**

Domain Name System (DNS) was originally designed as an open protocol and is therefore vulnerable to attackers. Windows Server 2003 DNS has improved the ability to prevent an attack on your DNS infrastructure through the addition of security features. Before considering which of the security features to use, you should be aware of the common threats to DNS security and the level of DNS security in your organization.

**DNS security threats**

The following are the typical ways in which your DNS infrastructure can be threatened by attackers:

- **Footprinting** is the process by which DNS zone data is obtained by an attacker to provide the attacker with the DNS domain names, computer names, and IP addresses for sensitive network resources. An attacker commonly begins an attack by using this DNS data to diagram, or footprint, a network. DNS domain and computer names usually indicate the function or location of a domain or computer in order to help users remember and identify domains and computers more easily. An attacker takes advantage of the same DNS principle to learn the function or location of domains and computers in the network.

- **Denial-of-service attack** is when an attacker attempts to deny the availability of network services by flooding one or more DNS servers in the network with recursive queries. As a DNS server is flooded with queries, its CPU usage will eventually reach its maximum and the DNS Server service will become unavailable. Without a fully operating DNS server on the network, network services that use DNS will become unavailable to network users.

- **Data modification** is an attempt by an attacker (that has footprinted a network using DNS) to use valid IP addresses in IP packets the attacker has created, thereby giving these packets the appearance of coming from a valid IP address in the network. This is commonly called IP spoofing. With a valid IP address (an IP address within the IP address range of a subnet), the attacker can gain access to the network and destroy data or conduct other attacks.

- **Redirection** is when an attacker is able to redirect queries for DNS names to servers under the control of the attacker. One method of redirection involves the attempt to pollute the DNS cache of a DNS server with erroneous DNS data that may direct future queries to servers under the control of the attacker. For example, if a query were originally made for example.microsoft.com and a referral answer provided a record for a name outside of the microsoft.com domain, such as malicious-user.com, then the DNS server would use the cached data for malicious-user.com to resolve a query for that name. Redirection can be accomplished whenever an attacker has writable access to DNS data, such as with insecure dynamic updates.

**Mitigating DNS security threats**

DNS can be configured to mitigate the common DNS security issues discussed above. The following table lists five main areas on which to concentrate when determining your DNS security.

| DNS security area | Description |
|---|---|
| DNS namespace | Incorporate DNS security into your DNS namespace design. For more information, see Securing DNS deployment. |
| DNS Server service | Review the default DNS Server service security settings and apply Active Directory security features when the DNS Server service is running on a domain controller. For more information, see Securing the DNS Server service. |
| DNS zones | Review the default DNS zone security settings and apply secure dynamic updates and Active Directory security features when the DNS zone is hosted on a domain controller. For more information, see Securing DNS zones. |

| | |
|---|---|
| DNS resource records | Review the default DNS resource record (RR) security settings and apply Active Directory security features when the DNS resource records are hosted on a domain controller. For more information, see Securing DNS resource records. |
| DNS clients | Control the DNS server IP addresses used by DNS clients. For more information, see Securing DNS clients. |

**Three levels of DNS security**
The following three levels of DNS security will help you understand your current DNS configuration and enable you to increase the DNS security of your organization.

**Low-level security**
Low-level security is a standard DNS deployment without any security precautions configured. Only deploy this level of DNS security in network environments where there is no concern for the integrity of your DNS data or in a private network where there is no threat of external connectivity.

- The DNS infrastructure of your organization is fully exposed to the Internet.
- Standard DNS resolution is performed by all DNS servers in your network.
- All DNS servers are configured with root hints pointing to the root servers for the Internet.
- All DNS servers permit zone transfers to any server.
- All DNS servers are configured to listen on all of their IP addresses.
- Cache pollution prevention is disabled on all DNS servers.
- Dynamic update is allowed for all DNS zones.
- User Datagram Protocol (UDP) and Transmission Control Protocol/Internet Protocol (TCP/IP) port 53 is open on the firewall for your network for both source and destination addresses.

**Medium-level security**
Medium-level security uses the DNS security features available without running DNS servers on domain controllers and storing DNS zones in Active Directory.

- The DNS infrastructure of your organization has limited exposure to the Internet.
- All DNS servers are configured to use forwarders to point to a specific list of internal DNS servers when they cannot resolve names locally.
- All DNS servers limit zone transfers to servers listed in the name server (NS) resource records in their zones.
- DNS servers are configured to listen on specified IP addresses.
- Cache pollution prevention is enabled on all DNS servers.
- Nonsecure dynamic update is not allowed for any DNS zones.
- Internal DNS servers communicate with external DNS servers through the firewall with a limited list of source and destination addresses allowed.
- External DNS servers in front of your firewall are configured with root hints pointing to the root servers for the Internet.
- All Internet name resolution is performed using proxy servers and gateways.

**High-level security**

High-level security uses the same configuration as medium-level security and also uses the security features available when the DNS Server service is running on a domain controller and DNS zones are stored in Active Directory. In addition, high-level security completely eliminates DNS communication with the Internet. This is not a typical configuration, but it is recommended whenever Internet connectivity is not required.

- The DNS infrastructure of your organization has no Internet communication by internal DNS servers.
- Your network uses an internal DNS root and namespace, where all authority for DNS zones is internal.
- DNS servers that are configured with forwarders use internal DNS server IP addresses only.
- All DNS servers limit zone transfers to specified IP addresses.
- DNS servers are configured to listen on specified IP addresses.
- Cache pollution prevention is enabled on all DNS servers.
- Internal DNS servers are configured with root hints pointing to the internal DNS servers hosting the root zone for your internal namespace.
- All DNS servers are running on domain controllers. A discretionary access control list (DACL) is configured on the DNS Server service to only allow specific individuals to perform administrative tasks on the DNS server.
- All DNS zones are stored in Active Directory. A DACL is configured to only allow specific individuals to create, delete, or modify DNS zones.
- DACLs are configured on DNS resource records to only allow specific individuals to create, delete, or modify DNS data.
- Secure dynamic update is configured for DNS zones, except the top-level and root zones, which do not allow dynamic updates at all.

# New features for DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New features for DNS**
The following new Domain Name System (DNS) features and feature enhancements are available with the Microsoft® Windows Server™ 2003 family.

- **Improved domain controller name resolution**

  In response to DNS name resolution failures that may be encountered during location of replication partners and global catalog servers, domain controllers running Windows Server 2003 with SP1 request other variations of the server name that might be registered, which results in fewer failures due to DNS delays and misconfiguration. For more information about DNS name resolution, see How DNS Support for Active Directory Works on the Microsoft Web site.

- **Conditional forwarders**

  Forward DNS queries according to the DNS domain name in the query using conditional forwarders. For example, a DNS server can be configured to forward all the queries it receives for names ending with widgets.example.com to the IP address of a specific DNS server or to the IP addresses of multiple DNS servers.

  For more information, see Using forwarders.

- **Stub zones**

  Using stub zones, keep a DNS server hosting a parent zone aware of the authoritative DNS servers for its child zone and, thereby, maintain DNS name resolution efficiency.

  For more information, see Understanding stub zones.

- **DNS zone replication in Active Directory**

  Choose from four default replication options for Active Directory-integrated DNS zone data.

  For more information, see DNS zone replication in Active Directory.

- **Enhanced DNS security features**

  DNS provides greater precision in its security administration for the DNS Server service, the DNS Client service, and DNS data.

  For more information, see Security information for DNS.

- **Round robin all resource record (RR) types**

  By default, the DNS Server service will perform round-robin rotation for all resource record (RR) types.

  For more information, see Configuring round robin.

- **Enhanced debug logging**

  Use the enhanced DNS Server service debug logging settings to troubleshoot DNS problems.

  For more information, see Using server debug logging options.

- **DNSSEC**

DNS provides basic support of DNS Security Extensions (DNSSEC) protocol as defined in RFC 2535.

For more information, see Using DNS Security Extensions (DNSSEC).

- **EDNS0**

  Enable DNS requestors to advertise the size of their UDP packets and facilitate the transfer of packets larger than 512 octets, the original DNS restriction for UDP packet size (RFC 1035).

  For more information, see Using Extension Mechanisms for DNS (EDNS0).

- **Control automatic NS resource record registration on a server and a zone basis**

  For more information, see Restrict NS resource record registration and Allow NS record creation for specific domain controllers.

# Understanding DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding DNS**
This section covers:

- DNS domain names
- How DNS query works
- Understanding zones and zone transfer
- Reverse lookup
- Understanding forwarders
- Understanding stub zones
- Dynamic update
- Active Directory integration
- DNS zone replication in Active Directory
- DNS requirements for installing Active Directory
- DNS requirements for joining an Active Directory domain
- Understanding aging and scavenging
- Unicode character support
- WINS lookup integration

# DNS domain names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS domain names**

Domain Name System (DNS) was originally defined in Request for Comments (RFCs) 1034 and 1035. These documents specify elements common to all implementations of DNS-related software, including:

- A DNS domain namespace, which specifies a structured hierarchy of domains used to organize names.
- Resource records, which map DNS domain names to a specific type of resource information for use when the name is registered or resolved in the namespace.
- DNS servers, which store and answer name queries for resource records.
- DNS clients, also known as resolvers, which query servers to look up and resolve names to a type of resource record specified in the query.

For more information about Requests for Comments (RFCs), see DNS RFCs.

**Understanding the DNS domain namespace**

The DNS domain namespace, as shown in the following figure, is based on the concept of a tree of named domains. Each level of the tree can represent either a branch or a leaf of the tree. A branch is a level where more than one name is used to identify a collection of named resources. A leaf represents a single name used once at that level to indicate a specific resource.

The previous figure shows how Microsoft is assigned authority by the Internet root servers for its own part of the DNS domain namespace tree on the Internet. DNS clients and servers use queries as the fundamental method of resolving names in the tree to specific types of resource information. This information is provided by DNS servers in query responses to DNS clients, who then extract the information and pass it to a requesting program for resolving the queried name.

In the process of resolving a name, keep in mind that DNS servers often function as DNS clients, querying other servers in order to fully resolve a queried name. For more information, see How DNS query works.

**How the DNS domain namespace is organized**

Any DNS domain name used in the tree is technically a domain. Most DNS discussions, however, identify names in one of five ways, based on the level and the way a name is commonly used. For example, the DNS domain name registered to Microsoft (microsoft.com.) is known as a second-level domain. This is because the name has two parts (known as labels) that indicate it is located two levels below the root or top of the tree. Most DNS domain names have two or more labels, each of which indicates a new level in the tree. Periods are used in names to separate labels.

In addition to second-level domains, other terms used to describe DNS domain names by their function in the namespace are described in the following table.

| Name type | Description | Example |
|---|---|---|
| The domain root | This is the top of the tree, representing an unnamed level; it is sometimes shown as two empty quotation marks (**""**), indicating a null value. When used in a DNS domain name, it is stated by a trailing period (**.**) to designate that the name is located at the root or highest level of the domain hierarchy. In this instance, the DNS domain name is considered to be complete and points to an exact location in the tree of names. Names stated this way are called fully qualified domain names (FQDNs). | A single period (**.**) or a period used at the end of a name, such as "example.microsoft.com.". |
| Top-level domain | A name of two or three letters used to indicate a country/region or the type of organization using a name. For more information, see Top-level domains. | ".com", which indicates a name registered to a business for commercial use on the Internet. |
| Second-level domain | Variable-length names registered to an individual or organization for use on the Internet. These names are always based upon an appropriate top-level domain, depending on the type of organization or geographic location where a name is used. | "microsoft.com.", which is the second-level domain name registered to Microsoft by the Internet DNS domain name registrar. |
| Subdomain | Additional names that an organization can create that are derived from the registered second-level domain name. These include names added to grow the DNS tree of names in an organization and divide it into departments or geographic locations. | "example.microsoft.com.", which is a fictitious subdomain assigned by Microsoft for use in documentation example names. |
| Host or resource name | Names that represent a leaf in the DNS tree of names and identify a specific resource. Typically, the leftmost label of a DNS domain name identifies a specific computer on the network. For example, if a name at this level is used in a host (A) RR, it is used to look up the IP address of computer based on its host name. | "host-a.example.microsoft.com.", where the first label ("host-a") is the DNS host name for a specific computer on the network. |

**Interpreting a DNS domain name**

DNS has a method of noting and interpreting the fully qualified path to a DNS domain name similar to the way full paths to files or directories are noted or displayed at a command prompt.

For example, a directory tree path helps point to the exact location of a file stored on your computer. For Windows computers, the back slash (****) indicates each new directory that leads to the exact location of a file. For DNS, the equivalent is a period (**.**) indicating each new domain level used in a name.

For example, for a file called Services, the full path to this file as displayed at a Windows command prompt would be:

C:\Windows\System32\Drivers\Etc\Services

To interpret the full path of the file, the name is read in a left-to-right direction from the highest or most general piece of information (drive C, the drive where the file is stored) to its most specific information, the file name "Services". This example shows five separate levels of hierarchy that lead toward the location of the Services file on drive C:

1. The root folder for drive C (C:\).

2. The system root folder where Windows is installed (Windows).

3. A system folder where system components are stored (System32).

4. A subfolder where system device drivers are stored (Drivers).

5. A subfolder where miscellaneous files used by system and network device drivers are stored (Etc).

For DNS, an example of a domain name with multiple levels is the following, a fully qualified domain name (FQDN):

host-a.example.microsoft.com.

Unlike the file name example, a DNS FQDN, when read from left to right, moves from its most specific information (the DNS name for a computer called "host-a") to its highest or most general piece of information (the trailing period (**.**) that indicates the root of the DNS name tree). This example shows the four separate DNS domain levels that lead away from the specific host location of "host-a":

1. The "example" domain, which corresponds to a subdomain where the computer name "host-a" is registered for use.

2. The "microsoft" domain, which corresponds to the parent domain that roots the "example" subdomain.

3. The "com" domain, which corresponds to the top-level domain designated for use by business or commercial organizations that roots the "microsoft" domain.

4. The trailing period (**.**), which is a standard separator character used to qualify the full DNS domain name to the root level of the DNS namespace tree.

**Background on DNS and the Internet**

Domain Name System (DNS) was developed because of the need to provide a name-to-address mapping service for computers on the Internet. Before DNS was introduced in 1987, the practice of mapping friendly computer names to IP addresses was done mainly through the use of a shared static file, known as a Hosts file.

Originally, the Internet was small enough to use one centrally administered file that was published and downloaded using FTP for Internet-connected sites. Periodically, each Internet site would update its copy of the Hosts file, and updated versions of the Hosts file were posted to reflect network changes.

As the number of computers on the Internet grew, it became unworkable to have one centralized authority managing a single Hosts file for all Internet hosts. The file became increasingly larger, which made it harder to maintain and distribute to all sites in a current and updated form.

The DNS standard was developed to provide an alternative to Hosts files. RFCs 1034 and 1035 specify most of the core protocols and have been added to and updated by additional RFCs submitted to the Internet Engineering Task Force (IETF). The IETF reviews and approves new drafts continuously, so the standards for DNS evolve and change as needed.

For more information, see DNS RFCs.

### Notes

- DNS domain names are required to be unique at each level, but individual name labels can be reused in other domains. For example, the name "mailserver" can be used one time only in both the example.microsoft.com and microsoft.com domains.

- For more information on the use of labels, FQDNs, and other DNS host naming requirements, see Namespace planning for DNS.

- Hosts files are supported as a local static file method of mapping DNS domain names for host computers to their IP addresses. When the DNS Client service is started, it preloads any mapped entries added to this file into the local DNS names caches.

- The Hosts file is provided in the systemroot\System32\Drivers\Etc folder. To view or modify this file, you can use Notepad or another text-based editor. For more information about creating or editing the Hosts file, refer to the comments and examples in the file.

# How DNS query works

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How DNS query works**

When a DNS client needs to look up a name used in a program, it queries DNS servers to resolve the name. Each query message the client sends contains three pieces of information, specifying a question for the server to answer:

- A specified DNS domain name, stated as a fully qualified domain name (FQDN)
- A specified query type, which can either specify a resource record by type or a specialized type of query operation
- A specified class for the DNS domain name.

  For Windows DNS servers, this should always be specified as the Internet (IN) class.

For example, the name specified could be the FQDN for a computer, such as "host-a.example.microsoft.com.", and the query type specified to look for an address (A) resource record by that name. Think of a DNS query as a client asking a server a two-part question, such as "Do you have any A resource records for a computer named 'hostname.example.microsoft.com.'?" When the client receives an answer from the server, it reads and interprets the answered A resource record, learning the IP address for the computer it asked for by name.

DNS queries resolve in a number of different ways. A client can sometimes answer a query locally using cached information obtained from a previous query. The DNS server can use its own cache of resource record information to answer a query. A DNS server can also query or contact other DNS servers on behalf of the requesting client to fully resolve the name, then send an answer back to the client. This process is known as recursion.

In addition, the client itself can attempt to contact additional DNS servers to resolve a name. When a client does so, it uses separate and additional nonrecursive queries based on referral answers from servers. This process is known as iteration.

In general, the DNS query process occurs in two parts:

- A name query begins at a client computer and is passed to a resolver, the DNS Client service, for resolution.
- When the query cannot be resolved locally, DNS servers can be queried as needed to resolve the name.

Both of these processes are explained in more detail in the following sections.

**Part 1: The local resolver**

The following figure shows an overview of the complete DNS query process.

As shown in the initial steps of the query process, a DNS domain name is used in a program on the local computer. The request is then passed to the DNS Client service for resolution using locally cached information. If the queried name can be resolved, the query is answered and the process is completed.

The local resolver cache can include name information obtained from two possible sources:

- If a Hosts file is configured locally, any host name-to-address mappings from that file are preloaded into the cache when

the DNS Client service is started.

- Resource records obtained in answered responses from previous DNS queries are added to the cache and kept for a period of time.

If the query does not match an entry in the cache, the resolution process continues with the client querying a DNS server to resolve the name.

**Part 2: Querying a DNS server**
As indicated in the previous figure, the client queries a preferred DNS server. The actual server used during the initial client/server query part of the process is selected from a global list. For more information about how this global list is compiled and updated, see Client features.

When the DNS server receives a query, it first checks to see if it can answer the query authoritatively based on resource record information contained in a locally configured zone on the server. If the queried name matches a corresponding resource record in local zone information, the server answers authoritatively, using this information to resolve the queried name.

If no zone information exists for the queried name, the server then checks to see if it can resolve the name using locally cached information from previous queries. If a match is found here, the server answers with this information. Again, if the preferred server can answer with a positive matched response from its cache to the requesting client, the query is completed.

If the queried name does not find a matched answer at its preferred server -- either from its cache or zone information -- the query process can continue, using recursion to fully resolve the name. This involves assistance from other DNS servers to help resolve the name. By default, the DNS Client service asks the server to use a process of recursion to fully resolve names on behalf of the client before returning an answer. In most cases, the DNS server is configured, by default, to support the recursion process as shown in the following figure.

In order for the DNS server to do recursion properly, it first needs some helpful contact information about other DNS servers in the DNS domain namespace. This information is provided in the form of *root hints*, a list of preliminary resource records that can be used by the DNS service to locate other DNS servers that are authoritative for the root of the DNS domain namespace tree. Root servers are authoritative for the domain root and top-level domains in the DNS domain namespace tree. For more information, see Updating root hints.

By using root hints to find root servers, a DNS server is able to complete the use of recursion. In theory, this process enables any DNS server to locate the servers that are authoritative for any other DNS domain name used at any level in the namespace tree.

For example, consider the use of the recursion process to locate the name "host-b.example.microsoft.com." when the client queries a single DNS server. The process occurs when a DNS server and client are first started and have no locally cached information available to help resolve a name query. It assumes that the name queried by the client is for a domain name of which the server has no local knowledge, based on its configured zones.

First, the preferred server parses the full name and determines that it needs the location of the server that is authoritative for the top-level domain, "com". It then uses an iterative (that is, a nonrecursive) query to the "com" DNS server to obtain a referral to the "microsoft.com" server. Next, a referral answer comes from the "microsoft.com" server to the DNS server for "example.microsoft.com".

Finally, the "example.microsoft.com." server is contacted. Because this server contains the queried name as part of its configured zones, it responds authoritatively back to the original server that initiated recursion. When the original server receives the response indicating that an authoritative answer was obtained to the requested query, it forwards this answer back to the requesting client and the recursive query process is completed.

Although the recursive query process can be resource-intensive when performed as described above, it has some performance advantages for the DNS server. For example, during the recursion process, the DNS server performing the recursive lookup

obtains information about the DNS domain namespace. This information is cached by the server and can be used again to help speed the answering of subsequent queries that use or match it. Over time, this cached information can grow to occupy a significant portion of server memory resources, although it is cleared whenever the DNS service is cycled on and off.

**Alternate query responses**
The previous discussion of DNS queries assumes that the process ends with a positive response returned to the client. However, queries can return other answers as well. These are the most common:

- An authoritative answer
- A positive answer
- A referral answer
- A negative answer

An authoritative answer is a positive answer returned to the client and delivered with the authority bit set in the DNS message to indicate the answer was obtained from a server with direct authority for the queried name.

A positive response can consist of the queried RR or a list of RRs (also known as an RRset) that fits the queried DNS domain name and record type specified in the query message.

A referral answer contains additional resource records not specified by name or type in the query. This type of answer is returned to the client if the recursion process is not supported. The records are meant to act as helpful reference answers that the client can use to continue the query using iteration.

A referral answer contains additional data such as resource records (RRs) that are other than the type queried. For example, if the queried host name was "www" and no A RRs for this name were found in this zone but a CNAME RR for "www" was found instead, the DNS server can include that information when responding to the client.

If the client is able to use iteration, it can make additional queries using the referral information in an attempt to fully resolve the name for itself.

A negative response from the server can indicate that one of two possible results was encountered while the server attempted to process and recursively resolve the query fully and authoritatively:

- An authoritative server reported that the queried name does not exist in the DNS namespace.
- An authoritative server reported that the queried name exists but no records of the specified type exist for that name.

The resolver passes the results of the query, in the form of either a positive or negative response, back to the requesting program and caches the response.

**Notes**

- If the resultant answer to a query is too long to be sent and resolved in a single UDP message packet, the DNS server can initiate a failover response over TCP port 53 to answer the client fully in a TCP connected session.
- Disabling the use of recursion on a DNS server is generally done when DNS clients are being limited to resolving names to a specific DNS server, such as one located on your intranet. Recursion might also be disabled when the DNS server is incapable of resolving external DNS names, and clients are expected to fail over to another DNS server for resolution of these names.

  You can disable the use of recursion by configuring in the **Advanced** properties in the DNS console on the applicable server. For more information, see Disable recursion on the DNS server.
- If you disable recursion on the DNS server, you will not be able to use forwarders on the same server.
- By default, DNS servers use several default timings when performing a recursive query and contacting other DNS servers. These are:

- A recursion retry interval of 3 seconds. This is the length of time the DNS service waits before retrying a query made during a recursive lookup.

- A recursion time-out interval of 15 seconds. This is the length of time the DNS service waits before failing a recursive lookup that has been retried.

Under most circumstances, these parameters do not need adjustment. However, if you are using recursive lookups over a slow-speed WAN link, you might be able to improve server performance and query completion by making slight adjustments to the settings. For more information, see Tuning advanced server parameters.

**How iteration works**

Iteration is the type of name resolution used between DNS clients and servers when the following conditions are in effect:

- The client requests the use of recursion, but recursion is disabled on the DNS server.

- The client does not request the use of recursion when querying the DNS server.

An iterative request from a client tells the DNS server that the client expects the best answer the DNS server can provide immediately, without contacting other DNS servers.

When iteration is used, a DNS server answers a client based on its own specific knowledge about the namespace with regard to the names data being queried. For example, if a DNS server on your intranet receives a query from a local client for "www.microsoft.com", it might return an answer from its names cache. If the queried name is not currently stored in the names cache of the server, the server might respond by providing a referral -- that is, a list of NS and A resource records for other DNS servers that are closer to the name queried by the client.

When a referral is made, the DNS client assumes responsibility to continue making iterative queries to other configured DNS servers to resolve the name. For example, in the most involved case, the DNS client might expand its search as far as the root domain servers on the Internet in an effort to locate the DNS servers that are authoritative for the "com" domain. Once it contacts the Internet root servers, it can be given further iterative responses from these DNS servers that point to actual Internet DNS servers for the "microsoft.com" domain. When the client is provided records for these DNS servers, it can send another iterative query to the external Microsoft DNS servers on the Internet, which can respond with a definitive and authoritative answer.

When iteration is used, a DNS server can further assist in a name query resolution beyond giving its own best answer back to the client. For most iterative queries, a client uses its locally configured list of DNS servers to contact other name servers throughout the DNS namespace if its primary DNS server cannot resolve the query.

**How caching works**

As DNS servers process client queries using recursion or iteration, they discover and acquire a significant store of information about the DNS namespace. This information is then cached by the server.

Caching provides a way to speed the performance of DNS resolution for subsequent queries of popular names, while substantially reducing DNS-related query traffic on the network.

As DNS servers make recursive queries on behalf of clients, they temporarily cache resource records (RRs). Cached RRs contain information obtained from DNS servers that are authoritative for DNS domain names learned while making iterative queries to search and fully answer a recursive query performed on behalf of a client. Later, when other clients place new queries that request RR information matching cached RRs, the DNS server can use the cached RR information to answer them.

When information is cached, a Time-To-Live (TTL) value applies to all cached RRs. As long as the TTL for a cached RR does not expire, a DNS server can continue to cache and use the RR again when answering queries by its clients that match these RRs. Caching TTL values used by RRs in most zone configurations are assigned the **Minimum (default) TTL** which is set used in the zone's start of authority (SOA) resource record. By default, the minimum TTL is 3,600 seconds (1 hour) but can be adjusted or, if needed, individual caching TTLs can be set at each RR.

**Notes**

- You can install a DNS server as a caching-only server. For more information, see Using caching-only servers.

- By default, DNS servers use a root hints file, Cache.dns, that is stored in the systemroot\System32\Dns folder on the server computer. The contents of this file are preloaded into server memory when the service is started and contain

pointer information to root servers for the DNS namespace where you are operating DNS servers. For more information about this file or how it is used, see DNS-related files.

# Understanding zones and zone transfer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding zones and zone transfer**
Domain Name System (DNS) allows a DNS namespace to be divided up into zones, which store name information about one or more DNS domains. For each DNS domain name included in a zone, the zone becomes the authoritative source for information about that domain.

**Understanding the difference between zones and domains**
A zone starts as a storage database for a single DNS domain name. If other domains are added below the domain used to create the zone, these domains can either be part of the same zone or belong to another zone. Once a subdomain is added, it can then either be:

- Managed and included as part of the original zone records, or
- Delegated away to another zone created to support the subdomain

For example, the following figure shows the microsoft.com domain, which contains domain names for Microsoft. When the microsoft.com domain is first created at a single server, it is configured as a single zone for all of the Microsoft DNS namespace. If, however, the microsoft.com domain needs to use subdomains, those subdomains must be included in the zone or delegated away to another zone.

In this example, the example.microsoft.com domain shows a new subdomain -- the example.microsoft.com domain -- delegated away from the microsoft.com zone and managed in its own zone. However, the microsoft.com zone needs to contain a few resource records to provide the delegation information that references the DNS servers that are authoritative for the delegated example.microsoft.com subdomain.

If the microsoft.com zone does not use delegation for a subdomain, any data for the subdomain remains part of the microsoft.com zone. For example, the subdomain dev.microsoft.com is not delegated away but is managed by the microsoft.com zone.

**Why zone replication and zone transfers are needed**
Because of the important role that zones play in DNS, it is intended that they be available from more than one DNS server on the network to provide availability and fault tolerance when resolving name queries. Otherwise, if a single server is used and that server is not responding, queries for names in the zone can fail. For additional servers to host a zone, zone transfers are required to replicate and synchronize all copies of the zone used at each server configured to host the zone.

When a new DNS server is added to the network and is configured as a new secondary server for an existing zone, it performs a full initial transfer of the zone to obtain and replicate a full copy of resource records for the zone. For most earlier DNS server implementations, this same method of full transfer for a zone is also used when the zone requires updating after changes are made to the zone. For DNS servers running Windows Server 2003, the DNS service supports *incremental zone transfer*, a revised DNS zone transfer process for intermediate changes.

**Incremental zone transfers**
Incremental zone transfers are described in Request for Comments (RFC) 1995 as an additional DNS standard for replicating DNS zones. For more information about RFCs, see the RFC Editor Web site. When incremental transfers are supported by both a DNS server acting as the source for a zone and any servers that copy the zone from it, it provides a more efficient method of propagating zone changes and updates.

In earlier DNS implementations, any request for an update of zone data required a full transfer of the entire zone database using an AXFR query. With incremental transfer, an alternate query type (IXFR) can be used instead. This allows the secondary server to pull only those zone changes it needs to synchronize its copy of the zone with its source, either a primary or secondary copy of the zone maintained by another DNS server.

With IXFR zone transfers, differences between the source and replicated versions of the zone are first determined. If the zones are identified to be the same version -- as indicated by the serial number field in the start of authority (SOA) resource record of each zone -- no transfer is made.

If the serial number for the zone at the source is greater than at the requesting secondary server, a transfer is made of only those changes to resource records (RRs) for each incremental version of the zone. For an IXFR query to succeed and changes to be sent, the source DNS server for the zone must keep a history of incremental zone changes to use when answering these queries. The incremental transfer process requires substantially less traffic on a network and zone transfers are completed much faster.

**Example: Zone transfer**
A zone transfer might occur during any of the following scenarios:

- When the refresh interval expires for the zone
- When a secondary server is notified of zone changes by its master server
- When the DNS Server service is started at a secondary server for the zone
- When the DNS console is used at a secondary server for the zone to manually initiate a transfer from its master server

Zone transfers are always initiated at the secondary server for a zone and sent to their configured master servers which act as their source for the zone. Master servers can be any other DNS server that loads the zone, such as either the primary server for the zone or another secondary server. When the master server receives the request for the zone, it can reply with either a partial or full transfer of the zone to the secondary server.

As shown in the following figure, zone transfers between servers follow an ordered process. This process varies depending on whether a zone has been previously replicated, or if initial replication of a new zone is being performed.

In this example, the following sequence is performed for a requesting secondary server -- the destination server -- for a zone and its source server, another DNS server that hosts the zone.

1. During new configuration, the destination server sends an initial "all zone" transfer (AXFR) request to the master DNS server configured as its source for the zone.

2. The master (source) server responds and fully transfers the zone to the secondary (destination) server.

   The zone is delivered to the destination server requesting the transfer with its version established by use of a **Serial number** field in the properties for the start of authority (SOA) resource record (RR). The SOA RR also contains a stated refresh interval in seconds (by default, 900 seconds or 15 minutes) to indicate when the destination server should next request to renew the zone with the source server.

3. When the refresh interval expires, an SOA query is used by the destination server to request renewal of the zone from the source server.

4. The source server answers the query for its SOA record.

   This response contains the serial number for the zone in its current state at the source server.

5. The destination server checks the serial number of the SOA record in the response and determines how to renew the zone.

   If the value of the serial number in the SOA response is equal to its current local serial number, it concludes that the zone is the same at both servers and that a zone transfer is not needed. The destination server then renews the zone by resetting its refresh interval based on the value of this field in the SOA response from its source server.

   If the value of the serial number in the SOA response is higher than its current local serial number, it concludes that the zone has been updated and that a transfer is needed.

6. If the destination server concludes that the zone has changed, it sends an IXFR query to the source server, containing its current local value for the serial number in the SOA record for the zone.

7. The source server responds with either an incremental or full transfer of the zone.

   If the source server supports incremental transfer by maintaining a history of recent incremental zone changes for modified resource records, it can answer with an incremental zone transfer (IXFR) of the zone.

   If the source server does not support incremental transfer, or does not have a history of zone changes, it can answer with a full (AXFR) transfer of the zone instead.

**Note**

- For servers running Windows 2000 and Windows Server 2003, incremental zone transfer through IXFR query is supported. For earlier versions of the DNS service and for many other DNS server implementations, incremental zone transfer is not available and only full-zone (AXFR) queries and transfers are used to replicate zones.

**DNS Notify**

Windows-based DNS servers support DNS Notify, an update to the original DNS protocol specification that permits a means of initiating notification to secondary servers when zone changes occur (RFC 1996). DNS notification implements a push mechanism for notifying a select set of secondary servers for a zone when it is updated. Servers that are notified can then initiate a zone transfer as described above to pull zone changes from their master servers and update their local replicas of the zone.

For secondaries to be notified by the DNS server acting as their configured source for a zone, each secondary server must first have its IP address in the notify list of the source server. When using the DNS console, this list is maintained in the **Notify** dialog box, which is accessible from the **Zone Transfer** tab located in *zone***Properties**.

In addition to notifying the listed servers, the DNS console permits you to use the contents of the notify list as a means to restrict or limit zone transfer access to only those secondary servers specified in the list. This can help prevent an undesired attempt by an unknown or unapproved DNS server to pull, or request, zone updates. For more information, see Create and manage a notify list for a zone.

The following is a brief summary of the typical DNS notification process for zone updates:

1. The local zone at a DNS server acting as a master server, a source for the zone to other servers, is updated. When the zone is updated at the master or source server, the serial number field in the SOA RR is also updated, indicating a new local version of the zone.

2. The master server sends a DNS notify message to other servers that are part of its configured notify list.

3. All secondary servers that receive the notify message can then respond by initiating a zone transfer request back to the notifying master server.

The normal zone transfer process can then continue as described in the previous section.

You cannot configure a notify list for a stub zone.

**Important**

- Use DNS notification only to notify servers operating as secondary servers for a zone. For replication of directory-integrated zones, DNS notification is not needed.

  This is because any DNS servers that load a zone from Active Directory automatically poll the directory (as specified by the SOA resource record's Refresh Interval) to update and refresh the zone.

  In these cases, configuring a notify list can actually degrade system performance by causing unnecessary additional transfer requests for the updated zone.

**Notes**

- By default, the DNS server will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Reverse lookup

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Reverse lookup**

In most DNS lookups, clients typically perform a forward lookup, which is a search based on the DNS name of another computer as stored in an address (A) resource record. This type of query expects an IP address as the resource data for the answered response.

DNS also provides a reverse lookup process, enabling clients to use a known IP address during a name query and look up a computer name based on its address. A reverse lookup takes the form of a question, such as "Can you tell me the DNS name of the computer that uses the IP address 192.168.1.20?"

DNS was not originally designed to support this type of query. One problem for supporting the reverse query process is the difference in how the DNS namespace organizes and indexes names and how IP addresses are assigned. If the only method to answer the previous question was to search in all domains in the DNS namespace, a reverse query would take too long and require too much processing to be useful.

To solve this problem, a special domain, the in-addr.arpa domain, was defined in the DNS standards and reserved in the Internet DNS namespace to provide a practical and reliable way to perform reverse queries. To create the reverse namespace, subdomains within the in-addr.arpa domain are formed using the reverse ordering of the numbers in the dotted-decimal notation of IP addresses.

This reversed ordering of the domains for each octet value is needed because, unlike DNS names, when IP addresses are read from left to right, they are interpreted in the opposite manner. When an IP address is read from left to right, it is viewed from its most generalized information (an IP network address) in the first part of the address to the more specific information (an IP host address) contained in the last octets.

For this reason, the order of IP address octets must be reversed when building the in-addr.arpa domain tree. The IP addresses of the DNS in-addr.arpa tree can be delegated to companies as they are assigned a specific or limited set of IP addresses within the Internet-defined address classes.

Finally, the in-addr.arpa domain tree, as built into DNS, requires that an additional resource record (RR) type — the pointer (PTR) RR — be defined. This RR is used to create a mapping in the reverse lookup zone that typically corresponds to a host (A) named RR for the DNS computer name of a host in its forward lookup zone.

### Note

- The in-addr.arpa domain applies for use in all TCP/IP networks that are based on Internet Protocol version 4 (IPv4) addressing. The New Zone Wizard automatically assumes that you are using this domain when creating a new reverse lookup zone.

  If you are installing DNS and configuring reverse lookup zones for an Internet Protocol version 6 (IPv6) network, you can specify an exact name in the New Zone wizard. This will permit you to create reverse lookup zones in the DNS console that can be used to support IPv6 networks, which uses a different special domain name, the ip6.arpa domain.

  Additional information is available on IPv6 and DNS, including examples of how to create and use ip6.arpa domain names in Request for Comments (RFC) 3596, "DNS Extensions to support IP version 6." For more information, refer directly to this RFC, which can be obtained from the RFC Editor Web site.

**Example: Reverse query (for IPv4 networks)**

The following figure shows an example of a reverse query initiated by a DNS client (host-b) to learn the name of another host (host-a) based on its IP address, 192.168.1.20.

The reverse query process as shown in this figure occurs in the following steps:

1. The client, "host-b", queries the DNS server for a pointer (PTR) RR that maps to the IP address of 192.168.1.20 for "host-a".

   Because the query is for PTR records, the resolver reverses the address and appends the in-addr.arpa domain to the end of the reverse address. This forms the fully qualified domain name ("20.1.168.192.in-addr.arpa.") for which to be searched in a reverse lookup zone.

2. Once located, the authoritative DNS server for "20.1.168.192.in-addr.arpa" can respond with the PTR record information. This includes the DNS domain name for "host-a", completing the reverse lookup process.

Keep in mind that if the queried reverse name is not answerable from the DNS server, normal DNS resolution (either recursion or iteration) can be used to locate a DNS server that is authoritative for the reverse lookup zone and that contains the queried name. In this sense, the name resolution process used in a reverse lookup is identical to that of a forward lookup.

**Note**

- The DNS console provides a means for you to configure a subnetted reverse lookup "classless" zone when the **Advanced** view is selected. This allows you to configure a zone in the in-addr.arpa domain for a limited set of assigned IP addresses where a nondefault IP subnet mask is used with those addresses. For more information, see Managing reverse lookup zones.

**Inverse queries**

Inverse queries are an outdated practice, originally proposed as part of the DNS standard to look up a host name based on its IP address. They use a nonstandard DNS query operation, and their use is limited to some of the earlier versions of Nslookup, a command-line utility for troubleshooting and testing DNS service.

The DNS service recognizes and accepts inverse query messages, answering them with a fake inverse query response. For DNS servers running in Windows NT Server 4.0, this support is available by default if the server computer has been updated to Service Pack 4 (SP4) or later.

**Notes**

- The configuration of PTR resource records and reverse lookup zones for identifying hosts by reverse query is strictly an optional part of the DNS standard implementation. You are not required to use reverse lookup zones, although for some networked applications, they are used to perform security checks.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Understanding forwarders

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding forwarders**

A forwarder is a Domain Name System (DNS) server on a network used to forward DNS queries for external DNS names to DNS servers outside of that network. You can also forward queries according to specific domain names using *conditional forwarders*.

A DNS server on a network is designated as a forwarder by having the other DNS servers in the network forward the queries they cannot resolve locally to that DNS server. By using a forwarder, you can manage name resolution for names outside of your network, such as names on the Internet, and improve the efficiency of name resolution for the computers in your network. For more information about forwarders and conditional forwarders, see Using forwarders.

The following figure illustrates how external name queries are directed using forwarders.

For more information about directing external queries, see Directing queries through forwarders.

Without having a specific DNS server designated as a forwarder, *all* DNS servers can send queries outside of a network using their root hints. As a result, a lot of internal, and possibly critical, DNS information can be exposed on the Internet. In addition to this security and privacy issue, this method of resolution can result in a large volume of external traffic that is costly and inefficient for a network with a slow Internet connection or a company with high Internet service costs.

When you designate a DNS server as a forwarder, you make that forwarder responsible for handling external traffic, thereby limiting DNS server exposure to the Internet. A forwarder will build up a large cache of external DNS information because all of the external DNS queries in the network are resolved through it. In a small amount of time, a forwarder will resolve a good portion of external DNS queries using this cached data and thereby decrease the Internet traffic over the network and the response time for DNS clients.

A DNS server configured to use a forwarder will behave differently than a DNS server that is not configured to use a forwarder. A DNS server configured to use a forwarder behaves as follows:

1. When the DNS server receives a query, it attempts to resolve this query using the primary and secondary zones that it hosts and its cache.

2. If the query cannot be resolved using this local data, then it will forward the query to the DNS server designated as a forwarder.

3. The DNS server will wait briefly for an answer from the forwarder before attempting to contact the DNS servers specified in its root hints.

When a DNS server forwards a query to a forwarder it sends a recursive query to the forwarder. This is different than the iterative query that a DNS server will send to an other DNS server during standard name resolution (name resolution that does not involve a forwarder).

**Conditional forwarders**

A conditional forwarder is a DNS server on a network that is used to forward DNS queries according to the DNS domain name in the query. For example, a DNS server can be configured to forward all the queries it receives for names ending with

widgets.example.com to the IP address of a specific DNS server or to the IP addresses of multiple DNS servers.

**Intranet name resolution**

A conditional forwarder can be used to improve name resolution for domains within your intranet. Intranet name resolution can be improved by configuring DNS servers with forwarders for specific internal domain names. For example, all DNS servers in the domain widgets.example.com could be configured to forward queries for names that end with test.example.com to the authoritative DNS servers for merged.widgets.example.com, thereby removing the step of querying the root servers of example.com, or removing the step of configuring DNS servers in the widgets.example.com zone with secondary zones for test.example.com.

**Internet name resolution**

DNS servers can use conditional forwarders to resolve queries between the DNS domain names of companies that share information. For example, two companies, Widgets Toys and TailspinToys, want to improve how the DNS clients of Widgets Toys resolve the names of the DNS clients of Tailspin Toys. The administrators from Tailspin Toys inform the administrators of Widgets Toys about the set of DNS servers in the Tailspin Toys network where Widgets can send queries for the domain dolls.tailspintoys.com. The DNS servers within the Widgets Toys network are configured to forward all queries for names ending with dolls.tailspintoys.com to the designated DNS servers in the network for Tailspin Toys. Consequently, the DNS servers in the Widgets Toys network do not need to query their internal root servers, or the Internet root servers, to resolve queries for names ending with dolls.tailspintoys.com.

# Understanding stub zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding stub zones**

A stub zone is a copy of a zone that contains only those resource records necessary to identify the authoritative Domain Name System (DNS) servers for that zone. A stub zone is used to resolve names between separate DNS namespaces. This type of resolution may be necessary when a corporate merger requires that the DNS servers for two separate DNS namespaces resolve names for clients in both namespaces.

A stub zone consists of:

- The start of authority (SOA) resource record, name server (NS) resource records, and the glue A resource records for the delegated zone.
- The IP address of one or more master servers that can be used to update the stub zone.

The master servers for a stub zone are one or more DNS servers authoritative for the child zone, usually the DNS server hosting the primary zone for the delegated domain name.

For more information, see Using stub zones.

**Stub zone resolution**

When a DNS client performs a recursive query operation on a DNS server hosting a stub zone, the DNS server uses the resource records in the stub zone to resolve the query. The DNS server sends an iterative query to the authoritative DNS servers specified in the NS resource records of the stub zone as if it were using NS resource records in its cache. If the DNS server cannot find the authoritative DNS servers in its stub zone, the DNS server hosting the stub zone attempts standard recursion using its root hints.

The DNS server will store the resource records it receives from the authoritative DNS servers listed in a stub zone in its cache, but it will not store these resource records in the stub zone itself; only the SOA, NS, and glue A resource records returned in response to the query are stored in the stub zone. The resource records stored in the cache are cached according to the Time-to-Live (TTL) value in each resource record. The SOA, NS, and glue A resource records, which are not written to cache, expire according to the expire interval specified in the stub zone's SOA record, which is created during the creation of the stub zone and updated during transfers to the stub zone from the original, primary zone.

If the query was an iterative query, the DNS server returns a referral containing the servers specified in the stub zone.

**Communication between DNS servers hosting parent and child zones**

A DNS server that has delegated a domain to a child zone on a different DNS server is made aware of new authoritative DNS servers for the child zone only when the resource records for these new DNS servers are added to the parent zone hosted on the DNS server. This is a manual process and requires that the administrators for the different DNS servers communicate often. With stub zones, a DNS server hosting a stub zone for one of its delegated domains can obtain updates of the authoritative DNS servers for the child zone when the stub zone is updated. The update is performed from the DNS server hosting the stub zone and the administrator for the DNS server hosting the child zone does not need to be contacted. This functionality is explained in the following example.

For more information, see Active Directory-integrated stub zones, Understanding zones and zone transfer, and Delegating zones.

# Dynamic update

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dynamic update**
Dynamic update enables DNS client computers to register and dynamically update their resource records with a DNS server whenever changes occur. This reduces the need for manual administration of zone records, especially for clients that frequently move or change locations and use DHCP to obtain an IP address.

The DNS Client and Server services support the use of dynamic updates, as described in Request for Comments (RFC) 2136, "Dynamic Updates in the Domain Name System." The DNS Server service allows dynamic update to be enabled or disabled on a per-zone basis at each server configured to load either a standard primary or directory-integrated zone. By default, the DNS Client service will dynamically update host (A) resource records (RRs) in DNS when configured for TCP/IP. For more information about RFCs, see DNS RFCs.

**How client and server computers update their DNS names**
By default, computers that are statically configured for TCP/IP attempt to dynamically register host (A) and pointer (PTR) resource records (RRs) for IP addresses configured and used by their installed network connections. By default, all computers register records based on their fully qualified domain name (FQDN).

The primary full computer name, a FQDN, is based on the **primary DNS suffix of a computer** appended to its **Computer name**.

Both of these settings are displayed or configured from the **Computer Name** tab in **System properties**. For more information, see View system properties.

**Notes**

- By default, the DNS client on Windows XP does not attempt dynamic update over a Remote Access Service (RAS) or virtual private network (VPN) connection. To modify this configuration, you can modify the advanced TCP/IP settings of the particular network connection or modify the registry. For more information, see Configure TCP/IP to use DNS and the Microsoft Windows Resource Kits Web site.

- By default, the DNS client does not attempt dynamic update of top-level domain (TLD) zones. Any zone named with a single-label name is considered a TLD zone, for example, com, edu, blank, my-company. To configure the DNS client to allow the dynamic update of TLD zones, you can use the **Update Top Level Domain Zones** policy setting or modify the registry.

- By default, the primary DNS suffix portion of a computer's FQDN is the same as the name of the Active Directory domain to which the computer is joined. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by modifying the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is managed by the domain administrator using Active Directory Service Interfaces (ADSI) or the Lightweight Directory Access Protocol (LDAP).

  For more information, see Programming interfaces and Directory access protocol.

Dynamic updates can be sent for any of the following reasons or events:

- An IP address is added, removed, or modified in the TCP/IP properties configuration for any one of the installed network connections.

- An IP address lease changes or renews with the DHCP server any one of the installed network connections. For example, when the computer is started or if the **ipconfig /renew** command is used.

- The **ipconfig /registerdns** command is used to manually force a refresh of the client name registration in DNS.

- At startup time, when the computer is turned on.

- A member server is promoted to a domain controller.

When one of the previous events triggers a dynamic update, the DHCP Client service (not the DNS Client service) sends updates. This is designed so that if a change to the IP address information occurs because of DHCP, corresponding updates in DNS are performed to synchronize name-to-address mappings for the computer. The DHCP Client service performs this function for all network connections used on the system, including connections not configured to use DHCP.

**Notes**

- The process of how dynamic updates are performed for computers running Windows 2000, Windows XP, or Windows Server 2003 operating systems that use DHCP to obtain their IP address is different than is described in this section. For more information, see Using DNS servers with DHCP.

- The update process described in this section assumes that installation defaults are in effect for computers running Windows 2000, Windows XP, or servers running Windows Server 2003. Specific names and update behavior is tunable where advanced TCP/IP properties are configured to use non-default DNS settings.

  In addition to the full computer name (or primary name) of the computer, additional connection-specific DNS names can be configured and optionally registered or updated in DNS. For more information, see Configuring multiple names or Configure TCP/IP to use DNS.

**Example: How dynamic update works**

Dynamic updates are typically requested when either a DNS name or IP address changes on the computer. For example, suppose a client named "oldhost" is first configured in **System properties** with the following names:

| | |
|---|---|
| **Computer name** | oldhost |
| **DNS domain name of computer** | example.microsoft.com |
| **Full computer name** | oldhost.example.microsoft.com |

In this example, no connection-specific DNS domain names are configured for the computer. Later, the computer is renamed from "oldhost" to "newhost", resulting in the following name changes on the system:

| | |
|---|---|
| **Computer name** | newhost |
| **DNS domain name of computer** | example.microsoft.com |
| **Full computer name** | newhost.example.microsoft.com |

Once the name change is applied in **System properties**, you are prompted to restart the computer. When the computer restarts Windows, the DHCP Client service performs the following sequence to update DNS:

1. **The DHCP Client service sends a start of authority (SOA) type query using the DNS domain name of the computer.**

   The client computer uses the currently configured FQDN of the computer (such as "newhost.example.microsoft.com") as the name specified in this query.

2. **The authoritative DNS server for the zone containing the client FQDN responds to the SOA-type query.**

   For standard primary zones, the primary server (owner) returned in the SOA query response is fixed and static. It always matches the exact DNS name as it appears in the SOA RR stored with the zone. If, however, the zone being updated is directory-integrated, any DNS server loading the zone can respond and dynamically insert its own name as the primary server (owner) of the zone in the SOA query response.

3. **The DHCP Client service then attempts to contact the primary DNS server.**

   The client processes the SOA query response for its name to determine the IP address of the DNS server authorized as

the primary server for accepting its name. It then proceeds to perform the following sequence of steps as needed to contact and dynamically update its primary server:

a. It sends a dynamic update request to the primary server determined in the SOA query response.

   If the update succeeds, no further action is taken.

b. If this update fails, the client next sends an NS-type query for the zone name specified in the SOA record.

c. When it receives a response to this query, it sends an SOA query to the first DNS server listed in the response.

d. After the SOA query is resolved, the client sends a dynamic update to the server specified in the returned SOA record.

   If the update succeeds, no further action is taken.

e. If this update fails, then the client repeats the SOA query process by sending to the next DNS server listed in the response.

4. **Once the primary server is contacted that can perform the update, the client sends the update request and the server processes it.**

   The contents of the update request include instructions to add A (and possibly PTR) RRs for "newhost.example.microsoft.com" and remove these same record types for "oldhost.example.microsoft.com", the name that was previously registered.

   The server also checks to ensure that updates are permitted for the client request. For standard primary zones, dynamic updates are not secured, so any client attempt to update succeeds. For Active Directory-integrated zones, updates are secured and performed using directory-based security settings.

Dynamic updates are sent or refreshed periodically. By default, computers send a refresh once every 7 days. If the update results in no changes to zone data, the zone remains at its current version and no changes are written. Updates result in actual zone changes or increased zone transfer only if names or addresses actually change.

Note that names are not removed from DNS zones if they become inactive or are not updated within the refresh interval (7 days). DNS does not use a mechanism to release or tombstone names, although DNS clients do attempt to delete or update old name records when a new name or address change is applied.

When the DHCP Client service registers A and PTR resource records for a computer, it uses a default caching Time to Live (TTL) of 15 minutes for host records. This determines how long other DNS servers and clients cache a computer's records when they are included in a query response.

**Secure dynamic update**

DNS update security is available only for zones that are integrated into Active Directory. Once you directory-integrate a zone, access control list (ACL) editing features are available in the DNS console so you can add or remove users or groups from the ACL for a specified zone or resource record. For more information, see Modify security for a resource record or Modify security for a directory-integrated zone.

By default, dynamic update security for DNS servers and clients can be handled as follows:

- **DNS clients attempt to use unsecured dynamic update first. If an unsecured update is refused, clients try to use secure update.**

  Also, clients use a default update policy that permits them to attempt to overwrite a previously registered resource record, unless they are specifically blocked by update security.

- **Once a zone becomes Active Directory-integrated, DNS servers running Windows Server 2003 default to allowing only secure dynamic updates.**

  When using standard zone storage, the default for the DNS Server service is to not allow dynamic updates on its zones.

For zones that are either directory-integrated or use standard file-based storage, you can change the zone to allow all dynamic updates which permits all updates to be accepted.

**Important**

- The DHCP Server service can perform proxy registration and update of DNS records for legacy clients that do not support dynamic updates.

  For information, see Using DNS servers with DHCP.

**Notes**

- Dynamic update is a recent additional DNS standard specification, defined in RFC 2136. For more information, refer to the RFC. For information on obtaining RFCs, see TCP/IP RFCs.

- For more information about DNS dynamic updates and secure updates, see Using the Windows Deployment and Resource Kits.

- The dynamic registration of DNS resource records can be restricted with the use of registry entries. For more information, see article Q246804, "How to Enable/Disable Windows 2000 Dynamic DNS Registrations," in the Microsoft Knowledge Base.

# Active Directory integration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory integration**
The DNS Server service is integrated into the design and implementation of Active Directory. Active Directory provides an enterprise-level tool for organizing, managing, and locating resources in a network.

**Note**

- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

When deploying DNS servers with Active Directory, consider the following:

- **DNS is required for locating domain controllers running Windows Server 2003.**

  The Net Logon service uses new DNS server support to provide registration of domain controllers in your DNS domain namespace.

- **DNS servers running Windows Server 2003 can use Active Directory for storing and replicating your zones.**

  By directory integrating your zones, you can take advantage of DNS features such as secure dynamic updates and record aging and scavenging features.

  For more information, see either Dynamic update or Understanding aging and scavenging.

**How DNS integrates with Active Directory**
When you install Active Directory on a server, you promote the server to the role of a domain controller for a specified domain. When completing this process, you are prompted to specify a DNS domain name for the Active Directory domain for which you are joining and promoting the server.

If during this process, a DNS server authoritative for the domain that you specified either cannot be located on the network or does not support the DNS dynamic update protocol, you are prompted with the option to install a DNS server. This option is provided because a DNS server is required to locate this server or other domain controllers for members of an Active Directory domain. For more information about how computers locate domain controllers using DNS, see the Using the Windows Deployment and Resource Kits.

Once you have installed Active Directory, you have two options for storing and replicating your zones when operating the DNS server at the new domain controller:

- **Standard zone storage, using a text-based file.**

  Zones stored this way are located in .Dns files that are stored in the systemroot\System32\Dns folder on each computer operating a DNS server. Zone file names correspond to the name you choose for the zone when creating it, such as example.microsoft.com.dns if the zone name was "example.microsoft.com."

- **Directory-integrated zone storage, using the Active Directory database.**

  Zones stored this way are located in the Active Directory tree under the domain or application directory partition. Each directory-integrated zone is stored in a *dnsZone* container object identified by the name you choose for the zone when creating it. For more information, see DNS zone replication in Active Directory and Directory data store.

**Benefits of Active Directory integration**
For networks deploying DNS to support Active Directory, directory-integrated primary zones are strongly recommended and provide the following benefits:

- **Multimaster update and enhanced security based on the capabilities of Active Directory.**

  In a standard zone storage model, DNS updates are conducted based upon a single-master update model. In this model, a single authoritative DNS server for a zone is designated as the primary source for the zone.

  This server maintains the master copy of the zone in a local file. With this model, the primary server for the zone represents a single fixed point of failure. If this server is not available, update requests from DNS clients are not processed for the zone.

  With directory-integrated storage, dynamic updates to DNS are conducted based upon a multimaster update model.

  In this model, any authoritative DNS server, such as a domain controller running a DNS server, is designated as a primary source for the zone. Because the master copy of the zone is maintained in the Active Directory database, which is fully replicated to all domain controllers, the zone can be updated by the DNS servers operating at any domain controller for the domain.

  With the multimaster update model of Active Directory, any of the primary servers for the directory-integrated zone can process requests from DNS clients to update the zone as long as a domain controller is available and reachable on the network.

  Also, when using directory-integrated zones, you can use access control list (ACL) editing to secure a dnsZone object container in the directory tree. This feature provides granulated access to either the zone or a specified RR in the zone.

  For example, an ACL for a zone RR can be restricted so that dynamic updates are only allowed for a specified client computer or a secure group such as a domain administrators group. This security feature is not available with standard primary zones.

  Note that when you change the zone type to be directory-integrated, the default for updating the zone changes to allow only secure updates. Also, while you may use ACLs on DNS-related Active Directory objects, ACLs may only be applied to the DNS client service.

- **Zones are replicated and synchronized to new domain controllers automatically whenever a new one is added to an Active Directory domain.**

  Although DNS service can be selectively removed from a domain controller, directory-integrated zones are already stored at each domain controller, so zone storage and management is not an additional resource. Also, the methods used to synchronize directory-stored information offer performance improvement over standard zone update methods, which can potentially require transfer of the entire zone.

- **By integrating storage of your DNS zone databases in Active Directory, you can streamline database replication planning for your network.**

  When your DNS namespace and Active Directory domains are stored and replicated separately, you need to plan and potentially administer each separately. For example, when using standard DNS zone storage and Active Directory together, you would need to design, implement, test, and maintain two different database replication topologies. For instance, one replication topology is needed for replicating directory data between domain controllers, and another topology would be needed for replicating zone databases between DNS servers.

  This can create additional administrative complexity for planning and designing your network and allowing for its eventual growth. By integrating DNS storage, you unify storage management and replication issues for both DNS and Active Directory, merging and viewing them together as a single administrative entity.

- **Directory replication is faster and more efficient than standard DNS replication.**

  Because Active Directory replication processing is performed on a per-property basis, only relevant changes are propagated. This allows less data to be used and submitted in updates for directory-stored zones.

**Notes**

- Only primary zones can be stored in the directory. A DNS server cannot store secondary zones in the directory. It must store them in standard text files. The multimaster replication model of Active Directory removes the need for secondary zones when all zones are stored in Active Directory.

- The DNS Server service includes an option to initialize the DNS Server service by reading parameters stored in the Active Directory database and the server registry. This is the default boot option. For more information, see Modifying server defaults.

- For more information about configuring DNS for Active Directory integration, see Configure a DNS server for use with Active Directory and Checklist: Verifying DNS before installing Active Directory.

# DNS zone replication in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS zone replication in Active Directory**
DNS zones can be stored in the domain or application directory partitions of Active Directory. A partition is a data structure within Active Directory used to distinguish data for different replication purposes. For more information, see Active Directory integration.

**Important**

- If you are changing the storage of a zone from the domain partition to an application directory partition, such as following the promotion of a new Windows Server 2003 domain controller in an existing Windows 2000 domain, the domain controller holding the domain naming master role must be running Windows Server 2003 for the DNS application directory partitions to exist. If you receive an error when changing the storage of a zone from the domain partition to an application directory partition, transfer the domain naming master role to a domain controller running Windows Server 2003, create the default DNS application directory partitions, and try again. For more information about creating the default DNS application directory partitions and transfering the domain naming master role, see Create the default DNS application directory partitions; Transfer the domain naming master role.

The following table describes the available zone replication scopes for Active Directory-integrated DNS zone data.

| Zone replication scope | Description |
|---|---|
| All DNS servers in the Active Directory forest | Replicates zone data to all DNS servers running on domain controllers in the Active Directory forest. Usually, this is the broadest scope of replication. |
| All DNS servers in the Active Directory domain | Replicates zone data to all DNS servers running on domain controllers in the Active Directory domain. This option is the default setting for Active Directory-integrated DNS zone replication in the Windows Server 2003 family. |
| All domain controllers in the Active Directory domain | Replicates zone data to all domain controllers in the Active Directory domain. If you want Windows 2000 DNS servers to load an Active Directory zone, this setting must be selected for that zone. |
| All domain controllers in a specified application directory partition | Replicates zone data according to the replication scope of the specified application directory partition. For a zone to be stored in the specified application directory partition, the DNS server hosting the zone must be enlisted in the specified application directory partition. For more information, see Create a DNS application directory partition and Enlist a DNS server in a DNS application directory partition. |

When deciding which replication option to choose, consider that the broader the replication scope, the greater the network traffic caused by replication. For example, if you choose to have Active Directory-integrated DNS zone data replicated to all DNS servers in the forest, this will produce greater network traffic than replicating the DNS zone data to all DNS servers in a single Active Directory domain in that forest. For information about changing zone replication scope, see Change zone replication scope.

**Notes**

- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

- Active Directory-integrated DNS zone data stored in an application directory partition is not replicated to the global

catalog for the forest. The domain controller that contains the global catalog can also host application directory partitions, but it will not replicate this data to its global catalog.

Active Directory-integrated DNS zone data stored in a domain partition is replicated to all domain controllers in its Active Directory domain and a portion of this data is stored in the global catalog. This setting is used to support Windows 2000.

- If an application directory partition's replication scope replicates across Active Directory sites, replication will occur with the same intersite replication schedule as used for domain partition data.

- Root hints are stored in the domain-wide application directory partition if the domain functional level is set to Windows Server 2003 . If the domain functional level is set to Windows 2000 mixed or Windows 2000 native, root hints are stored in the domain partition. For more information about functional levels, see Domain and forest functionality.

- By default, the Net Logon service registers domain controller locator (Locator) DNS resource records for the application directory partitions hosted on a domain controller in the same manner as it registers domain controller locator (Locator) DNS resource records for the domain partition hosted on a domain controller.

# DNS requirements for installing Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS requirements for installing Active Directory**

When you install Active Directory on a member server, the member server is promoted to a domain controller. Active Directory uses DNS as the location mechanism for domain controllers, enabling computers on the network to obtain IP addresses of domain controllers.

During the installation of Active Directory, the service (SRV) and address (A) resource records are dynamically registered in DNS, which are necessary for the successful functionality of the domain controller locator (Locator) mechanism.

To find domain controllers in a domain or forest, a client queries DNS for the SRV and A DNS resource records of the domain controller, which provide the client with the names and IP addresses of the domain controllers. In this context, the SRV and A resource records are referred to as Locator DNS resource records.

When adding a domain controller to a forest, you are updating a DNS zone hosted on a DNS server with the Locator DNS resource records and identifying the domain controller. For this reason, the DNS zone must allow dynamic updates (RFC 2136) and the DNS server hosting that zone must support the SRV resource records (RFC 2782) to advertise the Active Directory directory service. For more information about RFCs, see DNS RFCs.

If the DNS server hosting the authoritative DNS zone is not a server running Windows 2000 or Windows Server 2003, contact your DNS administrator to determine if the DNS server supports the required standards. If the server does not support the required standards, or the authoritative DNS zone cannot be configured to allow dynamic updates, then modification is required to your existing DNS infrastructure.

For more information, see Checklist: Verifying DNS before installing Active Directory and Using the Active Directory Installation Wizard.

**Important**

- The DNS server used to support Active Directory must support SRV resource records for the Locator mechanism to function. For more information, see Managing resource records.

- It is recommended that the DNS infrastructure allows dynamic updates of Locator DNS resource records (SRV and A) before installing Active Directory, but your DNS administrator may add these resource records manually after installation.

  After installing Active Directory, these records can be found on the domain controller in the following location: systemroot\System32\Config\Netlogon.dns

# DNS requirements for joining an Active Directory domain

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DNS requirements for joining an Active Directory domain**
Active Directory uses Domain Name System (DNS) to locate domain controllers, enabling computers joining the network to obtain a domain controller's IP address, and then begin the process of network authentication.

Computers joining an Active Directory domain must satisfy the following three DNS requirements:

- The computer must be configured with the IP address of a preferred DNS server.
- The **_ldap._tcp.dc._msdcs.***DNSDomainName*service (SRV) resource record must exist in DNS.
- The address (A) resource record for the DNS name of the domain controllers specified in the data field of the **_ldap._tcp.dc._msdcs.***DNSDomainName* SRV resource record must exist in DNS.

**Configuring a computer's preferred DNS server**
You must configure the computer with the static IP address of a preferred DNS server manually or assign the IP address of a preferred DNS server using Dynamic Host Configuration Protocol (DHCP).

For more information, see To configure a computer's preferred DNS server.

**Configuring the required DNS resource records**
Computers joining an Active Directory domain need the following resource records in DNS to locate a domain controller:

- **_ldap._tcp.dc._msdcs.** *DNSDomainName* SRV resource record, which identifies the name of the domain controller that hosts the Active Directory domain.

  *DNSDomainName* is the DNS name of the Active Directory domain the computer is attempting to join.

- A corresponding address (A) resource record that identifies the IP address for the domain controller listed in the **_ldap._tcp.dc._msdcs.***DNSDomainName* SRV resource record.

For more information, see To verify the DNS resource records needed to join an Active Directory domain using nslookup; Configure TCP/IP to use DNS.

# Understanding aging and scavenging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding aging and scavenging**

DNS servers running Windows Server 2003 support aging and scavenging features. These features are provided as a mechanism for performing cleanup and removal of stale resource records (RRs), which can accumulate in zone data over time.

With dynamic update, RRs are automatically added to zones when computers start on the network. However, in some cases, they are not automatically removed when computers leave the network. For example, if a computer registers its own host (A) RR at startup and is later improperly disconnected from the network, its host (A) RR might not be deleted. If your network has mobile users and computers, this situation can occur frequently.

If left unmanaged, the presence of stale RRs in zone data might cause some problems. The following are examples:

- If a large number of stale RRs remain in server zones, they can eventually take up server disk space and cause unnecessarily long zone transfers.
- DNS servers loading zones with stale RRs might use outdated information to answer client queries, potentially causing the clients to experience name resolution problems on the network.
- The accumulation of stale RRs at the DNS server can degrade its performance and responsiveness.
- In some cases, the presence of a stale RR in a zone could prevent a DNS domain name from being used by another computer or host device.

To solve these problems, the DNS Server service has the following features:

- Time stamping, based on the current date and time set at the server computer, for any RRs added dynamically to primary-type zones. In addition, time stamps are recorded in standard primary zones where aging/scavenging is enabled.

  For RRs that you add manually, a time stamp value of zero is used, indicating that they are not affected by the aging process and can remain without limitation in zone data unless you otherwise change their time stamp or delete them.

- Aging of RRs in local data, based on a specified refresh time period, for any eligible zones.

  Only primary type zones that are loaded by the DNS Server service are eligible to participate in this process.

- Scavenging for any RRs that persist beyond the specified refresh period.

  When a DNS server performs a scavenging operation, it can determine that RRs have aged to the point of becoming stale and remove them from zone data. Servers can be configured to perform recurring scavenging operations automatically, or you can initiate an immediate scavenging operation at the server.

  For more information, see either Enable automatic scavenging of stale resource records or Start immediate scavenging of stale resource records.

**Caution**

- By default, the aging and scavenging mechanism for the DNS Server service is disabled. It should only be enabled when all parameters are fully understood. Otherwise, the server could be accidentally configured to delete records that should not be deleted. If a record is accidentally deleted, not only will users fail to resolve queries for that record, but any user can create the record and take ownership of it, even on zones configured for secure dynamic update.

The server uses the contents of each RR-specific time stamp, along with other aging/scavenging properties that you can adjust or configure, to determine when it scavenges records.

**Prerequisites for aging/scavenging**

Before the aging and scavenging features of DNS can be used, several conditions must be met:

1. *Scavenging and aging must be enabled both at the DNS server and on the zone.*

   By default, aging and scavenging of resource records is disabled.

2. *Resource records must either be dynamically added to zones or manually modified to be used in aging and scavenging operations.*

   Typically, only those resource records added dynamically using the DNS dynamic update protocol are subject to aging and scavenging. For more information, see Dynamic update.

   You can, however, enable scavenging for other resource records added through non-dynamic means. For records added to zones in this way, either by loading a text-based zone file from another DNS server or by manually adding them to a zone, a time stamp of zero is set. This makes these records ineligible for use in aging/scavenging operations.

   In order to change this default, you can administer these records individually, to reset and permit them to use a current (non-zero) time stamp value. This enables these records to become aged and scavenged.

   For more information, see Reset scavenging and aging properties for a specified resource record.

### Note

- In the case of changing a zone from standard primary to Active Directory-integrated, you might want to enable scavenging of all existing resource records in the zone. To enable aging for all existing resource records in a zone, you can use the *AgeAllRecords* command, which is available through the **dnscmd** command-line tool. For more information, see Server administration using Dnscmd.

**Aging/scavenging terminology**

The following table indicates new or revised terms that have been introduced to help specifically when discussing aging and scavenging.

| Term | Description |
|---|---|
| Resource record (RR) time stamp | A date and time value used by the DNS server to determine removal of the resource record when it performs aging and scavenging operations. |
| Current server time | The current date and time on the DNS server. This number can be expressed as an exact numeric value at any point in time. |
| No-refresh interval | An interval of time, determined for each zone, as bounded by the following two events:<br>1. The date and time when the record was last refreshed and its time stamp set.<br>2. The date and time when the record next becomes eligible to be refreshed and have its time stamp reset.<br><br>This value is needed to decrease the number of write operations to the Active Directory database. By default, this interval is set to 7 days. It should not be increased to an unreasonably high level, because the benefits of the aging and scavenging feature might either be lost or diminished. |

| | |
|---|---|
| Refresh interval | An interval of time, determined for each zone, as bounded by the following two distinct events:<br>1. The earliest date and time when the record becomes eligible to be refreshed and have its time stamp reset.<br>2. The earliest date and time when the record becomes eligible to be scavenged and removed from the zone database.<br><br>This value should be large enough to allow all clients to refresh their records. By default, this interval is set to 7 days. It should not be increased to an unreasonably high level, because the benefits of the aging and scavenging feature might either be lost or diminished. |
| Start scavenging time | A specific time, expressed as a number. This time is used by the server to determine when a zone becomes available for scavenging. For more information, see Understanding aging and scavenging. |
| Scavenging period | When automatic scavenging is enabled at the server, this period represents the time between repetitions of the automated scavenging process. The default value for this is 7 days. To prevent deterioration of DNS server performance, the minimum allowed value for this is 1 hour. |
| Record refresh | When a DNS dynamic update is processed for a resource record when only the resource record time stamp, and no other characteristics of the record, are revised.<br><br>Refreshes generally occur for the following reasons:<br>1. When a computer is restarted on the network and, if at startup, its name and IP address information are consistent with the same name and address information it used prior to being shut down, it sends a refresh to renew its associated resource records for this information.<br>2. A periodic refresh is sent by the computer while it is running.<br><br>The Windows XP and Windows Server 2003 DNS Client service renews DNS registration of client resource records every 24 hours. When this dynamic update occurs, if the dynamic update request does not cause modification to the DNS database, then it is considered to be a refresh and not a resource record update.<br>3. Other network services make refresh attempts, such as: DHCP servers which renew client address leases, cluster servers which register and update records for a cluster, and the Net Logon service, which can register and update resource records used by Active Directory domain controllers. |
| Record update | When a DNS dynamic update is processed for a resource record where other characteristics of the record in addition to its time stamp are revised.<br><br>Updates generally occur for the following reasons:<br>1. When a new computer is added to the network and, at startup, it sends an update to register its resource records for the first time with its configured zone.<br>2. When a computer with existing records in the zone has a change in IP address, causing updates to be sent for its revised name-to-address mappings in DNS zone data.<br>3. When the Net Logon service registers a new Active Directory domain controller. |

| | |
|---|---|
| Scavenging servers | An optional advanced zone parameter that enables you to specify a restricted list of IP addresses for DNS servers that are enabled to perform scavenging of the zone.<br><br>By default, if this parameter is not specified, all DNS servers that load a directory-integrated zone (also enabled for scavenging) attempt to perform scavenging of the zone. In some cases, this parameter can be useful if it is preferable that scavenging only be performed at some servers loading the directory-integrated zone.<br><br>To set this parameter, you must specify the list of IP addresses for the servers enabled to scavenge the zone in the **ZoneResetScavengeServers** parameter for the zone. This can be done using the **dnscmd** command, a command-line based tool for administering Windows DNS servers. For more information, see Server administration using Dnscmd. |

**When scavenging can start**

Once all prerequisites for enabling the use of scavenging are met, it can start for a server zone when the current server time is greater than the value of the start scavenging time for the zone.

The server sets the time value to start scavenging on a per-zone basis whenever one of the following events occurs:

- Dynamic updates are enabled for the zone.
- A change in the state of the **Scavenge stale resource records** check box is applied. You can use the DNS console to modify this setting at either an applicable DNS server or one of its primary zones.
- The DNS server loads a primary zone enabled to use scavenging.

  This can occur when the server computer is started or when the DNS Server service is started.
- When a zone resumes service after having been paused.

When the previous events occur, the DNS server sets the value of start scavenging time by calculating the following sum:

Current server time + Refresh interval = Start scavenging time

This value is used as a basis of comparison during scavenging operations.

**Example of the aging/scavenging process for a sample record**

To understand the process of aging and scavenging at the server, consider the life span and successive stages of a single resource record, as it is added to a server and zone where this process is in effect and then aged and removed from the database.

1. A sample DNS host, "host-a.example.microsoft.com", registers its host (A) resource record at the DNS server for a zone where aging/scavenging is enabled for use.
2. When registering the record, the DNS server places a time stamp on this record based on current server time.

   After the record time stamp is written, the DNS server does not accept refreshes for this record for the duration of the zone no-refresh interval. It can, however, accept updates prior to that time. For example, if the IP address for "host-a.example.microsoft.com" changes, the DNS server can accept the update. In this case, the server also updates (resets) the record time stamp.
3. Upon expiration of the no-refresh period, the server begins to accept attempts to refresh this record.

   Once the initial no-refresh period ends, the refresh period immediately begins for the record. During this time, the server does not suppress attempts to refresh the record for its remaining life span.
4. During and after the refresh period, if the server receives a refresh for the record, it processes it.

   This resets the time stamp for the record based on the method described in step 2.
5. When subsequent scavenging is performed by the server for the "example.microsoft.com" zone, the record (and all other

zone records) are examined by the server.

Each record is compared to current server time on the basis of the following sum to determine whether the record should be removed:

Record time stamp + **No-refresh interval** for zone + **Refresh interval** for zone

- If the value of this sum is greater than current server time, no action is taken and the record continues to age in the zone.
- If the value of this sum is less than current server time, the record is deleted both from any zone data currently loaded in server memory and also from the applicable DnsZone object store in Active Directory for the directory-integrated "example.microsoft.com" zone.

**Note**

- For more information, see Managing the aging and scavenging of server data.

# Unicode character support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unicode character support**

Originally, Internet host names were restricted to the character set specified in Request for Comments (RFCs) 952 and 1123. These restrictions include limiting names to using uppercase and lowercase letters (A-Z, a-z), numbers (0-9) and hyphens (-). In addition, the first character of the DNS name can be a number and names must be encoded and represented using US-ASCII-based characters.

These requirement were maintained when DNS was introduced as part of RFC 1035, one of the core DNS standards specifications. For use of DNS in international settings, this requirement has significant limitations where extended character sets are used for local naming standards.

To remove these limitations, Microsoft expands DNS character support beyond the RFC 1035 specification. The DNS service now provides enhanced default support for UTF-8, a Unicode transformation format.

For more information about RFCs, see the RFC Editor Web site.

**What is UTF-8?**

UTF-8 is the recommended character set for protocols evolving beyond the use of ASCII. The UTF-8 protocol provides for support of extended ASCII characters and translation of UCS-2, a 16-bit Unicode character set that encompasses most of the world's writing systems. UTF-8 enables a far greater range of names than can be achieved using ASCII or extended ASCII encoding for character data.

Computers running Windows 2000, Windows XP, and Windows Server 2003 operating systems are UTF-8 aware. This means that when UTF-8 encoded characters are received or used as data by the server, the server can load and store this data in its zones. Although Windows-based DNS servers are UTF-8 aware, they remain compatible with other DNS servers that use traditional US-ASCII data encoding and current DNS standards.

**How the DNS service implements UTF-8**

To provide standards compatibility and interoperability with other DNS implementations, the DNS service uses uniform downcasing of any received character data. In this process, the DNS service converts all uppercase characters used in standard US-ASCII data to lowercase equivalent data for the following reasons:

- To maintain compatibility with current and existing DNS standards.
- To provide interoperability with DNS server implementations that do not recognize or support UTF-8 encoding.

To understand why uniform downcasing was chosen, several related points must first be considered from the current revised Internet standards for DNS. Several key points in the standards pertain directly to how character data is to be handled between DNS servers and other servers and clients. These include the following:

- Any binary string can be used in a DNS name. (RFC 2181)
- DNS servers must be able to compare names in a case-insensitive way. (RFC 1035)
- The original case for character data should be preserved whenever possible as the data is entered into the system. (RFC 1035)

Because case insensitivity is a required part of the core DNS standard and case preservation is an optional recommendation, uniform downcasing was chosen to provide an effective standards-compliant solution. By downcasing UTF-8 encoded names before transmission, other DNS servers (which are not UTF-8 aware) are able to receive and perform successful binary comparisons of the data and obtain the desired results.

**Considerations for interoperability with UTF-8**

The DNS Server service can be configured to allow or disallow the use of UTF-8 characters on a per-server basis. Although other DNS server implementations that are not UTF-8 aware might be able to accept the transfer of a zone containing UTF-8 encoded names, these servers might not be able to write back those names to a zone file or reload those names from a zone

file. Administrators should exercise caution when transferring a zone containing UTF-8 names to a DNS server that is not UTF-8-aware.

Some protocols place restrictions on the characters allowed in a name. In addition, names that are intended to be globally visible (RFC 1958) should contain ASCII-only characters, as recommended in RFC 1123.

**Notes**

- The use of UTF-8 for transformation of Unicode characters is not noticeable for general users. Only where Network Monitor or another similar tool is used to analyze DNS-related traffic over the physical network are UTF-8 encoded characters observable.

- In addition to DNS server support for the UTF-8 encoding format, the client resolver defaults to using the UTF-8 character encoding format.

- Names encoded in UTF-8 format must not exceed the size limits clarified in RFC 2181, which specifies a maximum of 63 octets per label and 255 octets per name. Character count is insufficient to determine size because some UTF-8 characters exceed one octet in length.

- The UTF-8 encoding protocol adapts to use with existing DNS protocol implementations that expect US-ASCII characters because representation of US-ASCII characters in UTF-8 is identical, byte for byte, to the US-ASCII representation. DNS client or server implementations that do not recognize UTF-8 characters always encode names in the US-ASCII format. Those names are correctly interpreted by the DNS Server service.

- The DNS service provides the ability to configure name checking to allow or restrict the use of UTF-8 characters in DNS data. For more information, see Change the name-checking method used by the DNS server.

  By default, multibyte UTF-8 name checking is used, allowing the greatest tolerance when the DNS service processes characters. This is the preferred name-checking method for most privately operated DNS servers that are not providing name service for Internet hosts.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# WINS lookup integration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**WINS lookup integration**

Support for using Windows Internet Name Service (WINS) is provided to look up DNS names that cannot be resolved by querying the DNS domain namespace. To accomplish WINS lookup, two specific resource record types are used and can be enabled for any zones loaded by the DNS service:

- The WINS resource record, which can be enabled to integrate WINS lookup into forward lookup zones
- The WINS-R resource record, which can be enabled to integrate node adapter status request for reverse lookup zones

**The WINS resource record**

The WINS and DNS services are used to provide name resolution for the NetBIOS namespace and the DNS domain namespace, respectively. Although both DNS and WINS can provide a separate and useful name service to clients, WINS is mainly needed to provide support for older clients and programs that require support for NetBIOS naming.

However, the DNS service can work with WINS to provide combined name searches in both namespaces when resolving a DNS domain name not found in zone information. To provide this interoperability, a new record (the WINS record) was defined as part of the zone database file.

The WINS resource record is specific to computers running Windows NT 4.0 and earlier, Windows 2000, and Windows Server 2003 operating systems and can be attached only to the domain of origin for a zone. The presence of a WINS resource record can instruct the DNS service to use WINS to look up any forward queries for host names or names that are not found in the zone database. This functionality is particularly useful for name resolution required by clients that are not WINS-aware (for example, UNIX) for the names of computers not registered with DNS, such as Windows 95 or Windows 98 computers.

**How WINS lookup works**

The following is an example of a DNS client (*host-b*) querying its DNS server in an attempt to look up the address for another computer named *host-a.example.microsoft.com*..

In Step 1, the client queries its preferred DNS server. In Steps 2 through 8, the normal process of recursion proceeds as the preferred DNS server queries other DNS servers in succession on behalf of the client. This process concludes at Step 8, when the DNS server for the example.microsoft.com zone is located through the previous chain of referral answers. At this point in the process, the server contacted is a DNS server either running Windows NT Server 4.0, Windows 2000, or Windows Server 2003 .

When the DNS server for the example.microsoft.com zone receives the query for *host-a*, it looks in its configured zone to see if a matching address (A) resource record (RR) can be found. If no A record is found and the zone is enabled to use WINS lookup, the server does the following:

- The DNS server separates the host part of the name (host-a) from the fully qualified domain name contained in the DNS query.

The host part of the name is the first label in the queried DNS domain name before a period is used in the name.

- The server then sends a NetBIOS name request to the WINS server using the host name, *host-a*.
- If the WINS server can resolve the name, it returns the IP address to the DNS server.
- The DNS server then compiles an A resource record using the IP address resolved through the WINS server and returns this record to the original preferred DNS server that was queried by the requesting client, *host-b*.
- The preferred DNS server then passes the query answer back to the requesting client.

**How WINS reverse lookup works**

There is also a WINS-R record or WINS reverse lookup entry that can be enabled and added to reverse lookup zones. However, because the WINS database is not indexed by IP address, the DNS service cannot send a reverse name lookup to WINS to get the name of a computer given its IP address.

Because WINS does not provide reverse lookup capability, the DNS service instead sends a *node adapter status request* directly to the IP address implied in the DNS reverse query. When the DNS server gets the NetBIOS name from the node status response, it appends the DNS domain name back onto the NetBIOS name provided in the node status response and forwards the result to the requesting client.

### Note

- The WINS and WINS-R resource records are proprietary to the DNS Server service provided by Windows. You can prevent these resource records from being included in zone transfers to other DNS server implementations. For more information, see Using WINS lookup.

# Deploying DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying DNS**
This section covers:

- Namespace planning for DNS
- Zone planning for DNS
- Server planning for DNS
- Migrating servers
- Interoperability issues
- Securing DNS deployment

# Namespace planning for DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Namespace planning for DNS**
Before you begin using DNS on your network, decide on a plan for your DNS domain namespace. Coming up with a namespace plan involves making some decisions about how you intend to use DNS naming and what goals you are trying to accomplish in using DNS. Some questions you might have at this stage include the following:

- Have you previously chosen and registered a DNS domain name for use on the Internet?
- Are you going to set up DNS servers on a private network or the Internet?
- Are you going to use DNS to support your use of Active Directory?
- What naming requirements do you need to follow when choosing DNS domain names for computers?

Each of these questions is further discussed in the following sections.

**Choosing your first DNS domain name**
When setting up DNS servers, it is recommended that you first choose and register a unique parent DNS domain name that can be used for hosting your organization on the Internet, for example, "microsoft.com". This name is a second-level domain within one of the top-level domains used on the Internet. For a list and description of the most common top-level domains used on the Internet, see Top-level domains.

Once you have chosen your parent domain name, you can combine this name with a location or organizational name used within your organization to form other subdomain names. For example, if a subdomain were added, such as the itg.example.microsoft.com domain tree (for resources used by the information technology group at your organization), additional subdomain names could be formed using this name. For instance, a group of programmers working on electronic data interchange (EDI) in this division could have a subdomain named edi.itg.example.microsoft.com. Likewise, another group of workers providing support in this division might use support.itg.example.microsoft.com.

Before you decide on a parent DNS domain name for your organization to use on the Internet, perform a search to see if the name is already registered to another organization or person. The Internet DNS namespace is currently managed by the Internet Network Information Center (InterNIC). In the future, other domain name registrars might also be available.

For more information, see Interoperability issues.

**DNS namespace planning for Active Directory**
If you are using Active Directory, you need to first establish a namespace plan. Before a DNS domain namespace can be properly implemented, the Active Directory structure needs to be available. Therefore, begin with the Active Directory design and support it with the appropriate DNS namespace. Upon review, if you detect unforeseen or undesirable consequences for either of your plans, make revisions as needed.

Active Directory domains are named with DNS names. When choosing DNS names to use for your Active Directory domains, start with the registered DNS domain name suffix that your organization has reserved for use on the Internet, such as microsoft.com and combine this name with either geographical or divisional names used in your organization to form full names for your Active Directory domains.

For example, the test group at Microsoft might call their domain test.example.microsoft.com. This method of naming ensures that each Active Directory domain name is globally unique. And, once employed, this naming method also makes it easy to use existing names as parents for creating additional subdomains and further grow the namespace to accommodate new departments within your organization.

For a small organization using only a single domain or a small multidomain model, planning can be straightforward and follow an approach similar to the previous examples. For a larger organization using a more complex domain model, refer to additional Microsoft resources. For more information, see Using the Windows Deployment and Resource Kits.

**Caution**

- When planning your DNS and Active Directory namespace, it is recommended that you use a differing set of

distinguished names that do not overlap as the basis for your internal and external DNS use. As an example, assuming your organization's parent domain name is "example.microsoft.com"

For internal DNS names usage you could use a name such as "internal.example.microsoft.com"

For external DNS names usage you could use a name such as "external.example.microsoft.com"

By keeping your internal and external namespaces separate and distinct in this way, you enable simplified maintenance of configurations such as domain name filter or exclusion lists.

**Choosing names**

It is strongly recommended that you use only characters in your names that are part of the Internet standard character set permitted for use in DNS host naming. Allowed characters are defined in Request for Comments (RFC) 1123 as follows: all uppercase letters (A-Z), lowercase letters (a-z), numbers (0-9), and the hyphen (-).

For organizations with a prior investment in Microsoft NetBIOS technology, existing computer names might conform to the NetBIOS naming standard. If this is the case, consider revising the names of your computers to the Internet DNS standard.

The process of adjusting your naming conventions might prove to be time consuming. To ease the transition from NetBIOS names to DNS domain names, the DNS Server service includes support for extended ASCII and Unicode characters. However, this additional character support can only be used in a network environment with computers running Windows 2000 or a product in the Windows Server 2003 family. This is because most other DNS resolver client software is based on RFC 1123, the specification that standardizes Internet host naming requirements. If a nonstandard DNS domain name is entered during setup, a warning message appears recommending that a standard DNS name be used instead.

In networks running Windows NT 4.0 and earlier, a NetBIOS name is used to identify a computer running a Windows operating system. In networks with computers running Windows 2000 or a product in the Windows Server 2003 family, a computer can be identified in any of the following ways:

- A NetBIOS computer name, which is optional and is used for interoperability with earlier Windows systems.
- The full computer name. This is the default name for the computer.

In addition to these, a computer might also be identified by the FQDN comprised of the computer (host) name and a connection-specific domain name, where one is configured and applied for a specific network connection on the computer.

The full computer name is a concatenation of both the computer name and the primary DNS suffix for the computer. The DNS domain name for the computer is part of the System properties for the computer and is not related to any specifically installed networking components. However, computers that do not use either networking or TCP/IP do not have a DNS domain name.

The following table is a comparison of NetBIOS and DNS computer names.

| Restriction | DNS in Windows NT 4.0 (standard DNS) | DNS in Windows 2000 and the Windows Server 2003 family | NetBIOS |
|---|---|---|---|
| Characters | Supports RFC 1123, which allows all uppercase letters (A-Z), lowercase letters (a-z), numbers (0-9), and the hyphen (-). | Supports RFC 1123 and UTF-8. You can configure the DNS server to allow or disallow the use of UTF-8 characters. You can do so on a per-server basis. For more information, see Unicode character support. | Not allowed: Unicode characters, numbers, white space, symbols: / \ [ ] : \| < > + = ; , ? and * |
| Host name and FQDN length. | 63 octets per label. 255 bytes per FQDN (254 bytes for the FQDN plus one byte for the terminating dot). | The same as standard DNS with the addition of UTF-8 support. Character count is insufficient to determine size because some UTF-8 characters exceed one octet in length. Domain controllers are limited to 155 bytes for an FQDN. Domain controllers are limited to 155 bytes for an FQDN. | 15 bytes in length. |

To ensure interoperability between NetBIOS and DNS naming in Windows, a new naming parameter called the NetBIOS computer name was introduced. The value of this parameter, which is not required in a Windows 2000 or Windows Server 2003 environment, is derived from the first 15 characters of the DNS full computer name.

When the full computer name is a combination of the computer name and the primary DNS suffix for the computer, the impact of renaming and making the transition from a NetBIOS namespace to a DNS namespace can be minimal. Users continue to focus on the short computer name. If this name is 15 characters or less, it can be made identical to the NetBIOS computer name. The administrator can then also assign a DNS domain name for each computer. This can be done using remote administration tools.

In this way, the **System** properties page can have the following settings on the **Computer Name** tab (or its related dialog boxes):

| | |
|---|---|
| **Computer name** | longer-than-15characters-name |
| **NetBIOS computer name** | longer-than-15c |
| **Primary DNS suffix for this computer** | example.microsoft.com |

**Important**

- By default, the primary DNS suffix portion of a computer's fully qualified domain name (FQDN) must be the same as the name of the Active Directory domain where the computer is located. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by creating the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is created and managed by the domain administrator using Active Directory Service Interfaces or the Lightweight Directory Access Protocol (LDAP).

  For more information, see Programming interfaces and Directory access protocol.

**Note**

- In addition to the primary DNS domain name for a computer, connection-specific DNS names can be configured. For more information, see Configuring multiple names.

  Because DNS host names are encoded in UTF-8 format, they do not necessarily have only 1 byte per character. ASCII characters are 1 byte each, but the size of extended characters is more than 1 byte.

  Some non-Microsoft resolver software supports only the characters listed in RFC 1123. If you have any non-Microsoft resolver software, that software is probably not able to look up computers with names that have non-standard characters.

  A DNS server that does not support UTF-8 encoding might accept a zone transfer of a zone containing UTF-8 names, but it cannot write back those names to a zone file or reload those names from a zone file. Therefore, you must not transfer a zone that contains UTF-8 characters to a DNS server that does not support them.

**Integration planning: Supporting multiple namespaces**

In addition to support for the internal DNS namespace, many networks require support for resolving external DNS names, such as those used on the Internet. The DNS Server service provides ways to integrate and manage disjointed namespaces where both external and internal DNS names are resolved on your network.

In deciding how to integrate namespaces, determine which of the following scenarios most closely resembles your situation and proposed use of DNS:

- An internal DNS namespace, used only on your own network.

- An internal DNS namespace with referral and access to an external namespace, such as referral or forwarding to a DNS server on the Internet.

- An external DNS namespace, used only on a public network such as the Internet.

If you decide to limit the use of DNS as a name service within your private namespace, there are no restrictions on how it is designed or implemented. For example, you can choose any DNS naming standard, configure DNS servers to be valid root servers for your network's DNS distributed design, or form an entirely self-contained DNS domain tree structure and

hierarchy.

When you start providing either referral to an external DNS namespace or full DNS service on the Internet, you need to consider compatibility between your private and external namespaces. Additionally, Internet service requires the registration of parent domain names for your organization.

For more information on planning secure integration of Internet DNS names referral through your secured private network, see the Microsoft Windows Resource Kits Web site.

**Notes**

- When you add and connect to a DNS server for the first time using the DNS console, the root hints file (Cache.dns) is automatically primed for use on your network. This occurs transparently and does not require that you take any further action for this to be done.

  Depending on how you use DNS, you can update this file in one of the following ways:

  - If you are connected to the Internet, you can either edit or update the local root hints file when the Internet root hints file (Named.root) is updated and released by the owners of the Internet root zone. For a current copy of this file, you can use anonymous FTP to the InterNIC Web site.

  - If you are not connected to the Internet, you can remove the default resource records contained in this file and replace them with NS and A resource records for the DNS authoritative servers at the root domain of your site. For root domain servers on your private network, you can safely remove this file entirely because servers operating at this domain level do not require or use a cache of root hints.

- If you delete the Cache.dns file for a private root domain server when you have configured the DNS Server service using the **From file** method, you also need to remove the **cache** directive from the server boot file before restarting the DNS Server service.

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Zone planning for DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Zone planning for DNS**

When first partitioning your namespace into zones, review traffic patterns in your current or proposed network. Although DNS is designed to help reduce broadcast traffic between local subnets, it does create some traffic between servers and clients that should be reviewed. This is particularly true in cases where DNS is used on routed networks.

To review DNS traffic, you can use DNS server statistics or the DNS performance counters provided with System Monitor. For more information, see Verifying server configuration or Monitoring DNS server performance.

In addition to routing traffic, consider the impact of the following common types of DNS-related communication, especially when you are operating across slow-speed links on a wide area network:

- Server-to-server traffic caused both by zone transfers with other DNS servers and by DNS interoperability with other servers (for example, when WINS lookup is enabled).

- Client-to-server traffic caused by both query loads and dynamic updates sent by DNS client computers or DHCP servers providing dynamic updating for earlier-version DNS clients that do not support dynamic updates.

For small, flat namespaces, you might use full replication of all DNS zones to all DNS servers in your network. For large, vertical namespaces, this is neither possible nor recommended. In larger networks, it is often necessary to study, test, analyze, and revise your zone plans based on observed or estimated traffic patterns. After careful analysis, you can partition and delegate your DNS zones based on what is required for providing efficient and fault-tolerant name service to each location or site.

**Notes**

- If you are using a mixture of Windows DNS servers, be aware that zone transfers can sometimes be slow between the DNS Server service and some other DNS server implementations. For more information, see Interoperability issues.

- The DNS Server service supports incremental zone transfers between servers replicating a standard zone. This feature can reduce DNS replication traffic considerations and should be reviewed in zone planning. For more information, see Understanding zones and zone transfer.

- Although it is useful to plan zones, you might also want to explore the use of caching-only servers, which do not host DNS zones. Caching-only servers are a good option at small remote sites that have a stable and minimal use for DNS name service but are located across a WAN where the transfer of a large zone over a slower link can be resource-intensive. For more information, see Using caching-only servers.

# Server planning for DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server planning for DNS**

When planning for your DNS servers, it is important to consider the following:

- Perform capacity planning and review server hardware requirements.
- Determine how many DNS servers you need and their role in your network.

  When deciding the number of DNS servers to use, decide which servers will host primary and secondary copies of zones. Also, if you are using Active Directory, determine whether the server computer will perform as a domain controller or a member server for the domain.
- Decide where you are going to place DNS servers on your network for traffic loads, replication, and fault tolerance.
- Decide whether to use only DNS servers running Windows Server 2003 for all your DNS servers or if you are operating a mixture of Windows and other DNS server implementations.

  For more information about migration and interoperability of the DNS Server service with other DNS server implementations, see Migrating servers or Interoperability issues.

**Server capacity planning**

Planning and deploying DNS servers on your network involves examining several aspects of your network and the capacity requirements for any DNS servers you intend to use in it. Some questions to consider when planning include the following:

- How many zones is the DNS server expected to load and host?
- For each zone the server is loading for service, how large is the zone (based on the size of the zone file or the number of resource records used in the zone)?
- For a multihomed DNS server, how many interfaces are to be enabled for listening to and servicing DNS clients on each of the server's connected subnets?
- How many total or overall DNS query requests from all of its clients is a DNS server expected to receive and service?

In many cases, adding more RAM to a DNS server can provide the most noticeable improvements in performance. This is because the DNS Server service fully loads all of its configured zones into memory at startup. If your server is operating and loading a large number of zones, and dynamic updates occur frequently for zone clients, additional memory can be helpful.

Keep in mind that for typical usage, the DNS server consumes system memory as follows:

- Approximately 4 MB of RAM is used when the DNS server is started without any zones.
- For each addition of zones or resource records to the server, the DNS server consumes additional server memory.
- It is estimated that for the addition of every resource record to a server zone, an average of approximately 100 bytes of server memory is used.

  For example, if a zone containing 1000 resource records is added to a server, it would require approximately 100 KB (kilobytes) of server memory.

In determining your DNS server plans, you can start by reviewing sample DNS server performance test results collected by the DNS development and testing teams. In addition, you can use DNS server-related counters provided for use with monitoring

tools to obtain your own performance measurements. For more information, see Monitoring DNS server performance.

**Important**

- The previous recommendations are not intended to indicate maximum performance or limitations for DNS servers.
- These numbers are approximate and can be influenced by the type of resource records entered in zones, the number of resource records with the same owner name, and the number of zones in use at a specific DNS server.

**Where to place DNS servers**

In general, place your DNS servers at a location on your network that is centrally accessible to your clients. It is often most practical to use a DNS server on each subnet. There are several factors to consider when deciding where a DNS server is needed:

- If you are deploying DNS to support Active Directory, is the DNS server computer also a domain controller or likely to be promoted to one in the future?
- If the DNS server stops responding, are its local clients able to gain access to an alternate DNS server?
- If the DNS server is located on a subnet that is remote to some of its clients, what other DNS servers or name resolution options are available if the routed connection stops responding?

For DNS server installations where the use of Active Directory is an issue, review special interoperability issues and installation details. For more information, see Interoperability issues.

For all DNS server installations including those in which the use of Active Directory is not an issue, the following server placement and planning guidelines can be usefully applied.

For example, if you have a routed local area network and high-speed links that are fairly reliable, you might be able to use one DNS server for a larger, multiple subnetted network area. If you have a high number of client nodes on a single subnet design, you might want to add more than one DNS server to the subnet to provide backup and failover if the preferred DNS server stops responding.

When determining the number of DNS servers you need to use, assess the effect of zone transfers and DNS query traffic on slower links in your network. Although DNS is designed to help reduce broadcast traffic between local subnets, it does create some traffic between servers and clients that should be reviewed, particularly when used in complexly routed LAN or WAN environments.

Consider the effects of zone transfer over slower speed links, like those typically used for a wide area network (WAN) connection. Although the DNS Server service supports incremental zone transfers and DNS clients and servers can cache recently used names, traffic considerations are sometimes still an issue, particularly when DHCP leases are shortened and, as a result, dynamic updates in DNS are performed more frequently. One option for dealing with remote locations on WAN links is to set up a DNS server at these locations to provide caching-only DNS service.

With most installations, you should have at least two server computers hosting each of your DNS zones for fault tolerance. DNS was designed to have two servers for each zone, one as a primary server and the other as a backup or secondary server. When making any final determinations about the number of servers to use, first assess the level of fault tolerance you need for your network.

**Notes**

- When only a single DNS server is used on a small LAN in a single-subnet environment, you can configure the single server to simulate both the primary and secondary servers for a zone.
- For best results and simplified DNS administration, consider using the Windows Server 2003 DNS Server service for all of your DNS servers.
- When administering zone files created by the DNS Server service, it is recommended that you use the DNS console tool to make changes. As an alternate option, it is possible to administer all of your DNS zone files manually using any application that supports file saving in text mode. Whether you decide to edit zone files manually in a text editor or use the DNS console to modify them, select one method for updating zones and use it consistently. This helps prevent having

zone edits overwritten or rejected, which might happen if you change from one method to another.

# Migrating servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Migrating servers**

DNS migration can occur in one of the following ways:

1. Upgrading a computer running the version of DNS included in Windows NT Server 4.0 or Windows 2000 to a server running Windows Server 2003 .

2. Moving zone files from an existing DNS server running another DNS server implementation, such as server running a version of the Berkeley Internet Name Domain (BIND) software.

3. Migrating zones using master-secondary zone transfer from BIND servers to DNS servers running Windows Server 2003 .

**Upgrading DNS servers from Windows NT Server 4.0 and Windows 2000**

Any zones or server configuration files and parameters created and stored using the Windows NT Server 4.0 or Windows 2000 version of the DNS Server service are stored in the same system folder locations. There is no conversion of data required during the upgrade process.

**Moving BIND-based files**

When moving from a BIND DNS server to a DNS server running Windows Server 2003 , however, you need to copy any BIND-created zone or boot files that you intend to use with the DNS Server service. Also, if you continue to use a BIND boot file to provide the initial configuration settings used by the DNS Server service when it is started, you need to change the boot method used by the DNS Server service or rename the zone files from the BIND naming convention to that used by DNS servers running under the DNS Server service provided in Windows operating systems. For more information, see Change the boot method used by the DNS server.

Any zone files created and stored on UNIX DNS servers that use BIND need to be manually copied from those servers to the systemroot\System32\Dns folder on the server running Windows Server 2003 .

If you do not migrate the BIND boot file or specify the BIND name when creating the zones using the DNS console, then you will need to rename these zones. The following table shows examples of how BIND server files are renamed for use with the DNS Server service that is provided on servers running a member of the Windows Server 2003 family.

| Description | UNIX file name | Windows Server 2003  file name |
|---|---|---|
| Boot file | named.boot | Boot |
| Forward lookup zone file | db.*domain_name* | *domain_name*.dns |
| Reverse lookup zone file | db.*IP_network_forward_notation* | *IP_network_reverse_notation*.dns |

For a reverse lookup zone, BIND uses a convention of noting reverse domain names as a forward notation of mapped IP network, such as db.192.1.168 for a reverse lookup zone created for an example IP network address of 192.168.1.0. DNS servers running Windows Server 2003 , however, use the fully qualified domain name (FQDN) for the zone, which includes the in-addr.arpa domain, to complete the file name. In this example, the correct name to use for the same zone in Windows Server 2003  DNS is 168.1.192.in-addr.arpa.dns when copying and renaming the file.

**Notes**

- If you are using the BIND boot file with the DNS Server service after migration, there are other limitations that apply to the use of this file by the DNS Server service. For example, some BIND boot directives are not supported -- in particular, **xfrnets** and other directives provided with versions of BIND, such as version 8.1.1 or later. For more information, see articles Q194513, "The Structure of a Domain Name System Boot File"; Q234144, "DNS Boot File Directives and Configuration for Windows NT 4.0," in the Microsoft Knowledge Base.

- If you are accustomed to manually editing DNS zone files, be aware that the DNS Server service uses RFC-compliant

notation for its supported resource records (RRs). In most cases, the DNS Server service interprets and loads RRs from zone files originally created for BIND DNS servers without any need for file changes. If, however, you have used non-standard record formatting, the DNS Server service can detect these edits and interpret them as bad or errored zone data. For more information about RFCs, see DNS RFCs.

**Migrating from third-party servers using zone transfer**

Another possible scenario for server migration is using zone transfer to migrate third-party server zones to DNS servers running Windows Server 2003 . To accomplish this, you can take the following steps:

1. At your server running Windows Server 2003 , install the DNS Server service.

2. Using the DNS console, at the new server add secondary zones for all of your existing zones hosted at the BIND-based DNS servers.

   Configure the third-party servers as the master servers for each of the secondary zones you need to create.

3. After completing the zone transfers, convert any of the secondary zones to primary zones for the zones that were obtained from primary zones at the third-party servers.

4. Configure the previous primary servers to be secondary servers for the migrated zones or demote the previous primary servers.

5. For the other secondary zones that remain, update the master servers for those zones to use the new primary DNS servers running Windows Server 2003 .

For more information, see Install a DNS server, Add a secondary server for an existing zone, Initiate a zone transfer at a secondary server, Change the zone type, and Update the master server for a secondary zone.

**Note**

- If you choose to continue to use your third-party DNS servers as secondary servers for zones for which your DNS server running Windows Server 2003 is the primary server, you should review interoperability issues related to zone transfer for this configuration. For more information, see Interoperability issues.

# Interoperability issues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Interoperability issues**

DNS servers running Windows Server 2003 are compliant with most of the Request for Comments (RFC) specifications used to define the DNS protocol. This provides clear benefits for operating DNS servers in mixed or heterogeneous environments. For more information about RFCs, see DNS RFCs.

The primary benefits for interoperability in these environments include:

- Full interoperability with other DNS server implementations that implement RFC-compliant behavior for DNS name service.
- Use of Windows DNS servers to provide DNS service on the Internet.

For interoperability testing, the Windows Server 2003 DNS development team has tested Windows Server 2003 DNS Server and Client services with the following versions of the Berkeley Internet Name Domain (BIND) DNS server implementation:

- BIND 4.9.7
- BIND 8.1.2
- BIND 8.2
- BIND 9.1.0

Interoperability and configuration issues related to using Windows Server 2003 DNS with other various environments, or when using DNS servers on the Internet, are covered in the following sections.

**DNS considerations for Active Directory**

DNS is required for network resources to locate Active Directory domain controllers. You can elect to set up the DNS Server service as part of the installation of Active Directory using the Active Directory Installation Wizard. When you install Active Directory on a server, the server is promoted to the role of a domain controller.

When you install Active Directory on a server, the Active Directory Installation Wizard provides the option to automatically install the DNS Server service and add new zones locally. When you select the option to install and configure a DNS server using the Active Directory Installation Wizard, zones are created based on the DNS name you have specified in the wizard.

A simple method of redundancy and fault tolerance planning is to have a DNS server running on each domain controller. For each subnet, have two domain controllers running the DNS Server service and hosting Active Directory-integrated zones.

**Zone transfer with BIND and other DNS server implementations**

When transferring a zone between two Windows DNS servers, the DNS Server services can utilize a fast transfer method that uses compression. This method includes multiple resource records (RRs) in each message sent to complete the transfer of the zone between servers.

By default, DNS servers running Windows Server 2003 are configured to transfer a zone using the slower uncompressed transfer format. This enables successful zone transfers to be made with DNS servers that do not support the faster transfer method, such as BIND servers prior to version 4.9.4.

If you clear the **Bind Secondaries** check box in advanced server properties, fast transfers are enabled. For more information, see Enable or disable fast transfer format during zone transfers.

**Supporting Active Directory with other DNS server implementations**

In many large organizations, DNS is already implemented using other solutions, such as UNIX DNS servers that run legacy versions of BIND software. In some cases, these DNS servers are not equipped to support the DNS requirements for deploying Active Directory. This issue can be addressed in one of two ways:

- Upgrade any BIND DNS servers to version 8.1.2 or later of the BIND software to meet the DNS requirements for Active Directory support.

- Use the DNS Server service provided with Windows Server 2003 family, migrating, if possible, any of your current DNS zones to DNS servers running Windows Server 2003.

Although the DNS Server service is recommended to support Active Directory, you can use other DNS server implementations for this purpose. These other implementations should, however, support the following standard specifications:

- The service location (SRV) resource record, as described in the Internet draft, "A DNS RR for specifying the location of services (DNS SRV)."

- Dynamic updates in DNS, as described in RFC 2136.

Support for dynamic updates is recommended but not essential. Support for the SRV resource record is mandatory because it is required to provide basic DNS support to Active Directory. For example, a DNS server that does not support dynamic updates, like that provided with Windows NT Server 4.0 (updated to Service Pack 4 or later) supports the DNS requirements of Active Directory because SRV resource record support was added with Service Pack 4.

Additional manual administration of SRV resource records is needed for DNS configuration support of Active Directory to function properly on a DNS server that does not support dynamic updates. For more information, see Managing resource records.

**Interoperating Windows DNS servers with other DNS server implementations**
If you decide to use the Windows DNS Server service and manage it with a split DNS configuration in which:

- Existing DNS servers for root zones are not to be upgraded or migrated to other DNS solutions.

- Windows Server 2003 DNS is to be deployed and is to provide management of any DNS domain names required to register, update, and support for use with Active Directory.

You can modify your DNS namespace design plans in either of the following ways:

1. Create a single new subdomain in your current DNS domain namespace to root your first Active Directory domain.

   For example, if your organization has registered and is using a second-level domain name, such as microsoft.com, you can create a single subdomain such as example.microsoft.com and use this domain to root the DNS domain namespace used by Active Directory. The DNS Server service is automatically configured to support Active Directory when you install the first domain controller.

   Before you have created a zone for the new subdomain at a computer running the DNS Server service, you can delegate these subdomains away at the primary zone for your second-level domain, such as "microsoft.com." In some cases, you might only need to notify another DNS or UNIX system administrator in your organization to make the delegation for you. For more information, see Delegating zones.

2. Create multiple subdomains based on your DNS second-level domain to support registration of Active Directory in DNS.

   For example, if your organization has a registered second-level DNS domain name already in use (such as microsoft.com), you can create additional subdomains that are delegated to Windows DNS servers and used only for registering DNS names related to Active Directory.

   This method is more complex to implement, but enables less change to your currently deployed DNS infrastructure that is not Windows-based. With this namespace design, you create only those additional subdomains and appropriate zones needed to support your Active Directory deployment. For example, in this configuration, the domain name microsoft.com is both the root DNS and the root Active Directory domain name for your organization.

   For this configuration, you first need to create zones for the following subdomains using the DNS Microsoft Management Console (MMC) console on a DNS server running Windows Server 2003:

child1.microsoft.com child2.microsoft.com

Before these zones are created, you can delegate these subdomains away at the primary zone for your parent or second-level domain name or notify another DNS administrator who manages these zones for your organization to do so. For more information, see Delegating zones.

**Using DNS on the Internet**

To establish a presence on the Internet, an individual or business must first apply for and register a second-level domain name with an authorized DNS domain name registration authority. Your Internet service provider (ISP) can often perform this function and obtain a name on your behalf, usually for an additional fee.

To register your domain name, there are several required tasks, including:

- Selecting and researching a second-level domain name that is not currently registered or in use.

  This can easily be done if you have Internet access by using a WHOIS query engine provided at the Web site for your applicable Internet DNS domain name registrar. Be prepared to select an alternate name if your WHOIS query indicates that your preferred selection is already registered and in use.

- Registering and obtaining at least one IP address valid for use on the Internet.

  This address is needed for the DNS server on the Internet that you want to establish as the host for the primary copy of the zone based on your second-level domain name. In many cases, if you are using an ISP to register a domain name on your behalf, they can specify the IP addresses for one or two of their servers as primary and secondary for the Internet.

  As part of the registration process, an applicant must provide at least two currently active DNS servers that are used on the Internet as the primary and secondary servers designated for the new domain. This requirement is necessary to ensure proper Internet root server configuration and referral for others that query for your registered DNS domain name on the Internet.

  After one IP address has been obtained, you can sometimes arrange (or your ISP can do so on your behalf) to use another company or ISP's DNS server as a secondary server for the zone. If you still need to obtain an IP address directly for use in the United States, a valid IP address can be obtained through the American Registry for Internet Numbers (ARIN). In other countries or regions, you might contact your local Internet service or telephony provider to find out how to register and acquire an IP address if one is needed.

- Complete the registration application form and submit it with your registration fee to the appropriate Internet DNS domain name registration authority. Registrations are typically in force for a finite period of time and must be periodically renewed.

For more information about selecting and registering your Internet DNS name, see the VeriSign Global Registry Services Web site.

**Interoperability planning: Configuring related services**

Windows Server 2003 DNS provides several interoperability options with other TCP/IP services. The following options can be used to reduce the amount of time you need to spend administering your DNS infrastructure:

- **WINS forward and reverse lookups.**

  The DNS Server service provides for the use of WINS lookup. This feature enables configured DNS zones to refer queries not answered from current zone information to a WINS server for further resolution. With this added search of the WINS namespace, both DNS and WINS are used to complete a full search of registered names for a matched response.

  WINS lookup is supported for both forward and reverse lookup zones and can be enabled on a per-zone basis or configured for selected zones. This feature should also be configured to prevent replication or zone transfer of WINS resource records to servers with other DNS implementations that do not recognize the WINS resource records.

- **Dynamic integration with DHCP servers.**

For Windows Server 2003 DNS, the DHCP service provides default support to register and update information for legacy DHCP clients in DNS zones. Legacy clients typically include other Microsoft TCP/IP client computers that were released prior to Windows 2000. The Windows Server 2003 DNS-DHCP integration enables a DHCP client that is unable to dynamically update DNS resource records directly to have this information updated in DNS forward and reverse lookup zones by the DHCP server.

**Notes**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

- Dynamic integration with the DHCP service is only available on DNS servers running Windows 2000 and Windows Server 2003. DNS-DHCP integration is not supported by DHCP servers running under Windows NT Server 4.0 and earlier.

- By default, a zone hosted on a DNS server running Windows Server 2003 will only allow a zone transfer to authoritative DNS servers listed in the name server (NS) resource records for the zone.

# Securing DNS deployment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing DNS deployment**

When designing your DNS server deployment, use the following DNS security guidelines:

- **If your network hosts are not required to resolve names on the Internet, eliminate DNS communication with the Internet.** In this DNS design, you can use a private DNS namespace that is hosted entirely in your network. The private DNS namespace is distributed just as the Internet DNS namespace, with your internal DNS servers hosting zones for the root domain and top-level domains.

- **Split the DNS namespace for your organization between internal DNS servers behind the firewall and external DNS servers in front of the firewall.** In this DNS design, your internal DNS namespace is a subdomain of your external DNS namespace. For example, if the Internet DNS namespace for your organization is adatum.com, then the internal DNS namespace for your network is corp.adatum.com.

- **Host your internal DNS namespace on internal DNS servers and host your external DNS namespace on external DNS servers exposed to the Internet.** To resolves queries for external names made by internal hosts, the internal DNS servers forward queries for external names to the external DNS servers. External hosts use only the external DNS servers for Internet name resolution.

- **Configure your packet-filtering firewall to only allow UDP and TCP port 53 communication between your external DNS server and a single internal DNS server.** This will facilitate communication between internal and external DNS servers and prevent any other external computer from gaining access to your internal DNS namespace.

For more information, see Security information for DNS.

# Administering DNS

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering DNS**
This section covers:

- Managing DNS Servers
- Managing Clients
- Managing Zones
- Monitoring and Optimizing Servers

# Managing DNS Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing servers**

This section covers:

- Configuring a new primary server
- Update existing servers
- Using secondary servers
- Securing the DNS Server service
- Using caching-only servers
- Modifying server defaults
- Managing the aging and scavenging of server data
- Using forwarders
- Directing queries through forwarders
- Updating root hints
- Configuring multihomed servers
- Server administration using Dnscmd

# Configuring a new primary server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring a new primary server**

There are several situations in which you might add and configure a new DNS server for your network:

- When you are adding a new DNS server to your network and configuring a new zone for first-time use.
- When you have already created a zone at another DNS server and are adding a new server that also needs to load and provide service for the zone.
- When you already have a DNS server configured with a zone or zones, but need to add a new zone for another domain name, such as a subdomain.

For first-time configuration of a new server and zone, it is best to use the checklists provided with DNS Help to begin your DNS deployment. If you are going to deploy a DNS server without using Active Directory, use Checklist: Deploying DNS. For deploying DNS to support your use of Active Directory, use Checklist: Deploying DNS for Active Directory.

**Adding a primary DNS server for an existing zone**

The primary DNS server for a zone acts as the point of update for the zone. Newly created zones are always this type. You can use primary zones in one of two ways: as standard primary zones or primary zones integrated with Active Directory.

For standard primary-type zones, only a single DNS server can host and load the master copy of the zone. If you create a zone and keep it as a standard primary zone, no additional primary servers for the zone are permitted. Only one server is allowed to accept dynamic updates and process zone changes.

The standard primary model implies a single point of failure. For example, if for any reason the primary server for a zone is unavailable to the network, no dynamic updates to the zone can be made. Note that queries for names in the zone are not affected and can continue uninterrupted, as long as secondary servers for the zone are available to answer them.

You can add more primary servers for a zone by using the directory-integrated storage and replication features of the DNS Server service. To do this, you need to change a zone and integrate it into Active Directory.

You can integrate an existing zone into Active Directory by changing the type of a zone at the originating primary server where it was first created. Once the zone type is changed from **Standard primary** to **Active Directory-integrated**, you can add the zone to other DNS servers by configuring them to use the **From Active Directory or registry** option when they initialize DNS Server service.

When the **From Active Directory or registry** option is selected, other DNS servers operating as part of the Active Directory domain namespace -- such as domain controllers for the Active Directory domain -- can query the directory and automatically load all directory-integrated zones, which are stored in the directory database. No other steps are necessary. With the **From Active Directory or registry** option, any DNS servers operating as part of Active Directory are, by default, also primary servers for directory-integrated zones.

For more information on changing the zone type, see Change the zone type. For more information on changing the server boot method, see Change the boot method used by the DNS server.

**Note**

- When using standard primary-type zones, other DNS servers should never be configured to act as primary servers for an existing zone. This design is not supported and might cause errors or inconsistencies in zone data between servers loading different versions of the same zone.

**Adding a new primary zone to an existing server**

Adding a new primary zone to an existing server can be done whenever additional domains or subdomains are needed in your DNS domain namespace. For example, you might have a zone for a second-level domain such as microsoft.com and want to add a primary zone for the new subdomain, example.microsoft.com.

In this example, you can create the new zone for the subdomain by using the DNS console and running the New Zone Wizard.

When you are done, you need to create a delegation in the parent zone for the new subdomain (such as the microsoft.com zone) to complete the addition of the new subdomain and its primary zone.

Once the new primary zone is added, you can perform other zone configuration tasks as needed to fully configure the zone for use. For more information, see Managing Zones.

# Update existing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Update existing servers**

Updating the configuration of your DNS servers can be necessary for various reasons, such as to:

- Change the computer (host) name of the server computer.
- Change the primary or parent DNS domain name of the server computer.
- Change the IP address for the server computer.
- Remove a DNS server from the network.
- Change the primary server for a zone (standard primary zones only).

Each of these is covered in the following sections.

**Changing the computer (host) name of the server**

If you need to change the host name of a DNS server (but not its parent or primary DNS domain name), make the following changes in the zone where the server is configured as an authoritative server for the zone:

1. Change the computer name for the server in System properties.
2. Restart the computer to initiate the following DNS dynamic updates:
   a. Add the new host (A) and pointer (PTR) resource records (RRs) for the new name and IP address of the server.
   b. Remove the old A and PTR RRs for the old name and IP address of the server.
3. Update the name server (NS) RR in zones where the server is configured as authoritative to point to the new A RR added in step 2.
4. If the server is the primary server for a standard zone, revise the name in the owner field of the start of authority (SOA) RR for the zone (If the zone is directory-integrated, this step is not needed).
5. Check in the zones to ensure that any delegation records -- NS or A RRs -- that are used, are updated for the new name of the server.

**Changing the primary DNS domain name of the server**

When changing the DNS domain name of a computer, the ability to change the primary DNS domain name of the server can depend on whether or not you are using the computer as a domain controller.

**Important**

- By default, the primary DNS suffix portion of a computer's fully qualified domain name (FQDN) must be the same as the name of the Active Directory domain where the computer is located. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by creating the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is created and managed by the domain administrator using Active Directory Service Interfaces or Lightweight Directory Access Protocol (LDAP).

  For more information, see Programming interfaces and Directory access protocol.

If you are running the server computer as a domain controller, the primary DNS domain name of the server computer is set to

be the same as the name of the Active Directory domain where the server was promoted to be a domain controller. To change this name, you must first demote the server so that it is no longer a domain controller. For a server changing its parent DNS domain name in this situation, the process of adding and deleting A and PTR RRs for the server is done automatically when joining and leaving an Active Directory domain. In this case, only manual updating of the name server (NS) RRs for the old and new DNS parent domains might be needed.

To change the DNS domain name for a DNS server computer not using Active Directory, such as a domain member server or a stand-alone server, some additional changes and manual administration might be necessary. For example, if the old and new DNS domain names are in two different zones, such as Zone A (the old zone) and Zone B (the new zone), you would need to make the following changes:

1. Change the **Primary DNS suffix for this computer** in System properties and restart the computer.

2. In Zone A, remove the host (A) RR for the server.

3. In Zone B, add the A RR for the server.

4. Update all start of authority (SOA) and name server (NS) RRs in zones containing the name of the renamed DNS server.

**Changing the IP address of the server**

To change the IP address for an existing DNS server, the process is the same as for any DNS host computer. Update the IP address in the server address (A) resource record. If the name of the server does not change, NS and SOA records are not affected.

A common configuration error that occurs when changing an IP address in the A resource record in a zone is that the same information used elsewhere in DNS is not updated. For example, if a DNS server that has a name or address change is used in a parent zone as part of a set of delegation records, the zone records might be updated but the delegation records left unchanged. For this reason, it is good to check the parent zone as well when changing or updating IP addresses for A resource records for DNS servers in a zone. Otherwise, zone delegation can fail.

Also, if you are using a multihomed server, be aware of the events and conditions under which a server running Windows Server 2003 can initiate a dynamic update when connection-specific DNS domain naming is used. For more information, see Configuring multiple names.

**Removing a DNS server from the network**

To remove a DNS server from the network, make the following changes in zones where the server is configured as an authoritative server for the zone:

1. Remove the address (A) resource record for the server.

2. Update the name server (NS) records in zones where the server is configured as authoritative to no longer include the server by name (as it appeared in the A record deleted in Step 1).

3. If the server is the primary server for a standard zone, revise the owner field of the SOA resource record for the zone to point to the new primary DNS server for the zone. (If the zone is directory-integrated, this step is not needed.)

4. Check the parent zone to ensure that any records (NS or A resource records) used for delegation to the zone are revised and no longer point to the removed server.

**Changing the primary server for a zone (standard primary zones only)**

For standard primary zones, it can sometimes be necessary to change the designated primary server for a zone. For example, suppose that the current primary server for a standard primary zone is Server A, and the new primary server for the zone is Server B.

To affect the changeover in status from Server A to Server B, make the following zone changes:

1. Add a new host (A) resource record (RR) for Server B.

2. Update the name server (NS) RR in the zone to remove Server A and include Server B as a configured server of authority that points to the new A RR added in Step 1.

3. Revise the name in the owner field of the start of authority (SOA) RR for the zone from Server A to Server B.

4. Remove the old A RR for Server A.

5. Check the parent zone to ensure that any delegation records (NS or A RRs) used are updated to refer to Server B.

# Using secondary servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using secondary servers**

DNS design specifications recommend that at least two DNS servers be used to host each zone. For standard primary-type zones, a secondary server is required to add and configure the zone to appear to other DNS servers in the network. For directory-integrated primary zones, secondary servers are supported but not required for this purpose. For example, two DNS servers running on domain controllers can be redundant primary servers for a zone, providing the same benefits of adding a secondary server while including additional advantages.

Secondary servers can provide a means to offload DNS query traffic in areas of the network where a zone is heavily queried and used. Additionally, if a primary server is down, a secondary server can provide some name resolution in the zone until the primary server is available.

If you add a secondary server, try to locate it as close as possible to clients that have a high demand for names used in the zone. Also, consider placing secondary servers across a router, either on other subnets (if you use a routed LAN) or across WAN links. This provides a good use of a secondary server as a local backup in cases where an intermediate network link becomes the point of failure between DNS servers and clients that use the zone.

Because a primary server always maintains the master copy of updates and changes to the zone, a secondary server relies on DNS zone transfer mechanisms to obtain its information and keep it current. Issues like zone transfer methods -- either using full or incremental zone transfers -- are more applicable when using secondary servers. For more information, see Understanding zones and zone transfer.

In considering the impact of zone transfers caused by secondary servers, consider their advantage as a backup source of information and measure this against the added cost they impose on your network infrastructure. A simple rule is that for each secondary server you add, network usage (because of added zone replication traffic) increases, and so does the time required to synchronize the zone at all secondary servers.

Secondary servers are most heavily used for forward lookup zones. If you are using reverse lookup zones, you can assume that you do not need to add as many secondary servers for those zones. Typically, a secondary server for a reverse lookup zone is not used outside of the network and subnet that correspond to the reverse zone.

**Note**

- For more information, see Add a secondary server for an existing zone.

# Securing the DNS Server service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing the DNS Server service**

To secure the DNS servers in your network, use the following guidelines:

- **Examine and configure the default DNS Server service settings that affect security.** The following DNS Server service configuration options have security implications for both the standard and the Active Directory-integrated DNS Server service.

| Default setting | Description |
|---|---|
| Interfaces | By default, a DNS Server service that is running on a multihomed computer is configured to listen for DNS queries using all of its IP addresses. Limit the IP addresses the DNS Server service listens on to the IP address used by its DNS clients as their preferred DNS server.<br><br>For more information, see Restrict a DNS server to listen only on selected addresses. |
| Secure cache against pollution | By default, the DNS Server service is secured from cache pollution, which results when DNS query responses contain nonauthoritative or malicious data. The **Secure cache against pollution** option prevents an attacker from successfully polluting the cache of a DNS server with resource records that were not requested by the DNS server. Changing this default setting will reduce the integrity of the responses provided by DNS Server service.<br><br>For more information, see Secure server cache against names pollution. |
| Disable recursion | By default, recursion is not disabled for the DNS Server service. This enables the DNS server to perform recursive queries on behalf of its DNS clients and DNS servers that have forwarded DNS client queries to it. Recursion can be used by attackers to deny the DNS Server service and therefore if a DNS server in your network is not intended to receive recursive queries, it should be disabled.<br><br>For more information, see Disable recursion on the DNS server. |
| Root hints | If you have an internal DNS root in your DNS infrastructure, configure the root hints of internal DNS servers to only point to the DNS servers hosting your root domain and not the DNS servers hosting the Internet root domain. This will prevent your internal DNS servers from sending private information over the Internet when resolving names.<br><br>For more information, see Update root hints on the DNS server and Updating root hints. |

For more information about default DNS Server service settings, see Restore server default preferences.

- **Manage the discretionary access control list (DACL) on DNS servers running on domain controllers.** In addition to the default DNS Server service settings that affect security described above, DNS servers configured as domain controllers use a DACL. The DACL allows you to control the permissions for the Active Directory users and groups that control the DNS Server service.

  The following table lists the default group or user names and permissions for the DNS Server service when it is running on a domain controller.

| Group or user names | Permissions |
|---|---|
| Administrators | Allow: Read, Write, Create All Child objects, Special Permissions |
| Authenticated Users | Allow: Read, Special Permissions |
| Creator Owner | Special Permissions |

| | |
|---|---|
| DnsAdmins | Allow: Read, Write, Create All Child objects, Delete Child objects, Special Permissions |
| Domain Admins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |
| Enterprise Admins | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |
| Enterprise Domain Controllers | Allow: Special Permissions |
| Pre-Windows 2000 Compatible Access | Allow: Special Permissions |
| System | Allow: Full Control, Read, Write, Create All Child objects, Delete Child objects |

For more information about assigning permissions on objects, see Best practices for assigning permissions on Active Directory objects, Best practices for permissions and user rights, and Understanding Groups.

When the DNS Server service is running on a domain controller, its DACL may be managed using the Active Directory object MicrosoftDNS. Configuring the DACL on the MicrosoftDNS Active Directory object has the same effect as configuring the DACL on the DNS server in the DNS console, which is the recommended method. Consequently, the security administrators of Active Directory objects and DNS servers should be in direct contact to ensure that the administrators do not reverse each other's security settings.

For more information, see Assign, change, or remove permissions on Active Directory objects or attributes.

- **Always use an NTFS file system for DNS servers running a** Windows Server 2003 **operating system.** The NTFS file system is a more powerful file system than FAT and FAT32 and provides a variety of features including Active Directory, which is needed for domains, user accounts, and other important security features.

  For more information about NTFS, see NTFS and NTFS compared to FAT and FAT32.

For more information, see Security information for DNS.

# Using caching-only servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using caching-only servers**

Although all DNS servers cache queries that they have resolved, caching-only servers are DNS servers that only perform queries, cache the answers, and return the results. They are not authoritative for any domains and the information that they contain is limited to what has been cached while resolving queries.

In determining when to use this kind of server, note that when this server is initially started, it has no cached information. This information is obtained over time as client requests are serviced. However, if you are dealing with a slow-speed WAN link between sites, this option might be ideal because, once the cache is built, traffic decreases. In addition, the caching-only server does not perform zone transfers, which can also be network intensive in WAN environments.

**Note**

- For more information, see Install a caching-only DNS server.

# Modifying server defaults

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Modifying server defaults**

The DNS console provides the ability to reconfigure some types of DNS server defaults for instances when defaults are not appropriate for use with a specific DNS server. Some configurable nondefault settings include:

- Selecting an alternate server configuration method to be used when initiating service.
- Disabling the use of recursion.

**Methods for initiating service**

The following methods are available to determine how the DNS Server service initializes and provides service when started.

| Method | Description |
|---|---|
| From registry | Initializes the DNS Server service by reading parameters stored in the registry. |
| From file | Initializes the DNS Server service using an optional boot file, as used by Berkeley Internet Name Domain (BIND) servers.<br><br>To use this file, supply a copy of a boot file from another DNS server running a DNS server that is based on the BIND implementation. On BIND-based DNS servers, this file is typically called the Named.boot file. The format of this file must be the older BIND 4 format, not the more recent BIND 8 boot file format.<br><br>If used, settings and directives in this file are used instead of comparable settings stored in the registry on the DNS server computer. For any parameters not configurable using boot file directives, registry defaults (or stored reconfigured server settings) are applied by the DNS Server service. |
| From Active Directory and registry | Initializes the DNS Server service by reading parameters stored in the Active Directory database and the server registry. This is the default boot option. |

**Notes**

- For more information on how to change the method used to initiate the DNS Server service, see Change the boot method used by the DNS server.
- For more information on Active Directory integration with the DNS Server service, see Active Directory integration.

**Disabling recursion**

By default, recursion is enabled for the DNS Server service, and clients typically request that the server use recursion to resolve a name when sending a query. If recursion is disabled, the DNS Server service always uses referral, regardless of the client request.

In general, DNS servers can answer queries for names outside of their authoritative zones in two ways:

- Servers can send referral answers, which are an immediate response to the requesting client with a list of resource records for other DNS servers it knows about that appear to be closer or more likely to be of help in resolving the queried name.
- Servers can use recursion to query other servers on behalf of the requesting client, attempting to fully resolve the name. Recursive lookups continue until the server receives an authoritative answer for the queried name. The server then forwards this answer in response to the original query from the requesting client.

In most cases, disabling recursion on a DNS server happens when DNS clients are to be limited to resolving names

authoritatively managed on a specific server. For example, this is the case when a DNS server has only DNS names data for an internal network or when the DNS server is incapable of resolving external DNS names (such as Internet DNS names) and clients are expected to retry another DNS server to resolve these names.

**Notes**

- For more information on how to enable or disable the use of recursion with the DNS Server service, see Disable recursion on the DNS server.

- If you disable recursion on the DNS server, you will not be able to use forwarders on the same server.

# Managing the aging and scavenging of server data

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing the aging and scavenging of server data**

Aging and scavenging of stale resource records are features of DNS available when deploying your server with primary zones.

Where aging and scavenging are available for use, you can use the DNS console to perform the following related tasks for your DNS servers and any directory-integrated zones that they load:

1. Enable or disable the use of scavenging at a DNS server.
2. Enable or disable the use of scavenging for selected zones at the DNS server.
3. Modify the no-refresh interval, either as a server default or by specifying an overriding value at selected zones.
4. Modify the refresh interval, either as a server default or by specifying an overriding value at selected zones.
5. Specify whether periodic scavenging occurs automatically at the DNS server for any of its eligible zones, and how often these operations are repeated.
6. Manually initiate a single scavenging operation for all eligible zones at the DNS server.
7. View other related properties, such as the time stamp for individual resource records or the start scavenging time for a specified zone.

**Enabling scavenging of stale resource records**

By default, aging and scavenging features are disabled on all DNS servers and any of their zones. Before using these features, you should configure these settings for the applicable server and its directory-integrated zones:

- **Server aging/scavenging properties** for determining the use of these features on a server-wide basis.

  First, you need to enable aging and scavenging of stale resource records for use at the server. These settings are used to determine the affect of zone-level properties for any directory-integrated zones loaded at the server.

  For more information, see Set aging/scavenging properties for the DNS server.

- **Zone aging/scavenging properties** for determining the use of these features on a per-zone basis.

  When zone-specific properties are set for a selected zone, these settings apply only to the applicable zone and its resource records. Unless these zone-level properties are otherwise configured, they inherit their defaults from comparable settings maintained in server aging/scavenging properties.

  For more information, see Set aging/scavenging properties for a zone.

**Modifying no-refresh intervals**

When the no-refresh interval is in effect for a specific resource record, attempts to dynamically refresh its time stamp are suppressed by the DNS server. This aspect of the aging/scavenging mechanism prevents unnecessary refreshes from being processed by the server for aged resource records. These early refresh attempts, if not handled in this way, might otherwise increase Active Directory replication traffic related to processing DNS zone changes.

To ensure that records do not refresh prematurely, keep the **No-refresh interval** comparable in length to the current refresh interval for each resource record. For example, if you increase the **Refresh interval** to a higher value you can similarly increase the no-refresh interval.

In most instances, the default interval of 7 days is sufficient and does not need to be changed.

**Modifying refresh intervals**
When the refresh interval is in effect for a resource record, attempts to dynamically refresh its time stamp are accepted and processed by the DNS server. When setting this interval, it is important that the length of time used be greater than the maximum possible refresh period for any resource records contained within the zone. This period is equal to the maximum amount of time that it might take the record to be refreshed under normal network conditions, based on the specific source generating the record refresh.

For example, the following table shows default refresh periods for various services known to dynamically register and refresh records in DNS:

| Service | Default refresh period |
|---|---|
| Net logon | 24 hours |
| Clustering | 24 hours |
| DHCP client | 24 hours<br>**Note**<br>• The DHCP Client service sends dynamic updates for the DNS records. This includes both computers that obtain a leased IP address using DHCP and those that are configured statically for TCP/IP. |
| DHCP server | 4 days (half of the lease interval, which is 8 days by default)<br>**Note**<br>• Refresh attempts are only made by the DHCP servers configured to perform DNS dynamic updates on behalf of their clients (for example Windows 2000 Server DHCP server and Windows Server 2003 DHCP server). The period is based on the frequency in which DHCP clients renew their IP address leases with the server. Typically, this occurs when 50% of the scope lease time has elapsed. If the DNS default scope lease duration of 8 days is used, then the maximum refresh period for records updated by DHCP servers on behalf of clients is 4 days. |

By default, the refresh interval is 7 days. In most instances, this value is sufficient and does not need to be changed, unless any resource records in the zone are refreshed less often than every 7 days.

**Automated and manually-initiated scavenging**
Although scavenging start time and other factors determine when zones and records are actually eligible for scavenging, you have the option to perform scavenging using either of two methods to initiate it:

- **Automatic scavenging** specifies that aging and scavenging of stale records is to be performed automatically by the server for any eligible zones at a recurring interval specified as the *scavenging period*. When using automatic scavenging, the default scavenging period is 1 day and the minimum allowed value you can use is 1 hour.

  For more information, see Enable automatic scavenging of stale resource records.

- **Manual scavenging** specifies that aging and scavenging of stale records is to be performed as a non-recurring operation for any eligible zones at the server.

  For more information, see Start immediate scavenging of stale resource records.

**Modifying time stamp values**
For resource records that are not dynamically added to DNS zone data, a record time stamp value of zero is applied, preventing these records from aging or removal during scavenging.

You can, however, manually reset record properties to enable any statically entered records to qualify for the aging/scavenging process. If you do this, the record will be deleted based upon the modified time stamp value, at which point, you might need to recreate a record if it is still needed.

For more information, see Reset scavenging and aging properties for a specified resource record.

**Caution**

- Enabling aging and scavenging for use with standard primary zones modifies the format of zone files. This change does not affect zone replication to secondary servers, but the modified file cannot be loaded by other versions of DNS servers.

- Before using information in this topic, be sure that you have reviewed the aging/scavenging process and use of its configurable properties and features. For more information, see Understanding aging and scavenging.

**Note**

- For information on using Active Directory and DNS, see Active Directory integration.

# Using forwarders

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using forwarders**

To use forwarders to manage the DNS traffic between your network and the Internet, configure the firewall used by your network to allow only one DNS server to communicate with the Internet. When you have configured the other DNS servers in your network to forward queries they cannot resolve locally to that DNS server it will act as your forwarder. For more information about forwarders, see Understanding forwarders.

**Forwarding sequence**

The order of the IP addresses listed as forwarders on a DNS server determines the sequence in which the IP addresses are used. After the DNS server forwards the query to the forwarder with the first IP address, it waits a short period for an answer from that forwarder (according to the DNS server's time out setting) before resuming the forwarding operation with the next IP address. It continues this process until it receives an affirmative answer from a forwarder.

For example, in the following figure the DNS servers with the first and second forwarder IP addresses do not respond to the DNS server. The DNS server with the third forwarder IP address responds and the query is forwarded to that DNS server.

Unlike conventional resolution, where a roundtrip time (RTT) is associated with each server, the IP addresses in the forwarders list are not ordered according to roundtrip time and must be reordered manually to change preference.

**Conditional forwarders**

Conditional forwarders are DNS servers that only forward queries for specific domain names. Instead of forwarding *all* queries it cannot resolve locally to a forwarder, a conditional forwarder is configured to forward a query to specific forwarders based on the domain name contained in the query. Forwarding according to domain names improves conventional forwarding by adding a name-based condition to the forwarding process.

The conditional forwarder setting for a DNS server consists of the following:

- The domain names for which the DNS server will forward queries.
- One or more DNS server IP addresses for each domain name specified.

When a DNS client or server performs a query operation against a DNS server, the DNS server looks to see if the query can be resolved using its own zone data or the data stored in its cache. If the DNS server is configured to forward for the domain name designated in the query, then the query is forwarded to the IP address of a forwarder associated with the domain name. For example, in the following figure, each of the queries for the domain names is forwarded to a DNS server associated with the domain name.

If the DNS server has no forwarder listed for the name designated in the query, it can attempt to resolve the query using standard recursion. For more information, see Configure a DNS server to use forwarders and How DNS query works.

Conditional forwarders allow you to improve name resolution between internal (private) DNS namespaces that are not part of the DNS namespace of the Internet, such as results from a company merger. By configuring the DNS servers in one internal namespace to forward all queries to the authoritative DNS servers in a second internal namespace, conditional forwarders enable name resolution between the two namespaces without performing recursion on the DNS namespace of the Internet. This enhancement to name resolution also avoids having your DNS servers perform recursion to your internal root for different namespaces within your network.

**Important**

- A DNS server cannot forward queries for the domain names in the zones it hosts. For example, the authoritative DNS server for the zone microsoft.com cannot forward queries according to the domain name microsoft.com. The DNS server authoritative for microsoft.com can forward queries for DNS names that end with example.microsoft.com, if example.microsoft.com is delegated to another DNS server.

**Conditional forwarder domain name length**

When a DNS server configured with a conditional forwarder receives a query for a domain name, it will compare that domain name with its list of domain name conditions and use the longest domain name condition that corresponds to the domain name in the query. For example, in the figure below, the DNS server performs the following conditional forwarding logic to determine how a query for a domain name will be forwarded:

1. The DNS server receives a query for networks.example.microsoft.com.

2. It compares that domain name with both microsoft.com and example.microsoft.com.

3. The DNS server determines that example.microsoft.com is the domain name that more closely matches the domain name query.

4. The DNS server forwards the query to the DNS server with the IP address 172.31.255.255, which is associated with example.microsoft.com.

**Forward-only servers**

When a DNS server configured to use forwarders cannot resolve a query locally, or using its forwarders, the server attempts to resolve the query using standard recursion. A DNS server can also be configured to not perform recursion after forwarders fail. In this configuration, the server does not attempt any further recursive queries to resolve the name. Instead, if it does not get a successful query response from any of the servers configured as forwarders, then it fails the query. A DNS server configured in this manner is called a forward-only DNS server. If all forwarders for a name in the query do not respond to a forward-only

DNS server, that DNS server will not attempt recursion.

A forward-only DNS server is different from a nonrecursive DNS server because it builds up a cache relating to the domain name and will use this cache to attempt to resolve the domain name. A nonrecursive DNS server will not build up a cache relating to the domain, nor will it perform recursion. In both configurations, the DNS servers will attempt to resolve the query using their authoritative data before using their forwarders.

**Note**

- You can disable recursion for the entire DNS server or on a per domain name basis. If you disable recursion on the entire DNS server, you will not be able to use forwarders on that DNS server.

For more information, see Directing queries through forwarders and Disable recursion on the DNS server.

# Directing queries through forwarders

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Directing queries through forwarders**
A DNS server that acts as a forwarder may serve other purposes in the DNS environment. For example, it could be a primary or secondary server, or it could be a caching-only server. Consider the activities of all DNS servers in your network when deploying forwarders to ensure that forwarding complements the other DNS server activities and benefits name resolution. For general information about forwarders, see Understanding forwarders.

**Forwarders and delegation**
A DNS server configured with a forwarder and hosting a parent zone will use its delegation information before forwarding queries. If no delegation record exists for the DNS name in the query, then the DNS server will use its forwarders to resolve the query.

**Forwarders and root servers**
A common error when configuring forwarding is to attempt to configure forwarding on root servers for a private DNS namespace. Root servers are authoritative for the root zone of your organization's DNS namespace. The goal of attempting to configure forwarding on root servers for a private DNS namespace is to forward all offsite queries to Internet DNS servers. *Root servers cannot be configured with standard forwarding*. If a root server is queried about any domain name, then it will refer to a DNS server that can answer the question (from its local zones, cache or root hints), or it will respond with a failure (NXDOMAIN), but it cannot be configured to forward to specific servers.

### Note

- A root server can be configured with a conditional forwarder. Conditional forwarding can be used to forward queries between root servers in separate DNS namespaces. For steps to configure internal root servers, see article 294906 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=82900). For more information about configuring conditional forwarding, see article 304491 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=82901).

**Forwarder configuration tips**
Consider the following tips for efficient forwarder configuration and use:

- **Keep forwarder configuration uncomplicated.** For every DNS server configured with a forwarder, queries can be sent to a number of different places. Each forwarder and each conditional forwarder must be administered for the benefit of DNS client queries, and this process can be time consuming. Use forwarders strategically, where they are needed the most, such as resolving offsite queries or sharing information between namespaces.

- **Avoid chaining your forwarders.** If you have configured a DNS server named server-1 to forward queries for widgets.example.com to DNS server server-2, do not configure server-2 to forward queries for widgets.example.com to DNS server server-3. This is an inefficient resolution process and could result in errors if server-3 is accidentally configured to forward queries for widgets.microsoft.com to server-1, in which case you would have a chain.

- **Do not concentrate too great of a load on forwarders.** The recursive queries that forwarders send to the Internet can require a significant amount of time to answer due to the nature of the Internet. With a large number of internal DNS servers using these forwarders for Internet queries, they can experience a substantial concentration of network traffic. If network load will be an issue, use more than one forwarder and distribute the load between them.

- **Do not create inefficient resolution using forwarders.** The DNS server will attempt to forward domain names according to the order in which they are configured in the DNS console. A DNS server in Seattle may be incorrectly configured to forward a query to a server in London instead of another server in Seattle because the server in London is higher in the forwarders list. This will decrease the efficiency of name resolution on the network. Evaluate your network's forwarding configuration periodically to see if there are similar configurations.

For more information, see Configure a DNS server to use forwarders.

# Updating root hints

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Updating root hints**

Root hints are used to prepare servers authoritative for non-root zones so that they can learn and discover authoritative servers that manage domains located at a higher level or in other subtrees of the DNS domain namespace. These hints are essential for servers authoritative at lower levels of the namespace when locating and finding servers under these conditions.

For example, suppose a DNS server (Server A) has a zone called sub.example.microsoft.com. In the process of answering a query for a higher-level domain, such as the example.microsoft.com domain, Server A needs some assistance to locate an authoritative server (such as Server B) for this domain.

In order for Server A to find Server B, or any other servers that are authoritative for the microsoft.com domain, it needs to be able to query the root servers for the DNS namespace. The root servers can then refer Server A to the authoritative servers for the com domain. The servers for the com domain can, in turn, offer referral to Server B or other servers that are authoritative for the microsoft.com domain.

The root hints used by Server A must have helpful hints to the root servers for this process to locate Server B (or another authoritative server) as intended.

To configure and use root hints correctly, first determine how the following applies to your DNS servers:

- Are you using DNS on the Internet or on a private network?
- Is the server used as a root server?

By default, the DNS Server service implements root hints using a file, Cache.dns, stored in the systemroot\System32\Dns folder on the server computer. This file normally contains the NS and A resource records for the Internet root servers. If, however, you are using the DNS Server service on a private network, you can edit or replace this file with similar records that point to your own internal root DNS servers.

Another server configuration in which root hints are treated differently is one in which a DNS server is configured to be used by other DNS servers in an internal namespace as a forwarder for any DNS queries of names managed externally (the Internet, for example). Even though the DNS server used as a forwarder can be located internally on the same network as servers using it as a forwarder, it needs hints for the Internet root servers to work properly and resolve external names.

To update root hints, see Update root hints on the DNS server.

**Notes**

- If you are operating internal root servers, do not use root hints. Instead, delete the Cache.dns file entirely for any of your root servers.
- If a DNS server is configured to know about other DNS servers, such as through a list of DNS servers configured in its client TCP/IP properties for an installed network connection, the DNS Server service is capable of gathering its own root hints during new server configuration. You can use the Configure a DNS Server Wizard provided with the DNS console to accomplish this.

# Configuring multihomed servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring multihomed servers**
For multihomed DNS servers, you can configure the DNS Server service to selectively enable and bind only to IP addresses that you specify using the DNS console. By default, the DNS Server service binds to all IP interfaces configured for the computer.

This can include:

- Any additional IP addresses configured for a single network connection.
- Individual IP addresses configured for each separate connection where more than one network connection is installed on the server computer.

For multihomed DNS servers, you can restrict DNS service for selected IP addresses. When this feature is used, the DNS Server service only listens for and answers DNS requests that are sent to the IP addresses specified on the **Interface** tab in Server properties.

**When to specify interfaces**
By default, the DNS Server service listens on all IP addresses and accepts all client requests sent to its default service port (UDP 53 or TCP 53). Some DNS resolvers (including original version Windows 95 clients) require that the source address of a DNS response be the same as the destination address that was used in the query. If these addresses differ, clients can reject the response. To accommodate these resolvers, you can specify the list of allowed interfaces for the DNS server. When a list is set, the DNS Server service binds sockets only to allowed IP addresses used on the computer.

In addition to providing support for clients that require explicit bindings to be used, specifying interfaces can be useful for other reasons:

1. If, for administrative reasons, you do not want to use some IP addresses or interfaces on a multihomed server computer.
2. If the server computer is configured to use a large number of IP addresses and you do not want the added expense of binding to all of them.

**Additional considerations for multihoming DNS servers**
When configuring additional IP addresses and enabling them for use with a DNS server, consider the following:

- Additional system resources are consumed at the server computer.
- Although DNS provides the means to configure multiple IP addresses for use with any of your installed network adapters, there is no performance benefit for doing so.
- Even if the DNS server is handling multiple zones registered for Internet use, it is not necessary or required by the Internet registration process to have different IP addresses registered for each zone.

Given these considerations:

- Recognize that when adding IP addresses for DNS server use, each additional address might only slightly increase server performance. In instances when a large overall number of IP addresses are enabled for use, server performance can be degraded noticeably.
- In general, when adding network adapter hardware to the server computer, assign only a single primary IP address for each network connection.
- Whenever possible, remove non-essential IP addresses from existing server TCP/IP configurations.

**Note**

- For more information on how to specify interfaces with the DNS Server service, see Restrict a DNS server to listen only on selected addresses.

# Server administration using Dnscmd

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server administration using Dnscmd**

Dnscmd is provided as a command-line tool for managing DNS servers. This tool can be used to script batch files, to help automate the management and update of existing DNS server configurations, or to perform set up and configuration of DNS servers.

For information about installing this tool, see Install Windows Support Tools. For help in using the command, type **dnscmd /?** at a command prompt or use the Windows Support Tools help.

# Managing Clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing clients**
This section covers:

- Configuring DNS client settings
- Configuring multiple names
- Updating DNS client information
- Securing DNS clients

# Configuring DNS client settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring DNS client settings**

DNS configuration involves the following tasks when configuring TCP/IP properties for each computer:

- Setting a DNS computer or host name for each computer. For example, in the fully qualified domain name (FQDN) *wkstn1.example.microsoft.com.*, the DNS computer name is the leftmost label *wkstn1*.
- Setting a primary DNS suffix for the computer, which is placed after the computer or host name to form the FQDN. Using the previous example, the primary DNS suffix would be *example.microsoft.com*.
- Setting a list of DNS servers for clients to use when resolving DNS names, such as a preferred DNS server, and any alternate DNS servers to use if the preferred server is not available.
- Setting the DNS suffix search list or search method to be used by the client when it performs DNS query searches for short, unqualified domain names.

These tasks are discussed in more detail in each of the following sections.

**Setting computer names**

When setting computer names for DNS, it is useful to think of the name as the leftmost portion of a fully qualified domain name (FQDN). For example, in *wkstn1.example.microsoft.com.*, *wkstn1* is the computer name.

You can configure all Windows DNS clients with a computer name based on any of the standard supported characters defined in Request for Comments (RFC) 1123, "Requirements for Internet Hosts -- Application and Support." These characters include the use of:

- Uppercase letters, A through Z
- Lowercase letters, a through z
- Numbers, 0 through 9
- Hyphens (**-**)

If you are supporting both NetBIOS and DNS namespaces on your network, you can use a different computer name within each namespace. It is recommended that wherever possible, however, you try to use computer names that are 15 characters or less and that you follow the RFC 1123 naming requirements outlined above.

By default, the leftmost label in the FQDN for clients equals the NetBIOS computer name, unless this label is 16 or more characters, which is the maximum for NetBIOS names. When the computer name exceeds the maximum length for NetBIOS, the NetBIOS computer name is truncated based on the full label that is specified.

Before configuring computers with varying DNS and NetBIOS names, consider the following implications and their related issues for your deployment:

- If WINS lookup is enabled for zones hosted by your DNS servers, you need to use the same name for both NetBIOS and DNS computer naming. Otherwise, the results of clients attempting to query and resolve the names of these computers will be inconsistent.

If you have an investment in using NetBIOS names to support legacy Microsoft networking technology, it is recommended that you revise NetBIOS computer names used on your network to prepare for migration to a standard DNS-only environment. This prepares your network well for long-term growth and interoperability with future naming requirements. For example, if you use the same computer name for both NetBIOS and DNS resolution, consider converting any special characters such as the underscore (_) in your current NetBIOS names that do not comply with DNS naming standards. While these characters are

permitted in NetBIOS names, they are more often incompatible with traditional DNS host naming requirements and most existing DNS resolver client software.

**Notes**

- Although the use of the underscore (_) in DNS host names or in host (A) resource records has been traditionally prohibited by DNS standards, the use of underscores in service-related names--such as those used for service locator (SRV) resource records--has been proposed to avoid naming collisions in the Internet DNS namespace. For more information, see DNS RFCs.

- In addition to DNS standard naming conventions, Windows Server 2003 DNS supports the use of extended ASCII and Unicode characters. However, since most resolver software written for other platforms (such as UNIX) is based on the Internet DNS standards, this enhanced character support can be used only in private networks with computers running Windows 2000 or Windows Server 2003 DNS.

- The initial setup of DNS and TCP/IP displays a warning to suggest a standard DNS name if a nonstandard DNS name is entered.

- By default, computers and servers use DNS to resolve any name that is greater than 15 characters in length. If the name is less than or equal to 15 characters, then both NetBIOS and DNS name resolution can be attempted and used to resolve the name.

**Setting domain names**

The domain name is used with the client computer name to form the fully qualified domain name (FQDN), known also as the full computer name. In general, the DNS domain name is the remainder of the FQDN that is not used as the unique host name for the computer.

For example, the DNS domain name used for a client computer could be the following: If the FQDN, or **Full computer name**, is wkstn1.example.microsoft.com, the domain name is the example.microsoft.com portion of this name.

DNS domain names have two variations--a DNS name and a NetBIOS name. The full computer name (a fully qualified DNS name) is used during querying and location of named resources on your network. For earlier version clients, the NetBIOS name is used to locate various types of NetBIOS services that are shared on your network.

An example that shows the need for both NetBIOS and DNS names is the Net Logon service. In Windows Server 2003 DNS, the Net Logon service on a domain controller registers its service (SRV) resource records on a DNS server. For Windows NT Server 4.0 and earlier versions, domain controllers register a *DomainName* entry in WINS to perform the same registration and to advertise their availability for providing authentication service to the network.

When a client computer is started on the network, it uses the DNS resolver to query a DNS server for SRV records for its configured domain name. This query is used to locate domain controllers and provide logon authentication for accessing network resources. A client or a domain controller on the network optionally uses the NetBIOS resolver service to query WINS servers, attempting to locate *DomainName* [1C] entries to complete the logon process.

Your DNS domain names should follow the same standards and recommended practices that apply to DNS computer naming described in the previous section. In general, acceptable naming conventions for domain names include the use of letters A through Z, numerals 0 through 9, and the hyphen (**-**). The use of the period (**.**) in a domain name is always used to separate the discrete parts of a domain name, commonly known as *labels*. Each label corresponds to an additional level defined in the DNS namespace tree.

For most computers, the primary DNS suffix configured for the computer can be the same as its Active Directory domain name, although the two values can also be different.

**Important**

- By default, the primary DNS suffix portion of a computer's FQDN must be the same as the name of the Active Directory domain where the computer is located. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by creating the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is created and managed by the domain administrator using Active Directory Service Interfaces or the Lightweight Directory Access Protocol (LDAP).

  For more information, see Programming interfaces and Directory access protocol.

**Configuring a DNS servers list**

For DNS clients to operate effectively, a prioritized list of DNS name servers must be configured for each computer to use when processing queries and resolving DNS names. In most cases, the client computer contacts and uses its preferred DNS server, which is the first DNS server on its locally configured list. Listed alternate DNS servers are contacted and used when the preferred server is not available. For this reason, it is important that the preferred DNS server be appropriate for continuous client use under normal conditions.

### Notes

- For computers running Windows XP, the DNS server list is used by clients only to resolve DNS names. When clients send dynamic updates, such as when they change their DNS domain name or a configured IP address, they might contact these servers or other DNS servers as needed to update their DNS resource records. For more information, see Dynamic update.

- By default, the DNS client on Windows XP does not attempt dynamic update over a Remote Access Service (RAS) or virtual private network connection. To modify this configuration, you can modify the advanced TCP/IP settings of the particular network connection or modify the registry. For more information, see Configure TCP/IP to use DNS and Microsoft Windows Resource Kits Web site.

- By default, the DNS client does not attempt dynamic update of top-level domain (TLD) zones. Any zone named with a single-label name is considered a TLD zone, for example, com, edu, blank, my-company. To configure the DNS client to allow the dynamic update of TLD zones, you can use the **Update Top Level Domain Zones** policy setting or modify the registry.

- When DNS clients are configured dynamically using a DHCP server, it is possible to have a larger list of provided DNS servers. To provide an IP address list of DNS servers to your DHCP clients, enable option code 6 on the configured options types provided by your DHCP server. For Windows Server 2003 DHCP servers, you can configure a list of up to 25 DNS servers for each client with this option.

- To effectively share the load when multiple DNS servers are provided in a DHCP options-specified list, you can configure a separate DHCP scope that rotates the listed order of DNS and WINS servers provided to clients. For more information, see Configuring scopes.

**Configuring a DNS suffix search list**

For DNS clients, you can configure a DNS domain suffix search list that extends or revises their DNS search capabilities. By adding additional suffixes to the list, you can search for short, unqualified computer names in more than one specified DNS domain. Then, if a DNS query fails, the DNS Client service can use this list to append other name suffix endings to your original name and repeat DNS queries to the DNS server for these alternate FQDNs.

For computers and servers, the following default DNS search behavior is predetermined and used when completing and resolving short, unqualified names.

When the suffix search list is empty or unspecified, the primary DNS suffix of the computer is appended to short unqualified names, and a DNS query is used to resolve the resultant FQDN. If this query fails, the computer can try additional queries for alternate FQDNs by appending any connection-specific DNS suffix configured for network connections.

If no connection-specific suffixes are configured or queries for these resultant connection-specific FQDNs fail, then the client can then begin to retry queries based on systematic reduction of the primary suffix (also known as *devolution*).

For example, if the primary suffix were "example.microsoft.com", the devolution process would be able to retry queries for the short name by searching for it in the "microsoft.com" and "com" domains.

When the suffix search list is not empty and has at least one DNS suffix specified, attempts to qualify and resolve short DNS names is limited to searching only those FQDNs made possible by the specified suffix list. If queries for all FQDNs formed as a result of appending and trying each suffix in the list are not resolved, the query process fails, producing a "name not found" result.

### Notes

- If the domain suffix list is used, clients continue to send additional alternate queries based on different DNS domain

names when a query is not answered or resolved. Once a name is resolved using an entry in the suffix list, unused list entries are not tried. For this reason, it is most efficient to order the list with the most used domain suffixes first.

- Domain name suffix searches are used only when a DNS name entry is not fully qualified. To fully qualify a DNS name, a trailing period (**.**) is entered at the end of the name.

# Configuring multiple names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring multiple names**
Computers running Windows XP and servers running Windows Server 2003 are given DNS names by default. Each computer can have its DNS names configured using one of two possible methods:

- A primary DNS domain name, which applies as the default fully qualified DNS name for the computer and all of its configured network connections.
- A connection-specific DNS domain name, which can be configured as an alternate DNS domain name that applies only for a single network adapter installed and configured on the computer.

Although most computers do not need to support or use more than one name in DNS, support for configuring multiple connection-specific DNS names is sometimes useful. For example, by using multiple names, a user could specify which network connection to use when connecting to a multihomed computer.

**Example: Using connection-specific names**
As shown in the following figure, a multihomed server computer named "host-a" can be named according to both its primary and connection-specific DNS domain names.

In this example, the server computer host-a attaches to two separate subnets -- Subnet 1 and Subnet 2 -- which are also linked at redundant points using two routers for additional paths between each subnet. Given this configuration, host-a provides access as follows through its separately named local area network (LAN) connections:

- The name "host-a.public.example.microsoft.com" provides access using LAN connection 1 over Subnet 1, a lower-speed (10 megabit) Ethernet LAN, for normal access to users who have typical file and print service needs.
- The name "host-a.backup.example.microsoft.com" provides access using LAN connection 2 over Subnet 2, a higher-speed (100 megabit) Ethernet LAN, for reserved access by server applications and administrators who have special needs, such as troubleshooting server networking problems, performing network-based backup, or replicating zone data between servers.

In addition to the connection-specific DNS names, the computer can also be accessible using either of the two LAN connections by specifying its primary DNS domain name, "host-a.example.microsoft.com".

When configured as shown, a computer can register resource records in DNS according to its three distinct names and sets of IP addresses, as shown in the following table:

| DNS name | IP addresses | Description |
|---|---|---|

| | | |
|---|---|---|
| host-a.example.microsoft.com | 10.1.1.11, 10.2.2.22 | Primary DNS name for computer. The computer registers A and PTR resource records for all configured IP addresses under this name in the "example.microsoft.com" zone. |
| host-a.public.example.microsoft.com | 10.1.1.11 | Connection-specific DNS name for LAN connection 1, which registers A and PTR resource records for IP address 10.1.1.11 in the "public.example.microsoft.com" zone. |
| host-a.backup.example.microsoft.com | 10.2.2.22 | Connection-specific DNS name for LAN connection 2, which registers A and PTR resource records for IP address 10.2.2.22 in the "backup.example.microsoft.com" zone. |

**Important**

- By default, the primary DNS suffix portion of a computer's fully qualified domain name (FQDN) must be the same as the name of the Active Directory domain where the computer is located. To allow different primary DNS suffixes, a domain administrator may create a restricted list of allowed suffixes by creating the **msDS-AllowedDNSSuffixes** attribute in the domain object container. This attribute is created and managed by the domain administrator using Active Directory Service Interfaces or the Lightweight Directory Access Protocol (LDAP).

  For more information, see Programming interfaces and Directory access protocol.

**Notes**

- DNS names can be set using remote administration and other remote configuration services, such as DHCP. For a DNS server running Windows Server 2003, the primary DNS domain name can be set using either remote administration or the unattended setup option.

- For connection-specific naming, you can use TCP/IP configuration methods. You can manually configure the DNS domain name for each connection that appears in the Network Connections folder or use a DHCP option type (option code 15). For more information, see Advanced configuration.

- For more information about DHCP options, see "DHCP Options" at the Microsoft Windows Resource Kits Web site.

# Updating DNS client information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Updating DNS client information**

Updating DNS client information on a computer is sometimes necessary, for example, when a computer is added or removed from an Active Directory domain. In most cases, clients perform dynamic updates for the following changes when entering or leaving a domain:

- When a computer is joined to a domain, it adds its A and PTR resource records to DNS.
- When a computer is removed from a domain, it deletes its A and PTR resource records from DNS.

If you have enabled dynamic update for zones, these changes occur automatically. For more information, see Dynamic update.

# Securing DNS clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing DNS clients**

The following DNS client considerations have security implications for DNS clients in a DNS infrastructure:

- **Whenever possible, specify static IP addresses for the preferred and alternate DNS servers used by a DNS client.** If a DNS client is configured to obtain its DNS server addresses automatically, it will obtain them from a DHCP server. While this method of obtaining DNS server addresses is secure, it is only as secure as the DHCP server. By configuring DNS clients with static IP addresses for the preferred and alternate DNS servers, you eliminate one possible avenue of attack.

  For more information, see Configure TCP/IP to use DNS; Enable DNS for DHCP-enabled clients.

- **Control which DNS clients have access to the DNS server.** If a DNS server is configured to listen only on specific IP addresses, then only DNS clients configured to use these IP addresses as preferred and alternate DNS servers will contact the DNS server.

  For more information, see Restrict a DNS server to listen only on selected addresses.

For more information, see Security information for DNS.

# Managing Zones

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing zones**

This section covers:

- Managing general properties
- Managing authority records
- Managing resource records
- Delegating zones
- Configuring notify lists
- Securing DNS zones
- Securing DNS resource records
- Using stub zones
- Active Directory-integrated stub zones
- Contrasting stub zones and conditional forwarders
- Checking names and zone data
- Using WINS lookup
- Managing reverse lookup zones

# Managing general properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing general properties**

When you add a zone using the DNS console, you can manage these general properties for it:

- Pause or start the zone to interrupt or restore service for it.
- Change or convert the type for the zone.
- Disable or enable dynamic updates for the zone.

For Active Directory-integrated zones, you can enable the use of secure dynamic updates. This enables you to restrict updates to only a specific set of authorized users or systems. When a secure update policy is enabled for the zone, only users, systems, or groups authorized through Active Directory and included in the access control list (ACL) for each directory-integrated zone, are permitted to update the zone or specific resource records used in it.

In addition to these general zone properties, you can configure or manage the following zone properties using the DNS console:
