2. Right-click the icon for the printer you are using, and then click **Printing Preferences**.
3. On the **Layout** tab, under **Orientation**, click one of the following options:
   - **Portrait** to print vertically on the page.
   - **Landscape** to print horizontally on the page.
   - **Rotated Landscape** to rotate the print 90 degrees counterclockwise on the page.

   A representation of your selection will appear in the display area of the dialog box.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open printing preferences in Printers and Faxes by clicking a printer, and then clicking **Select printing preferences** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- The **Orientation** options appear in the dialog box only if your printer supports this feature. The specific options available depend on the printer you are using.
- To set the printing default for all users connected to the printer, see Set printing defaults.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Specify paper size

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify paper size**

To change printing preferences, you must have the Print permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **Printing Preferences**.
3. Click **Advanced**, and under **Paper/Output** click **Paper Size**.
4. Click the paper size (form) you want.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open printing preferences in Printers and Faxes by clicking a printer, and then clicking **Select printing preferences** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- Any changes you make in **Printing Preferences** will alter the default document settings for the printer and will affect all documents you send to the printer. To change print settings for individual documents from within a program, click **Page Setup** (or **Print Setup**) on the program`s **File** menu, and then make selections.
- To set the printing default for all users connected to the printer, see Set printing defaults.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set printing resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set printing resolution**

To create a document, your printer applies tiny dots of ink to the paper. The more dots per inch (dpi) your printer sends, the crisper and better the results, or the *higher its resolution*. For most printers, selecting a higher printer resolution increases the time it takes for the file to print.

Printer resolution settings are not available if your printer does not support the ability to change the resolution. Also, you must have the Print permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **Printing Preferences**.
3. Click **Advanced**, and under **Graphic**, click **Print Quality**.
4. Click the resolution option you want.

**Notes**

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- In Windows, printer resolution is specified using two numbers. The first represents horizontal resolution and the second represents vertical resolution. For example, 240 X 144 specifies a resolution of 240 dots per inch across (horizontally) and 144 dots per inch down (vertically). Changing the resolution does not change the quality of the printed text unless you are using a LaserJet printer and printing TrueType fonts as graphics.
- Any changes you make in **Printing Preferences** will alter the default document settings for the printer and will affect all documents you send to the printer. To change print settings for individual documents from within a program, click **Page Setup** (or **Print Setup**) on the program`s **File** menu, and then make selections.
- To set the printing default for all users connected to the printer, see Set printing defaults.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Print on one or both sides of the paper

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To print on one or both sides of the paper**

To change printing preferences, you must have the Print permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **Printing Preferences**.
3. On the **Layout** tab, under **Print on Both Sides**, click one of the following options:
   - **None** to print on only one side of the paper.
   - **Flip on Long Edge** to print on both sides of the paper with pages that are bound on the left edge.
   - **Flip on Short Edge** to print on both sides of the paper with pages that are bound on the top edge.

   A representation of your selection will appear in the display area of the dialog box.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- The options available on the **Layout** tab depend on the printer you are using. For example, the **Print on Both Sides** options appear only if your printer supports this feature.
- You can also open printing preferences in Printers and Faxes by clicking a printer, and then clicking **Select printing preferences** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- For information about setting the printing default for all users connected to the printer, click **Related Topics**.

# Print multiple pages per sheet

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To print multiple pages per sheet**

To print multiple pages on one sheet of paper, your printer must support this feature, and you must have the Print permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **Printing Preferences**.
3. On the **Layout** tab, click the number of pages you want to print on a sheet in **Pages Per Sheet**.

   A representation of your selection will appear in the display area of the dialog box.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- Any changes you make in **Printing Preferences** will alter the default document settings for the printer and will affect all documents you send to the printer. To change print settings for individual documents from within a program, click **Page Setup** (or **Print Setup**) on the program`s **File** menu, and then make selections.
- For information about setting the printing default for all users connected to the printer, click **Related Topics**.

# Set the number of copies to print

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the number of copies to print**
To change printing preferences, you must have the Print permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **Printing Preferences**.
3. Click **Advanced**.
4. Under **Paper/Output**, specify the **Copy Count**.

   If your printer supports collation, the pages will be collated by default when you print multiple copies.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open printing preferences in Printers and Faxes by clicking a printer, and then clicking **Select printing preferences** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- Any changes you make in **Printing Preferences** will alter the default document settings for the printer and will affect all documents you send to the printer. To change print settings for individual documents from within a program, click **Page Setup** (or **Print Setup**) on the program`s **File** menu, and then make selections.
- For information about setting the printing default for all users connected to the printer, click **Related Topics**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Printer Options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure printer options**

- Set installable options for a printer
- Set printer memory
- Match a form to a printer tray
- Ensure that complex pages print properly
- Install or remove external PCL soft fonts
- Make cartridge fonts available

# Set installable options for a printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set installable options for a printer**

1. Open Printers and Faxes.
2. Right-click the printer you want to set options for, and then click **Properties**.
3. On the **Device Settings** tab, under **Installable Options**, click any option to set it.

## Notes

- To change device settings, you must have the Manage Printers permission. For information about printing security permissions, see Related Topics.
- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- Only installable options supported by the specific printer will be shown in the **Installable Options** list.
- Administrators need to set the installable options that actually exist for the specific printer. Users will only be able to see and choose from the installable options the administrator sets as available.

  Examples of installable options include: printing on both sides of a page (duplex unit), envelope feeder, multiple bin mailbox trays, stapler, internal disk, and others.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set printer memory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set printer memory**

To change the amount of printer memory in Windows, your printer must support the ability to change the amount of printer memory. Otherwise, the options described here will not appear in Windows. Also, you must have the Manage Printers permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. If you do not know already, find out how much memory is installed in your printer. Many printers - especially laser printers - have a self-test feature that will print a document containing the current memory configuration. For more information on how to determine your printer's memory amount, see your printer's operating manual.

2. Open Printers and Faxes.

3. Right-click the icon for the printer you are using, and then click **properties**.

4. On the **Device Settings** tab, under **Installable Options**, click **Printer Memory**, and then click the number that matches the amount of memory installed in your printer or plotter.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

- Your printer has memory chips for storing information that is sent to it. When you install a printer, Windows reads the amount of printer memory so the printer and Windows work properly together. When you install additional memory into your printer, you need to change the printer memory setting in Windows so that the two match. If Windows is configured to require more or less memory than actually resides in your printer, Windows might display a message.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Match a form to a printer tray

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To match a form to a printer tray**

Many printers have upper and lower trays that contain different sizes of paper. Matching a form to a source ensures that documents always print on the correct paper size when the form is selected from within a program. To make these changes, you must have the Manage Printers permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **properties**.
3. On the **Device Settings** tab, under **Form To Tray Assignment**, click a printer tray.
4. Click one of the available paper sizes for the selected tray.
5. Repeat steps 3 and 4 for each paper source.

### Note

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Ensure that complex pages print properly

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To ensure that complex pages print properly**

To change device settings, you must have the Manage Printers permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **properties**.
3. On the **Device Settings** tab, click **Page Protection**, and then click **On**.

   When page protection is active, the printer creates the entire printed page in memory before starting to print. To use page protection, your printer must have at least 1 megabyte (MB) of optional memory available. If your printer does not support page protection, this option is not available.

### Note

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Install or remove external PCL soft fonts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install or remove external PCL soft fonts**

This procedure enables you to install PCL format fonts on Hewlett-Packard LaserJet, DeskJet, or compatible printers. External fonts can be PCL soft fonts or cartridge fonts. Refer to your font documentation to check the format of your fonts.

You must also have the Manage Printers permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the icon for the printer you are using, and then click **properties**.
3. On the **Device Settings** tab, click **External Fonts**, and then click **Properties**.
4. Do one of the following:
   - To install external PCL soft fonts, in **New Soft Font Directory**, type the path to the folder or drive where the fonts are located, and then click **Open**. Click the fonts you want to install in **New Soft Fonts**, and then click **Add** after each selection.
   - To remove external PCL soft fonts, in **Installed Soft Fonts**, click the fonts you want to remove, and then click **Delete**.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- If you need to add or remove TrueType fonts, use the Fonts folder in Control Panel.
- You can also open printer properties in Printers and Faxes by clicking a printer, and then clicking **Set printer properties** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Make cartridge fonts available

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To make cartridge fonts available**

1. Make sure that the cartridges are properly inserted into the cartridge slots on your printer.
2. Open Printers and Faxes.
3. Right-click the icon for the printer you are using, and then click **properties**.
4. On the **Device Settings** tab, under **Installed Font Cartridges**, click the slot number in which the cartridge is installed.

   The **Installed Font Cartridges** options appear only if your printer supports this feature. To change this option, you must have the Manage Printers permission, which is one of several printer permissions.

### Note

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use Advanced Options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Use advanced options**

- Schedule alternate printing times
- Set different print priority to different groups
- Enable Postscript and PCL on the same printer
- Keep a copy of everything you print
- Set up a printer to print to multiple devices
- Add a color profile to a printer
- Enable printer location tracking
- Start and stop the print spooler
- Run printing commands from the command prompt

# Schedule alternate printing times

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To schedule alternate printing times**

1. Open Printers and Faxes.
2. Right-click the printer you want to set, and then click **Properties**.
3. Click the **Advanced** tab, and then click **Available from**.
4. To set the time period that the printer will be available, do one of the following:
   - Click the up or down arrows.
   - Or, type a start and end time, such as **6:00 PM To 6:00 AM**.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- By default, printers are set to be always available.
- For more information on using different printing times for a printer, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set different print priority to different groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set different print priority to different groups**

1. Open Printers and Faxes.
2. Right-click the printer you want to set, click **Properties**, and then click the **Advanced** tab.
3. In **Priority**, click the up or down arrows, and then click **OK**.

   Or, type a priority level, where 1 is the lowest level and 99 is the highest, and then click **OK**.
4. Click **Add Printer** to add a second logical printer for the same physical printer. For instructions, see Related Topics.
5. Click the **Advanced** tab.
6. In **Priority**, set a priority higher than that of the first logical printer.
7. Instruct the regular group of users to use the first logical printer name and the group with higher priority to use the second logical printer name. Set the appropriate permissions for the different groups.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You gain no benefits just from setting a priority to a printer. You need to set at least two different logical printers for the same physical printer to take advantage of this option.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable Postscript and PCL on the same printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Postscript and PCL on the same printer**

1. Open Printers and Faxes.

2. Double-click **Add Printer**, and then click **Next**. For instructions on how to add a printer, see Related Topics.

3. When the Add Printer Wizard prompts you to select the printer manufacturer and model, from the **Manufacturers** list, click the correct name; from the **printers** list, click the appropriate model, with either Postscript (PS) or PCL.

   For example, for HP LaserJet 8100 Series, click **HP LaserJet 8100 Series PS** to set the printer with a Postscript driver.

   Follow the instructions on the screen to finish setting up the printer with the Add Printer Wizard.

4. Double-click **Add Printer** again to add a second logical printer for the same physical printer. For instructions on how to add a printer, see Related Topics.

5. When the Add Printer Wizard prompts you to select the printer manufacturer and model, select the same manufacturer name again. For model, from the **Printers** list, click the model for the other printer's language.

   For the same HP LaserJet 8100 Series as in the previous example, click **HP LaserJet 8100 Series PCL 5e** to set this logical printer with a PCL driver.

6. Follow the instructions on the screen to finish setting up the printer.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

- Users with Postscript documents will send their documents to be printed to the Postscript logical printer (the first printer in the previous example); users with Printer Control Language (PCL) documents will use the PCL logical printer (the second printer in the previous example).

- Use the same procedure to allow printing to any printer that supports multiple languages.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

# Keep a copy of everything you print

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To keep a copy of everything you print**

1. Open Printers and Faxes.
2. Right-click the printer you want to set, click **Properties**, and then click the **Advanced** tab.
3. Select the **Keep printed documents** check box.
4. If you have compatibility problems with your printing, clear the **Enable advanced printing features** check box.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- If you keep printed documents in the spool, carefully monitor the spool folder and the available disk space.
- To purge all printed documents from the spool, clear the **Keep printed documents** check box (default).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set up a printer to print to multiple devices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set up a printer to print to multiple devices**

1. Open Printers and Faxes.
2. Right-click the printer you are using, and then click **Properties**.
3. On the **Ports** tab, select the **Enable printer pooling** check box.
4. Click each port where the printers you want to pool are connected.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- With printer pooling, the printers must be the same type of printer using the same printer driver.
- The previous procedure assumes the printers you want to pool are already in the Printers and Faxes folder.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a color profile to a printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a color profile to a printer**

1. Open Printers and Faxes.
2. Right-click the printer that you want to associate with a color profile, click **Properties**, and then click the **Color Management** tab.
3. Click **Add** to open the **Add Profile Association** dialog box.
4. Locate the new color profile you want to associate with the printer.
5. Click the new profile, and then click **Add**.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- Color profiles communicate the color characteristics of a device to the color management system. Associating the correct color profile with all of your publishing tools helps to ensure consistent color application throughout the publishing process.
- The Color Management tab is only visible for color printers that support color management.
- For more information about a profile in the **Add Profile Association** dialog box, right-click the profile, and then click **Properties**.
- Color profiles are usually installed in the systemroot\System32\Spool\Drivers\Color folder.
- Windows provides a color profile named sRGB Color Space Profile.icm, which you can use with any device that supports Image Color Management 2.0.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Change the rendering intent for viewing or printing an image or page

# Enable printer location tracking

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable printer location tracking**

1. Open Active Directory Sites and Services.
2. Create the sites you want, if you haven't done so already. To create a site, see Related Topics.
3. Associate a subnet for this newly created site, if you haven't done so already. To associate a subnet for the site, see Related Topics.
4. Right-click each subnet you created, and then click **Properties**.
5. Click the **Location** tab, enter the location of the subnet in the following format based on your location naming convention, and then click **OK**:

   *location/location*

6. Using Group Policy, double-click the **Pre-populate printer search location** policy setting, and then click to enable it.

   The following example demonstrates how to set the policy to a group (organizational unit in Active Directory terms) of users that use that printer. However, you can set the policy to a different object using the appropriate Active Directory utility.

   - Start Group Policy from Active Directory Users and Computers. To apply Group Policy to a domain or organizational unit, see Related Topics.
   - Right-click the organizational unit you want to apply the policy to, and then click **Properties**.
   - Click the **Group Policy** tab, and then click **New** to create a new object. Type the name of the new object, and then click **OK**.
   - Select the newly created object and then click **Edit**.
   - Expand **Computer Configuration**, then **Administrative Templates**, and then **Printers**.
   - Double-click the policy setting **Pre-populate printer search location**, and then click to enable it. When you search the directory service for printers, it automatically fills in your location field using the value specified in the **Location** tab of the Subnet properties page. If this policy is disabled (default), the location will be empty.

7. Open Printers and Faxes.
8. Right-click the printer, and then click **Properties**.
9. Type the printer location, or click **Browse** to find it. You probably want to be more precise in describing the printer location than the subnet location. For example, for the subnet location US/NYC, you might enter **US/NYC/Floor42/Room4207**.
10. Repeat the last two steps for each printer in Active Directory.

**Notes**

- To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.
- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- To enable printer location tracking, you must have the following:
    - A working directory service with more than one site or more than one subnet.
    - A network IP addressing scheme that corresponds roughly to the physical layout of your enterprise.
    - Client computers that can query the directory service.
    - A subnet object for each site. You can create them using Active Directory Sites and Services.
    - Your own naming convention for printer location.
    - Administrative credentials.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start and stop the print spooler

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start and stop the print spooler**

1. Open Computer Management.
2. In the console tree, click **Services**.

   **Where?**

   - Computer Management/Services and Applications/Services

3. In the details pane, double-click **Print Spooler**.
4. Do one of the following depending on the task you want to do:

   Click **Stop** to stop the service.

   Click **Start** to start the service.

## Notes

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.
- When you stop the Print Spooler service, it might stop other dependent services.
- The print spooler runs under the Local Computer system account by default.
- You can also start and stop the Print Spooler service through a command-prompt command. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Run printing commands from the command prompt
Enable or disable logging of printing events

# Run printing commands from the command prompt

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To run printing commands from the command prompt**

1. Open Command Prompt.
2. At the command prompt, you can run the following printing-related commands:

   - To print a text file or display the contents of a print queue.
   - To display or control print jobs and printer queues.
   - To connect to, or disconnect from, a shared printer.
   - To start the print spooler service.
   - To stop the print spooler service.

**To print a text file or display the contents of a print queue.**
For command syntax, see Print.

Example:

To print the text file Autoexec.bat to a printer on parallel port LPT2:

**print /d:LPT2: C:\autoexec.bat**

**To display or control print jobs and printer queues.**
For command syntax, see Net print.

Examples:

To view the print queue of MyPrinter1 on print server W2KPRN1:

**net print \\W2KPRN1\MyPrinter1**

To delete print job number 2 on MyPrinter1 on print server W2KPRN1:

**net print \\W2KPRN1 2/delete**

**To connect to, or disconnect from, a shared printer.**
For command syntax, see Net use.

Examples:

To redirect print output for the LPT1 port to MyPrinter1 on print server W2KPRN1:

**net use LPT1: \\W2KPRN1\MyPrinter1**

To display information about the LPT1 port:

**net use LPT1:**

**To start the print spooler service.**
For command syntax, see Net start.

Example:

To start the Print Spooler service:

**net start** *spooler*

**To stop the print spooler service.**
For command syntax, see Net stop.

Example:

To stop the Print Spooler service:

**net stop** *spooler*

Note that other dependent services might need to be stopped as well. The system prompts you to confirm, while listing the other service names.

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- Command-prompt commands can be useful if you need to connect users to shared printers through a login script or any other automated batch or a script procedure.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the rendering intent for viewing or printing an image or page

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the rendering intent for viewing or printing an image or page**

1. In the graphics program in which you are creating your image or page, on the **File** menu, click **Color Management**.
2. Select the **Enable Color Management** check box, and then click **Basic color management**.
3. In **Rendering Intent**, click the rendering intent you want to use.

**Note**

- Your graphics program must support Image Color Management 2.0 in order to implement color management options.

# Manage Printers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage printers**

- Remotely manage printers
- Manage printers from a browser
- Manually publish a printer in Active Directory
- Set Group Policy for printers
- Block the installation of kernel-mode printer drivers
- Take ownership of a printer
- Track printer usage
- Monitor print queue performance
- Search for Printers

# Remotely manage printers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remotely manage printers**

1. Double-click **My Network Places**, and then locate the print server for the printers you want to manage.

2. Double-click the print server, double-click the **Printer folder** icon on that server, and then click a printer.

   **Important**

   - To facilitate stronger network security, remote printer management is not available by default. To enable remote printer management, in Group Policy, you must enable the Allow Print Spooler to Accept Client Connections policy. For more information, see Related Topics.

3. Change the print server, printer, or printing preference settings as required.

## Notes

- You can change printer settings only if you have Manage Printers permission.

- If you are having trouble finding your printer and you are logged on to a Windows Server 2003 family domain, you can find your printer by clicking **Start**, pointing to **Search**, and then clicking **Printers**.

- You can also drag the Printers and Faxes folder of any print server (or specific printers from any Printers and Faxes folder) to the Printers and Faxes folder on your computer. This is an easy way to manage any printer without having to search for it.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

# Manage printers from a browser

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manage printers from a browser**

1. From Internet Explorer, or any other browser, type the following URL:

   **http://***PrintServerName*/**printers/**

   Or, type a specific printer URL:

   **http://***PrintServerName/PrinterName/*

2. In **All Printers on***PrintServerName*, click the printer you want to manage.

   **Important**

   - To facilitate stronger network security, remote printer management is not available by default. To enable remote printer management, in Group Policy, you must enable the Allow Print Spooler to Accept Client Connections policy. For more information, see Related Topics.

3. In *PrinterName* **on** *PrintServerName*, you can click any function on the left pane to stop, resume, or cancel a specific document or all documents. You can also click a specific document in the queue to see its properties.

**Notes**

- An administrator can disable Internet printing with the Group Policy setting **Disable Web-based Printing**.

- For Internet printing you must have Internet Information Services (IIS) installed on a computer running a Windows Server 2003 family operating system (this is installed by default) or Peer Web Services (PWS) on a computer running Windows XP Professional.

- You can also access the Web-based view from the **Printers** folder if **Enabled Web view content in folder** is selected (the folder has the Web-based view in the left pane). If you click any printer in the right pane, you can select **Get More Info** in the left pane to view the printer's content in Web-based view.

  In addition, you can use the left pane to jump to the Microsoft support Web site, and, if available, the printer's vendor support Web site.

- You can manage any printer connected to a computer running a Windows Server 2003 family operating system from any other computer running a Windows Server 2003 family operating system, when Web-based printing is enabled. Web-based printing is enabled by default.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

# Manually publish a printer in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manually publish a printer in Active Directory**

1. Open **Active Directory Users and Computers**.
2. In **Name**, right-click the container object folder in which you want to publish the printer.
3. Point to **New**, and then click **Printer**.
4. Type the UNC name of the printer that you want to publish in the directory.

## Notes

- To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
- To perform this procedure, you must be a member of the Print Operators group, Domain Admins group, or the Enterprise Admins group in Active Directory, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- Group Policy settings for printers determine whether printers published with a print server running Windows NT 4.0 or an earlier operating system should be pruned if the print server becomes unavailable.
- You can also use the **Pubprn.vbs** script, provided in the System32 folder, to publish printers with print servers running Windows NT 4.0 or an older operating system.
- The printer you want to publish must be shared.
- You must have directory service administration rights to publish printers.
- You must have the Manage Printers permission for the printer you want to share or to publish.
- You can create printer names that contain spaces, special characters, and more than eight characters. However, some clients do not recognize or correctly handle such names. The entire qualified name of a shared printer (for example, \\PRINTER2\PSCRIPT) must contain 32 or fewer characters.

Group Policy and printing
Publish a printer in Active Directory

# Set Group Policy for printers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set Group Policy for printers**

1. Start Group Policy according to the object you want to set printer policy to. For more information on how to start Group Policy, see Related Topics.

2. After selecting the properties page of the object you want to set printer policy to, select the Group Policy node.

   - If you want to set policies that apply only to computers, expand the **Computer Configuration** node, and then expand **Administrative Templates**.

   - If you want to set policies that apply only to users, expand the **User Configuration** node, expand **Administrative Templates**, and then expand **Control Panel**.

3. Double-click **Printers** to open a listing of policies.

4. Double-click the printer policy you want to set.

5. On the **Policy** tab, enable or disable the policy by selecting or clearing the appropriate radio button. With some policies, you might need to enter additional information.

### Note

- If you do not want to change the current state of the policy setting, leave it as it is (not configured) to save processing time.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Block the installation of kernel-mode printer drivers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To block the installation of kernel-mode printer drivers**

1. Open Group Policy.
2. Under **Local Computer Policy**, double-click **Computer Configuration**.
3. Double-click **Administrative Templates**, and then double-click **Printers**.
4. Right-click **Disallow installation of printers using kernel mode drivers**, and then click **properties**.
5. On the **Setting** tab, click **Enabled**, and then click **OK**.

### Important

- This policy does not affect existing kernel-mode printer drivers. Kernel-mode printer drivers that were installed before you set this policy will not be disabled or removed. You can upgrade existing non-kernel-mode printer drivers whether you set this policy or not.

### Notes

- To open Group Policy so that you can edit the local Group Policy object, click **Start**, click **Run**, type **gpedit.msc**, and then press ENTER.
- In Windows Server 2003, Standard Edition and Windows Server 2003, Enterprise Edition, installation of kernel-mode drivers is blocked by default. In Windows XP Professional, installation of kernel-mode drivers is not blocked by default.
- You must click **Enabled** to block the installation of kernel-mode printer drivers. Clicking **Not Configured** or **Disabled** allows kernel-mode printer drivers to be installed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Take ownership of a printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To take ownership of a printer**

1. Open Printers and Faxes.
2. Right-click the printer icon, and then click **Properties**.
3. Click the **Security** tab, and then click **Advanced**.
4. Click the **Owner** tab, click your user account under **Change owner to**, and then click **OK** twice.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- If you are a member of the Administrators group and you want this group to take ownership of the printer, click the Administrators group.
- By default, the user who installed the printer owns it.
- A user or a member of a group who has Manage Printers permission for the printer can take ownership.
- By default, members of the Administrators, Print Operators, Server Operators, and Power Users groups have Manage Printers permission, which allows them to take ownership of a printer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Track printer usage

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To track printer usage**

1. Open Printers and Faxes.
2. Right-click the printer you want to audit, and then click **Properties**.
3. Click the **Security** tab, click the **Advanced** button, and then click the **Auditing** tab.
4. Click **Add**, and then click the user or group whose printer access you want to audit.
5. In the **Access** column, click successful and failed printing events you want to audit, and then click **OK** twice.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- **Successful** means you want to audit all successful attempts to perform this action.
- **Failed** means you want to audit all failed attempts to perform this action.
- You can view the audit information in the security log file.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Monitor print queue performance

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To monitor print queue performance**

1. Open Performance.
2. Click the plus sign (**+**) on the Performance toolbar.
3. From the **Select counters from computer** list box, click the print server computer.
4. From the **Performance object** list box, click **Print Queue**.
5. Click the counters you want to monitor.

## Notes

- To open Performance, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Performance**.
- To view a detailed explanation of a counter, select it, and then click **Explain**.
- You can also add System Monitor to any new Microsoft Management Console (MMC).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Search for Printers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Search for printers**

- Search for a printer
- Filter your search results
- Use advanced options to search for a printer
- Add or remove columns in the search results list
- Create a custom printer search

# Create a custom printer search

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a custom printer search**

1. Search for printers in Active Directory. For more information, see Related Topics.

2. After the search results appear, you can refine the search as necessary by using any of the search options. In particular, the **Advanced** tab can be a powerful way to build custom printer queries.

   To change the appearance of search results to the way you want them to appear to users, click **View**.

3. Click **File**, and then click **Save Search**. Select where you want the search to be saved, type a name for the search, and then click **Save**.

## Notes

- As administrator, you can save search results into users profiles, which allow you to distribute the search results file to users' Printers and Faxes folders, desktops, or any other location on users' computers.

- You and your users can further narrow search results by using the **Filter** option on the **View** menu, which is available only when you click **Details**. However, filtering criteria are not saved by **Save Search**.

- Users can use the saved search file by double-clicking the file name. The saved search runs in the background, and only the result of the saved search appears.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Set or remove permissions for a printer

# Connect clients to a printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connect clients to a printer**

- Connect to a printer published in Active Directory
- Connect to a printer on a network
- Connect to a printer with a browser
- Connect Windows NT 4.0, Windows 95, and Windows 98 clients
- Connect MS-DOS, Windows 3.x, and OS/2 clients
- Connect Macintosh clients to a printer
- Print from an LPR client to a printer
- Connect to a printer on a NetWare server
- Connect to a printer on a Macintosh server

# Connect to a printer published in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a printer published in Active Directory**

1. Find the printer you want to connect to. For instructions on how to search for a printer, see Related Topics.

2. In the details pane, right-click the printer you want to use, and then click **Connect**, or double-click the printer name from the list.

## Notes

- You can search for printers in Active Directory only if you are logged on to a Windows Server 2003 family or Windows 2000 domain, and your client is running Windows XP Professional, Windows 2000, Windows 95, or Windows 98.

- Windows 95 and Windows 98 clients must run the directory service to query Active Directory.

- Windows NT 4.0 clients can connect to a shared printer on a print server by browsing My Network Places, or by using the Add Printer Wizard.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Connect Windows NT 4.0, Windows 95, and Windows 98 clients

# Connect to a printer on a network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a printer on a network**

1. Open Printers and Faxes.
2. Double-click **Add Printer** to start the Add Printer Wizard, and then click **Next**.
3. Click **A network printer, or a printer attached to another computer**, and then click **Next**.
4. Connect to the desired printer using one of the following three methods.

   **Searching for it in the Active Directory**

   If you are not logged on to a domain running Active Directory, this method will not be available.

   a. Click **Find a printer in the Directory**, and then click **Next**.

      If needed, change the default printer location listed in the **Location** field by clicking the Location **Browse** button, and then choosing the appropriate location.

   b. Click **Find Now**.

   c. In the list that appears, click the printer you want to connect to, and then click **OK**.

   **Typing the printer name or browsing for it**

   a. Click **Connect to this printer**, or click **Next** to browse for a printer.

   b. Do one of the following:

      • Type the printer name using the following format, and then click **Next**:

      *****printserver_name******share_name*

      • Browse for it on the network by clicking **Next**, locating the printer in **Shared printers**, and then clicking **Next**.

   **Connecting to an Internet or intranet printer**

   Connecting to a printer using its URL allows you to connect to printers across the Internet, provided you have permission to use that printer. If you cannot connect to your printer using the general URL format above, please see your printer's documentation or contact your network administrator.

   a. Click **Connect to a printer on the Internet or on a home or office network**.

   b. Type the URL to the printer using the following format, and then click **Next**:

      http://*printserver_name*/Printers/*share_name*/.printer

5. Follow the instructions on the screen to finish connecting to the printer.

The icon for the printer appears in your Printers and Faxes folder.

### Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also connect to a printer by dragging the printer from the Printers and Faxes folder on the print server and dropping it into your Printers and Faxes folder, or by right-clicking the icon and then clicking **Connect**.
- After you have connected to a shared printer on the network, you can use it as if it were attached to your computer.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**Concepts**
Connect to a printer on a NetWare server

# Connect to a printer with a browser

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a printer with a browser**

1. Open Internet Explorer, or open Printers and Faxes.
2. In the Address bar, type one of the following:
   - If you do not know the printer name, type the following, using the format: **http://***PrintServerName***/printers/**

     For example, type **http://PrintSrv1/printers** to receive a page listing all the printers, and then click the printer you want.
   - If you know the printer name, type its URL using the format: **http://***PrintServerName/PrinterName/*

     For example, type **http://PrintSrv1/ColorPrinter5/** to go directly to that printer's page.
3. When viewing the printer's page, click **Connect** to connect to that printer.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- A server running a Windows Server 2003 family operating system automatically copies the appropriate printer driver to the client computer.
- The administrator can disable Internet printing using the Group Policy setting **Disable Web-based Printing** for printers.
- For Internet printing, you must have Internet Information Services (IIS) installed on the server (or Peer Web Services (PWS) on a computer running Windows XP Professional .
- You must use Internet Explorer version 4.0 or higher to connect to a printer.
- After you connect to a shared printer from a Web browser, you can use it as if it were attached to your computer. You can also add it to your browser Favorites.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Connect to a printer on a network

# Connect Windows NT 4.0, Windows 95, and Windows 98 clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect Windows NT 4.0, Windows 95, and Windows 98 clients**

1. Open Printers and Faxes.
2. Double-click **Add Printer**, and then click **Next**.
3. Click **A network printer, or a printer attached to another computer**, and then click **Next**.
4. Click the printer in **Connect to this printer**.

   Or, in **Name**, type the name of a printer on your network using the following format:

   *server_name**share_name*

5. Follow the instructions on the screen to finish connecting to the printer.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- After you complete these procedures, the printer driver downloads automatically, and the icon for that printer appears in your Printers and Faxes folder.
- To connect a printer to a Windows NT 4.0, Windows 95, or Windows 98 client, you must install the print drivers for these clients on the print server. During connection, the print driver downloads to the client without the need for the original compact disc or discs.
- To install additional printer driver for previous Windows NT clients and for Windows 95 and Windows 98 clients, see Related Topics.
- If directory services is not installed, double-click **My Network Places** to locate the print server and the printer you want to connect to. Then, right-click the printer and select **Install**.
- If directory services is installed (directory service clients are available for Windows 95 and Windows 98 only), you can use Active Directory to find the printer you want to connect to. Right-click the printer's name, and then click **Connect**.
- For Windows NT 4.0 clients, the print driver is automatically downloaded if it does not exist. If it already exists, it is updated on the print server. For Windows 95 and Windows 98 clients, the print driver is downloaded automatically only the first time (if it does not exist). When an updated driver is installed on the print server, the printer driver must be updated manually from the print server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Connect to a printer with a browser

# Connect MS-DOS, Windows 3.x, and OS/2 clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect MS-DOS, Windows 3.x, and OS/2 clients**

1. Install the appropriate printer driver on the client computer.

2. Redirect an output port (such as LPT1) of the client computer to the logical printer (in the form of \\PrintServerName\sharename) on the Windows Server 2003 family print server, using the command specific to its operating system.

   Typically, the command for clients that add the **Clients for Microsoft Networks** option is:

   **net use lptx***server_name******share_name*

## Notes

- Other Microsoft clients include Windows 3.x, Windows for Workgroups, MS-DOS, and OS/2 with the LAN Manager 2.x client installed.

- If the client is not connected to the network, install the network client on the client computer first, and then verify active connection to the network.

- Fonts and forms available on a Windows Server 2003 family operating system might not be available on client computers running other operating systems.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect Macintosh clients to a printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect Macintosh clients to a printer**

1. Verify that the print server is running the AppleTalk protocol, and Print Server for Macintosh.
2. Set up a user account for Macintosh print jobs. For more information, see Related Topics.
3. From a Macintosh client computer, connect to the printer using Macintosh Chooser.

## Notes

- Macintosh clients can connect to any printer on the Windows Server 2003 family network that runs the AppleTalk protocol.
- Install the printer driver for Macintosh on each client that you want to connect to the printer.
- Macintosh clients can search for printers on print server computers running a Windows Server 2003 family operating system by browsing for all printer addresses using Macintosh Chooser. Macintosh users do not have access to Active Directory.
- If your Macintosh uses a protocol other than AppleTalk, such as TCP/IP, verify that both the clients and the print server run that protocol.
- Because AppleTalk does not support client user names or passwords, Macintosh clients cannot identify themselves on a Windows Server 2003 family network, and the print server cannot impose user-level security on them. If a Macintosh client is physically able to send a job to the printer, it has implicit permission. However, an administrator can set user-level permission for all Macintosh print clients as a group.
- Print Server for Macintosh is not available on the 64-bit versions of the Windows operating systems.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Print from an LPR client to a printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To print from an LPR client to a printer**

1. Install the appropriate printer driver on the client.

2. Install Print Services for Unix on the Windows Server 2003 family print server, and then start the Line Printer Daemon (LPD) service (if not started automatically) from Services.

3. Use the Line Printer Remote (LPR) utility on your client to connect to the logical printer on the print server. Refer to your client operating system documentation for the correct command. Typically the LPR command is in the following format:

   **lpr -S***server_name***-P***queue_name file_name*

## Notes

- Both client and server must run TCP/IP, and the client must have an RFC-compliant version of LPR.

- Some hosts do not support LPR. Refer to your operating system documentation to make sure your host does support LPR.

- If documents sent by LPR services on a UNIX client do not print correctly on the print server, try reconfiguring the LPR software to use a lowercase control command.

- The Lpdsvc service is independent of the Lprmon, which allows a computer running a Windows Server 2003 family operating system (and all clients who can access this computer) to print to a printer connected to a UNIX system.

- If you send a document from a Windows XP client to another LPD-enabled target (for example, a UNIX host), the Windows XP client must run Print Services for Unix.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to a printer on a NetWare server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a printer on a NetWare server**

1. Open Printers and Faxes.
2. Double-click **Add Printer**, and then click **Next**.
3. Click **A network printer, or a printer attached to another computer**, and then click **Next**.
4. Click **Connect to this printer**.
5. In **Name**, type the name of a printer in the following format:

   *****servername******sharename*

   Or, to find the NetWare printer in **Shared printers**, click **Next**.
6. Follow the remaining instructions in the Add Printer Wizard to finish connecting to the NetWare printer.

   The icon for that printer appears in your Printers and Faxes folder.

### Important

- The IPX/SPX protocol is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. Due to its dependency on the IPX/SPX protocol, Client Service for NetWare is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family.

### Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- To connect to a printer on a NetWare server, you must have Client Service for NetWare and NWLink IPX/SPX/NetBIOS Compatible Transport Protocol (NWLink) installed. For information on how to do this, see Related Topics.
- If a printer driver is not available locally for a NetWare printer, you are prompted to install one.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Connect to a printer attached to a NetWare server
Add a port

# Connect to a printer on a Macintosh server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a printer on a Macintosh server**

1. Open Printers and Faxes.

2. Double-click **Add Printer** to start the Add Printer Wizard, and then click **Next**.

3. Click **Local printer attached to this computer**, and then click **Next**.

4. Follow the instructions on the screen to finish setting up the printer by selecting a printer port, selecting the manufacturer and model of your printer, and typing a name for your printer.

   When the wizard prompts you to select the printer port, click **Create a new port**. From the drop-down list, click **AppleTalk Printing Device**, and then click **Next**.

   When you're prompted for available AppleTalk printing devices, select a zone and a printer, and then click **OK**.

   When you're asked whether you want to capture the printer, you normally click **Yes**; see the notes following this procedure.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

- Capturing the printer is the recommended procedure, because a captured printer accepts print jobs only from print server computers running a Windows Server 2003 family operating system. This provides the administrator complete control over the printer. However, if the printer is also being used by a Macintosh server, you cannot capture the printer.

- Because AppleTalk does not support client user names or passwords, Macintosh clients cannot identify themselves on a Windows Server 2003 family network, and the print server cannot impose user-level security on them. If a Macintosh client is physically able to send a job to the printer, it has implicit permission. However, an administrator can set user-level permission for all Macintosh print clients as a group.

- Print Server for Macintosh is not available on the 64-bit versions of the Windows operating systems.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage and Set Print Servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage and set print servers**

- Add printer drivers for other clients
- Update printer drivers
- Remove printer drivers
- List all files on a printer driver
- Change the spool folder location
- Enable or disable logging of printing events
- Enable or disable notifying users when printing completes
- Create a custom printer form
- Set Ports and Protocols

# Add printer drivers for other clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add printer drivers for other clients**

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**, and then click the **Drivers** tab.
3. Click **Add**, click **Next**, and then follow the instructions on the Add Printer Driver Wizard.
4. After selecting the printer's manufacturer and model, you are prompted to select the environment and operating systems for which you want to install drivers.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can add printer drivers for other platforms (such as Alpha-based or x86-based), or for other operating systems, using the **Sharing** tab on each printer's properties page. If you need to add additional drivers for multiple printers, it might be easier to use the **Drivers** tab on the properties page of the print server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**Concepts**
Update printer drivers
Remove printer drivers
List all files on a printer driver

# Update printer drivers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To update printer drivers**

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**, and then click the **Drivers** tab.
3. In the **Installed printer drivers** list, click the driver you want to update, and then click **Replace**.
4. Click **Yes**. The driver files are copied for all the installed environments and versions. The system might prompt you for the path to the drivers.

### Note

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove printer drivers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove printer drivers**

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**, and then click the **Drivers** tab.
3. In the **Installed printer drivers** list, click the driver you want to remove, click **Remove**, and then click **Yes** to confirm.

### Note

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

List all files on a printer driver

# List all files on a printer driver

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To list all files on a printer driver**

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**, and then click the **Drivers** tab.
3. In the **Installed printer drivers** list, click the driver you want, and then click **Properties**.

   The names and descriptions of all the files that are part of the specific driver are listed.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can view details on any of the files by clicking the file and then clicking **Properties**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the spool folder location

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the spool folder location**

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**, and then click the **Advanced** tab.
3. In the **Spool folder** window, enter the path and the name of the new default spool folder for this print server, and then click **Apply** or **OK**.
4. Stop and restart the spooler service, or reboot the server.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- If the server functions as the print server for a large number of printers or for print jobs that are typically very long, you should consider moving the spool folder to another location.
- The spool folder might require a large amount of disk space to spool all the jobs.
- The spool folder should not be located at the root directory (generally C:\).
- If the new folder does not exist, this procedure creates it.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Setting the location of the spool folder
Enable or disable logging of printing events

# Enable or disable logging of printing events

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To enable or disable logging of printing events

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**, and then click the **Advanced** tab.
3. To enable or disable writing spooler error events to the system log file, select or clear the **Log spooler error events** check box.
4. To enable or disable writing spooler warning events to the system log file, select or clear the **Log spooler warning events** check box.
5. To enable or disable writing spooler information events to the system log file, select or clear the **Log spooler information events** check box.
6. Stop and restart the spooler service, or reboot the server.

### Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- By default, all printing events are written to the system log file. If you want to reduce the amount of data that is logged, disable the logging of information events. If you want to further reduce the amount, disable the warning events. Disabling the logging of spooler error events is not recommended.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable or disable notifying users when printing completes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable notifying users when printing completes**

1. Open Printers and Faxes.
2. Click **File**, click **Server Properties**, and then click the **Advanced** tab.
3. To enable or disable notifying users when their print jobs finish printing, select or clear the **Notify when remote documents are printed** check box.
4. Stop and restart the spooler service, or reboot the server.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- When the Group Policy setting **Notify Computer, not User** is enabled, the computer that originated the print job is notified, even if the user who submitted the print job has logged off and another user has logged on.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a custom printer form

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a custom printer form**

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**.
3. On the **Forms** tab, select the **Create a new form** check box.
4. In **Form name**, type a name for the new form.
5. Under **Form description (measurements)**, type the dimensions you want for the new form.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- Printer forms define a paper size and type used by a print device. Forms are provided for all standard paper sizes. You can define a custom paper form for nonstandard paper sizes.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set Ports and Protocols

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Set ports and protocols**

- Add a port
- Delete a port
- Add a local port
- Add a standard TCP/IP port
- Add an LPR port
- Add an AppleTalk printing device port

# Add a port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a port**

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**.
3. Click the **Ports** tab, and then click **Add Port**.
4. In the **Available port types** list, click a port name to select it. By default, only **Local Port** and **Standard TCP/IP Port** appear in the **Available port types** list.

   If you want to add a Line Printer Remote (LPR) port, you need to install the optional networking component, **Print Services for Unix**. Once you do so, **LPR Port** will display as one of the available port types. For more information, click **Related Topics**.

   To add other port types, click **New Port Type**, type the path to the compact disc containing the necessary files, and click **OK**.
5. After clicking the port type in the **Printer Ports** dialog box, click **New Port**.
6. Type a name that describes this port, and then click **OK**.
7. On the **Printer Ports** dialog box, click **Close**.
8. If necessary, configure the port by clicking **Configure Port**. Different types of ports have different characteristics that you can configure. After you have finished configuring the port, click **OK**.
9. Click **Close** to close the **Print Server Properties** dialog box.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- For a list of ports you can add, and information about adding them, click **Related Topics**.
- If you add a port using the Add Printer Wizard, the port you add will appear in the list.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Delete a port
Add a printer attached directly to the network
Add a standard TCP/IP port
Add a local port
Add an LPR port
Add an AppleTalk printing device port

## Add optional networking components

# Delete a port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a port**

For this procedure, you must have the Manage Printers permission, which is one of several printer permissions.

1. Open Printers and Faxes.
2. On the **File** menu, click **Server Properties**, and then click the **Ports** tab.
3. In the list of ports, click the port you want to delete, and then click **Delete Port**.
4. Click **Yes** to confirm.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- If you are unable to delete the port and you know that you have printer permissions to do so, it may be that one or more of your printers is set up to print to that port. Reassign the printer or printers to another port, and then try to delete the port again. Deleting a port removes it from the available port list. Any printer that communicates through that port is disconnected.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

**Concepts**

Add a port
Add a local port
Add an LPR port
Add a standard TCP/IP port

# Add a local port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a local port**

1. Open Printers and Faxes.
2. Double-click **Add Printer** to open the Add Printer Wizard, and then click **Next**.
3. Click **Local printer attached to this computer**, clear the **Automatically detect and install my Plug and Play printer** check box, and then click **Next**.
4. Click **Create a new port**, click **Local Port**, and then click **Next**.
5. Type the port name, and then click **OK**.
6. Follow the instructions on the screen to finish adding a printer with the Add Printer Wizard.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also add ports using the **Print Server Properties** dialog box.
- You can configure the time-out for parallel (LPT) ports by selecting any LPT port and then clicking **Configure Port**.
- In a network environment, it is better to use a printer that is connected directly to the network through a network adapter than through a parallel port.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Delete a port
Add a printer attached directly to the network

Add a port
To change the parallel port time-out settings
Add an LPR port
Add an AppleTalk printing device port

# Add a standard TCP/IP port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a standard TCP/IP port**

1. Open Printers and Faxes.
2. Double-click **Add Printer** to open the Add Printer Wizard, and then click **Next**.
3. Click **Local printer attached to this computer**, clear the **Automatically detect and install my Plug and Play printer** check box, and then click **Next**.
4. Click **Create a new port**, and then click **Standard TCP/IP Port**.
5. Click **Next** to run the Add Standard TCP/IP Printer Port Wizard.
6. Follow the instructions on the screen to finish installing the TCP/IP printer.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- Most network printers support the TCP/IP protocol. The standard TCP/IP port simplifies connecting to remote printers using the TCP/IP protocol. A computer that acts as a print server must run the TCP/IP protocol in order to print.
- To connect to a print server running NetWare, you need to install Client Services for NetWare.
- You can also add ports using the **Print Server Properties** dialog box. For more information, click **Related Topics**.
- For print servers that need to communicate with host computers (such as UNIX or VAX computers), it is best to install an LPR port. For more information, click **Related Topics**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Add a port

Print from an LPR client to a printer

# Add an LPR port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an LPR port**

1. Open Printers and Faxes.
2. Double-click **Add Printer** to open the Add Printer Wizard, and then click **Next**.
3. Click **Local printer attached to this computer**, clear the **Automatically detect and install my Plug and Play printer** check box, and then click **Next**.
4. Click **Create a new port**, and then click **LPR Port**.

   If **LPR Port** is not available, click **Cancel** to stop the wizard. To add the LPR port, you need to install the optional networking component, **Print Services for Unix**. For more information, click **Related Topics**.
5. Click **Next**, and then provide the following information:

   - In **Name or address of server providing LPD**, type the Domain Name System (DNS) name or Internet Protocol (IP) address of the host for the printer you are adding. The host may be the direct-connect TCP/IP printing device or the UNIX computer to which the printing device is connected. The DNS name can be the name specified for the host in the Hosts file.
   - In **Name of printer or print queue on that server**, type the name of the printer as it is identified by the host, which is either the direct-connect printer itself or the UNIX computer.
6. Follow the instructions on the screen to finish installing the TCP/IP printer.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- The Line Printer Remote (LPR) port is best suited to servers that need to communicate with host computers (such as UNIX or VAX computers) by way of RFC 1179.
- A network-connected printer must have a card that supports LPD for LPR printing to work properly.
- You can also add ports using the **Print Server Properties** dialog box. For more information, click **Related Topics**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Add an AppleTalk printing device port
Add optional networking components

# Add an AppleTalk printing device port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add an AppleTalk printing device port**

1. Open Printers and Faxes.
2. Double-click **Add Printer**, and then click **Next**.
3. Click **Local printer attached to this computer**, clear the **Automatically detect and install my Plug and Play printer** check box, and then click **Next**.
4. Click **Create a new port**, click **AppleTalk Printing Devices**, and then click **Next**.
5. In the **AppleTalk Printing Devices** list, click the AppleTalk printer you want to add, and then click **OK**.
6. Click **Yes** to capture this AppleTalk printer.

   **Important**

   - If you capture a printer, some users may be unable to print to it.

7. Follow the instructions on the screen to finish installing the AppleTalk printer.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also add ports on the **Ports** tab in the **Print Server Properties** dialog box. To open the **Print Server Properties** dialog box, click **Start**, point to **Settings**, and then click **Printers and Faxes**. On the **File** menu, click **Server Properties**.
- **AppleTalk Printing Devices** is available only when AppleTalk protocol is installed. If **AppleTalk Printing Devices** is not available, click **Cancel** to close the Add Printer Wizard and follow the procedures to add optional networking components (see Related Topics).
- Your system must use the AppleTalk protocol if you want to add an AppleTalk printing device. You might need other Macintosh services if you want to coexist with an AppleTalk network system. For more information, see Related Topics.
- Print Server for Macintosh is not available on the 64-bit versions of the Windows operating systems.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Documents

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage documents**

- Print a document
- View documents waiting to print
- Change the printing priority of documents waiting to print
- Cancel printing a document
- Pause or resume printing a document
- Restart printing a document
- Transfer documents to another printer
- Pause or resume printing all documents
- Cancel printing all documents

# Print a document

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To print a document**

1. Open the document you want to print.
2. On the **File** menu of the program you are using, click **Print**.

## Notes

- In the **Print** dialog box, you can see the number of documents waiting to print on any printer installed on your computer by right-clicking the printer in **Select Printer** and then clicking **Open**.
- If you are logged on to a domain running Active Directory, you can click **Find Printer** to search for a printer on the network with the capabilities you want, such as high-speed or color printing. For more information on searching for a printer, see Related Topics.
- To store a document as a file rather than sending it to the printer, click the **Print to file** check box in the **Print** dialog box.
- For easy access to your printer, you can create a shortcut to it on the desktop. You can double-click the shortcut to open the print queue and view the documents waiting to print. For more information on how to create a shortcut, see Related Topics.
- You can print a document without opening it by dragging its icon to a printer in the Printers and Faxes folder or to a shortcut on your desktop.
- While a document is printing, a printer icon appears next to the clock in the notification area on the taskbar. When this icon disappears, it means that your document has finished printing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View documents waiting to print

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view documents waiting to print**

1. Open Printers and Faxes.
2. Double-click the printer for which you want to view the documents waiting to print.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- The print queue displays information about a document such as print status, owner, and number of pages to be printed. From the print queue, you can cancel or pause printing for any document you send to the printer.
- You can also open the print queue by double-clicking the printer icon in the notification area.
- Another way to open the print queue is to click the printer in Printers and Faxes, and then click **See what's printing** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the printing priority of documents waiting to print

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the printing priority of documents waiting to print**

You can change the printing priority of documents waiting to print only if you have the Manage Documents permission, which is one of several printer permissions. Once a document has started printing, any printing priority changes you make will not affect that document. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Double-click the printer you are using to open the print queue.
3. Right-click the document you want to move in the print order, and then click **Properties**.
4. On the **General** tab, drag the **Priority** slider to raise or lower the document priority. The higher the number, the higher the priority.

   When you click **OK**, the documents will print in the order you want even though your changes may not be reflected in the list of documents.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open the print queue in Printers and Faxes by clicking a printer, and then clicking **See what's printing** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Cancel printing a document

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To cancel printing a document**

By default, all users can pause, resume, restart, and cancel printing of their own documents. However, to manage documents printed by other users, you must have the Manage Documents permission, which is one of several printer permissions.

1. Open Printers and Faxes.
2. Double-click the printer you are using to open the print queue.
3. Right-click the document you want to stop printing, and then click **Cancel**.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open the print queue in Printers and Faxes by clicking a printer, and then clicking **See what's printing** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- You can cancel the printing of more than one document by holding down the CTRL key and then clicking each document you want to cancel. Once all the documents are selected, right click one of them and click **Cancel**.
- You can also open the print queue by right-clicking the printer icon in the notification area.
- For more information on administering printers from the command line, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Pause or resume printing a document

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To pause or resume printing a document**

By default, all users can pause, resume, restart, and cancel printing of their own documents. However, to manage documents printed by other users, you must have the Manage Documents permission, which is one of several printer permissions.

1. Open Printers and Faxes.
2. Double-click the printer you are using to open the print queue.
3. Right-click the document for which you want to pause or resume printing.
4. Do one of the following:
   - To pause printing, click **Pause**.

     The document will not print until you resume printing.
   - To resume printing, click **Resume**.

     The document will begin printing. However, if higher priority documents are waiting to print, they will print first.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open the print queue in Printers and Faxes by clicking a printer, and then clicking **See what's printing** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- In general, once a document has started printing, it will finish printing even if you pause it.
- For more information on administering printers from the command line, see Related Topics.

# Restart printing a document

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restart printing a document**

When you restart printing a document, it starts printing again from the beginning. If higher priority documents are in the print queue, they will print first.

By default, all users can pause, resume, restart, and cancel printing of their own documents. However, to manage documents printed by other users, you must have the Manage Documents permission, which is one of several printer permissions.

1. Open Printers and Faxes.
2. Double-click the printer you are using to open the print queue.
3. Right-click the document for which you want to restart printing, and then click **Restart**.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open the print queue in Printers and Faxes by clicking a printer, and then clicking **See what's printing** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.

# Transfer documents to another printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To transfer documents to another printer**

Use this procedure to send your documents to an alternate printer when your printer has failed and your documents are stuck in the print queue. To redirect documents to another printer, you must have the Manage Printers permission for both printers, which is one of several printer permissions. For more information, click **Related Topics**.

Since the documents you send to the printer are converted into that printer's language, you must redirect the documents to the same type of printer, such as a laser, ink-jet, or dot-matrix.

1. Open Printers and Faxes.
2. Double-click the printer that holds the document(s) you want to redirect.
3. On the **Printer** menu, click **Properties**.
4. Click the **Ports** tab, and then do one of the following:

   **To send documents to another printer on the same print server**

   - Click the port to which the other printer is assigned and then click **OK**.

   **To send documents to a printer on a different print server**

   The printer must already exist and be shared on the print server.

   - Click **Add Port**, click **Local Port**, and then click **New Port**. Type the name of the other print server and the share name of the shared printer in the following format:

     *****other_print_server******share_name*

### Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open printer properties in Printers and Faxes by clicking a printer, and then clicking **Set printer properties** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- The document currently printing cannot be transferred to another printer.
- If the printer holding the print jobs is offline or has a paper jam, the document showing the error cannot be moved to a new port.
- If a print job shows an error, all subsequent print jobs will be held until the document is deleted from the print queue.
- For more information on administering printers from the command line, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your

account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Pause or resume printing all documents

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To pause or resume printing all documents**

To pause, or resume printing on the printer, you must have the Manage Printers permission, which is one of several printer permissions.

1. Open Printers and Faxes.

2. Right-click the printer for which you want to pause or resume printing, and then click **Pause Printing**.

   When you pause printing, the document currently printing will finish, and then no documents will print until you resume printing.

   A check mark appears next to **Pause Printing** when the printer is paused. To clear the check mark and resume printing, click **Pause Printing** again.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.

- You can also open the print queue in Printers and Faxes by clicking a printer, and then clicking **See what's printing** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.

- For more information on administering printers from the command line, see Related Topics.

# Cancel printing all documents

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To cancel printing all documents**

To cancel, pause, or resume printing on the printer, you must have the Manage Printers permission, which is one of several printer permissions. For more information, click **Related Topics**.

1. Open Printers and Faxes.
2. Right-click the printer for which you want to cancel printing, and then click **Cancel All Documents**.
3. When prompted to cancel all documents, click **Yes**.

   In some cases, the document currently printing will finish, and then all other documents are cancelled.

## Notes

- To open Printers and Faxes, click **Start**, and then click **Printers and Faxes**.
- You can also open the print queue in Printers and Faxes by clicking a printer, and then clicking **See what's printing** under **Tasks** on the left side of the window. This option is available only if folders are set to look like a Web page and a printer is selected. For more information, click **Related Topics**.
- For more information on administering printers from the command line, see Related Topics.

# Printing Overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Printing overview**

Using products in the Microsoft® Windows Server 2003 family, you can share printing resources across your entire network. Clients on a variety of computers and operating systems can send print jobs to printers attached locally to a print server computer running a Windows Server 2003 family operating system, across the Internet, or to printers connected to the network using internal or external network adapters, or another server.

Products in the Windows Server 2003 family support several advanced printing features. For example, you can administer a print server computer running a Windows Server 2003 family operating system that exists anywhere on your network. Another advanced feature is that you do not have to install a printer driver on a Microsoft® Windows® XP client computer to enable it to use a printer. The driver is downloaded automatically when the client connects to a print server computer running a Windows Server 2003 family operating system.

Although you can, of course, print locally from a server running a product in the Windows Server 2003 family or a computer running Windows XP to a locally attached printer, this Help is primarily concerned with printing across the network with a computer running a Windows Server 2003 family product functioning as a print server.

You should make sure to distinguish between a printer (the device that does the actual printing) and a logical printer (its software interface on the print server). When you initiate a print job, it is spooled on the logical printer, which is also called a printer, before it is sent to the printer itself.

See New printing features for a list of Windows Server 2003 family printing enhancements.

# New printing features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New features**

### Printing setup

For the administrator, products in the Windows Server 2003 family provide improved setup tools for common network configurations. For example, the new standard port (described later in this topic), simplifies installation of most TCP/IP printers on your network.

### Installing printer drivers on all nodes in a cluster

Previously, you had to manually install printer drivers on every node of a cluster. Using products in the Windows Server 2003 family, this is no longer necessary. You can now install printer drivers on one node and the drivers are automatically propagated to the other nodes. The procedure for adding a printer driver to a cluster is the same as the procedure for adding printer drivers to any other computer. For more information on adding printer drivers, see Install new or updated printer drivers.

### Printing administration

The Windows Server 2003 family operating systems provide improved remote administration by adding remote port administration. You can now perform a full remote administration and configuration (including remote port administration) of printers from any computer running a Windows Server 2003 family operating system.

### Printers folder

The **Printers** folder has been renamed to **Printers and Faxes** for all Windows Server 2003 family and Windows XP products. All fax-related tasks are available through this folder.

### Internet printing

The Windows Server 2003 family printing architecture is now seamlessly integrated with the Internet. For the end user, the Windows Server 2003 family offers printing across the Internet.

- You can print from Windows XP clients to print server computers running a Windows Server 2003 family operating system by using a Uniform Resource Locator (URL).
- You can use a browser to manage printers. You can pause, resume, or delete a print job, and view the printer and print job's status.
- You can connect to printers on your network using Web point-and-print for single-click installation of a shared printer. You can click the shared printer to install the required printer driver on your local computer. To facilitate stronger network security, Web point-and-print is not enabled on the print server by default because it is possible to include malicious code in a printer driver. To enable Web point-and-print functionality, in Group Policy, you must enable the Point-and-Print Restrictions policy. For more information, see Set Group Policy for printers

### Directory services

By default, a Windows Server 2003 family server makes all shared printers in the domain available as objects in Active Directory. When you list, or *publish*, shared printers in the directory, you can use search tools to quickly locate the most convenient printing resources. For example, you can search by feature (such as color printing) or by location (such as a specific floor in a building).

### Standard port monitor

The new standard port monitor connects a print server computer running a Windows Server 2003 family operating system to network-interface printers that use the TCP/IP protocol. It replaces LPRMON for TCP/IP printers connected directly to the network or through a network adapter. The new standard port 50 is faster than LPRMON for many print jobs. LPRMON is still required for a printer connected to a UNIX or VAX host.

### Print queue monitoring

You can monitor the performance of a local or a remote printer using the System Monitor's new Print Queue object. Counters can be set up for a variety of performance criteria such as bytes printed per second, job errors, and total pages printed.

### User settings

The ability to change personal document default settings has now been extended to Windows XP Professional clients and products in the Windows Server 2003 family. Previously, only Windows 95 and Windows 98 users could modify their document settings after they were initially set by an administrator.

### Printing from an application

When printing from an application, the standard print dialog box has been enhanced and improved. You can now search for printers in Active Directory, or even add printers.

### Kernel-mode printer driver blocking

Using a Windows Server 2003 family product, administrators can block the installation of kernel-mode printer drivers by using Group Policy. For more information on how to block kernel-mode printer driver installation, see Block the installation of kernel-mode printer drivers.

### Automate printing administration using scripts

Windows Management Instrumentation (WMI) is the management API created by Microsoft to allow all system components to be monitored and controlled, either locally or remotely. The WMI Print provider allows you to manage print servers, print devices, and other printing-related objects from the command line. With WMI Print provider, you can use Visual Basic (VB) scripts to perform administrative printer functions. You can create your own scripts or modify one of the VB scripts that are provided with a Windows Server 2003 family product. Either way, you can manage local and remote printers using these scripts.

# Understanding Printing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding printing**
As a system administrator responsible for a Windows Server 2003 family printing environment, you need to understand the printing process and the options available for print servers and clients to communicate within computers running Windows, with computers running other operating systems, and across the Internet.

This section covers:

- The printing process
- Internet printing
- Printing and print servers
- Printer drivers overview
- Printer fonts overview
- Print processors and data types
- Choosing and configuring a port
- Installing printers with Plug and Play
- Find printers overview
- Printer properties overview
- Assigning printer permissions
- Enabling printer location tracking
- Group Policy and printing

# The printing process

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The printing process**

The following is an overview of the operations performed on a document submitted to a printer from a Windows XP client. The printer is attached to a computer running a Windows Server 2003 family operating system. (Some processes are slightly different for non-Windows brand operating system print clients.)

1. A user on a Windows XP client computer chooses to print a document.

2. If the document is submitted from a Windows application, the application calls the graphics device interface (GDI), which calls the printer driver associated with the target printer. Using the document information from the application, the GDI and the driver exchange data to render the print job in the printer language of the printer, and then pass it to the client-side print spooler. If the client is using an operating system other than Windows, or a non-Windows application, another component replaces the GDI to perform a similar task.

3. The client computer delivers the print job to the print server. For Windows XP, Windows 2000, or Windows NT 4.0 clients, the client-side spooler makes a remote procedure call (RPC) to the server side of the spooler, which uses the print router to poll the remote print provider on the client side. The remote print provider initiates another RPC to the server spooler, which receives the print job over the network.

4. On the print server, print jobs from Windows XP, Windows 2000, or Windows NT 4.0 clients are of the enhanced metafiles (EMF) data type. Many other applications use the RAW (ready to print) data type.

5. The router on the server passes the print job to the local print provider on the server (component of the spooler), which spools the print job (writes it to the disk).

6. The local print provider polls the print processor. The print processor recognizes the job's data type and receives the print job. The print processor then converts the print job according to its data type.

7. If the target printer is defined on the client computer, the print server service decides whether the server's spooler should alter the print job or assign a different data type. The print job then passes to the local print provider, which writes it to the disk.

8. Control of the print job is passed to the separator page processor, which adds a separator page, if specified, to the front of the job.

9. The job is despooled to the print monitors. For bidirectional printers, a language monitor handles the two-way communication between the sender and the printer, and then it passes the print job to a port monitor. If the printer is not bidirectional, the print job goes directly to the port monitor, which sends it to the target printer (or, to another network print server).

10. The printer receives the print job, converts each page into bitmap format, and prints it.

# Internet printing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet printing**
Internet printing provides a way to submit print jobs to a printer across the Internet. For example, you can send your company's new catalog directly to your publisher's printer, providing you have your publisher's printer name and the proper permission. You can also use this technology with your local area network (LAN) or intranet.

- To install a printer from the Internet you use the printer's URL as the name of the printer. Administrators can also use the URL format within an intranet.
- For a computer running a Windows Server 2003 family operating system and Windows XP to process print jobs that contain URLs, it must be running Microsoft Internet Information Services (IIS).
- Internet printing uses Internet Printing Protocol (IPP) as its low-level protocol, which is encapsulated within HTTP, using it as a carrier. When accessing a printer through a browser, the system first attempts to connect using RPC (on Intranets and LANs), which is fast and efficient.
- Print server security is provided by IIS. To support all browsers and all Internet clients, the administrator must choose basic authentication. Alternatively, the administrator can use Microsoft challenge/response or Kerberos authentication, both of which are supported by Microsoft Internet Explorer.
- You can manage printers from any browser, but you must use Internet Explorer version 4.0 or higher to be able to connect to a printer using a browser.

# Printing and print servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Printing and print servers**

When you add a printer that is attached directly to the network through a network adapter, you can implement printing in two ways: adding a printer directly to each user's computer without the use of a print server computer, or adding the printer once to a print server computer and then connecting each user to the printer through the print server computer.

### Printing without using a print server

For the first method, consider the following scenario: A small workgroup network has only a few computers and a printer that is connected directly to the network. Each user on the network adds the printer to his or her Printers and Faxes folder without sharing the printer, and sets his or her own driver setting.

The disadvantage of this configuration is the users do not know the true state of the printer. Each computer has its own print queue displaying only those print jobs sent from that computer. You cannot determine where your print job is in relation to all the print jobs from other computers. Another drawback is that error messages--such as paper jams or empty paper trays--appear only on the print queue for the current print job. Finally, all the processes on a document submitted for printing are done on that one computer.

### Printing with a print server

The second way to set up printing is to have one computer running a Windows Server 2003 family operating system function as a print server. That computer adds the printer and shares it with the other users. A computer running Windows XP Professional can also function as a print server but with some limitations; it cannot support Macintosh or NetWare services, and it is limited to only 10 connections within the same local area network (LAN).

Printing with a print server provides the following advantages:

- The print server manages the printer driver settings.
- A single print queue appears on every computer connected to the printer, letting each user see where his or her print job is in relation to others waiting to print.
- Because error messages appear on all computers, everyone knows the true state of the printer.
- Some processing is passed from the client computer to the print server.
- You can have a single log for administrators wanting to audit the printer events.

The only disadvantage of using a print server is that it requires a computer to function as the print server. However, it does not need to be a dedicated computer; typically, print servers are implemented on servers that also perform other duties.

# Printer drivers overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Printer drivers overview**
A printer driver is software used by computer programs to communicate with printers and plotters. Printer drivers translate the information you send from the computer into commands that the printer understands. Usually, printer drivers are not compatible across platforms, so various drivers must be installed on the print server to support different hardware and operating systems. For example, if you are running Windows XP and you share a printer with users running Windows 3.1, you might need to install multiple printer drivers.

In general, printer drivers are made up of three types of files:

- Configuration or printer interface file
- Data file
- Printer graphics driver file

**Configuration or printer interface file**
Displays the **Properties** and **Preferences** dialog boxes when you configure a printer. This file has a .dll extension.

**Data file**
Provides information about the capabilities of a specific printer, including its resolution capability, whether it can print on both sides of the page, and what size paper it can accept. This file could have a .dll, .pcd, .gpd, or .ppd extension.

**Printer graphics driver file**
Translates device driver interface (DDI) commands into commands that a printer can understand. Each driver translates a different printer language. For example, the file Pscript.dll translates the PostScript printer language. This file has a .dll extension.

These files, which are usually accompanied by a Help file, work together to make printing possible. For example, when you install a new printer, the configuration file reads the data file and displays the available printer options. When you print, the graphics driver file queries the configuration file about your selections so that it can create the proper printer commands.

For information about installing printer drivers, see Install new or updated printer drivers.

# Printer fonts overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Printer fonts overview**

Most programs that support printing allow you to choose from a number of different fonts. Printers offering the widest assortment of fonts include laser, ink-jet, and dot-matrix printers. They support a fixed set of resident fonts, which you can expand by installing font cartridges or loading fonts from software.

- Internal fonts (resident fonts) are used most often by laser, dot-matrix, and ink-jet printers. Pre-loaded into the printer's memory (ROM), internal fonts are always available for printing.
- Cartridge fonts are stored in a cartridge or a card that plugs into the printer.
- Downloadable fonts are sets of characters sent from the computer to a printer's memory when needed for printing. Also called soft fonts, downloadable fonts are used most often with laser printers and other page printers, although some dot-matrix printers also use them. Clients that use downloadable fonts and that print to Windows print servers should install the fonts locally to increase the printing speed.

For each document you print, Windows may need to send the required screen and downloadable fonts to the printer. To increase printing speed, use fonts that do not need to be downloaded (such as internal fonts or cartridge fonts). Some printers have the ability to keep a list of downloadable fonts. If your printer supports this feature, enable it to increase printing speed. Not all printers can use all three types of fonts. Pen plotters, for example, cannot normally use downloadable fonts. For more information on the types of fonts you can use, see your printer's operating manual.

For information about installing fonts, see Install or remove external PCL soft fonts.

# Print processors and data types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Print processors and data types**

The print processor tells the spooler to alter a job according to the document data type. It works in conjunction with the printer driver to send the spooled print jobs from the hard drive to the printer.

Software vendors occasionally develop their own print processors to support custom data types. Normally, the print processor does not require any settings or intervention from administrators.

**Data types**

The Windows printing process normally supports five data types. The two most commonly used data types, enhanced metafile (EMF) and ready to print (RAW), affect performance in different ways on both the client computer and the print server computer.

**EMF**

EMF, or enhanced metafile, is the default datatype with most Windows-based programs. With EMF, the printed document is altered into a metafile format that is more portable than RAW files and usually can be printed on any printer. EMF files tend to be smaller than RAW files that contain the same print job. Regarding performance, only the first portion of a print job is altered, or rendered on the client computer, but most of the impact is on the print server computer, which also helps the application on the client computer to return control to the user faster.

**RAW**

RAW is the default data type for clients other than Windows-based programs. The RAW data type tells the spooler not to alter the print job at all prior to printing. With this data type, the entire process of preparing the print job is done on the client computer.

The following table shows the five different data types supported by the default Windows print processor.

| Data type | Directions to spooler | Use |
|---|---|---|
| | | |
| RAW | Print the document with no changes. | This is the data type for all clients not based on Windows. |
| RAW [FF appended] | Append a form-feed character (0x0C), but make no other changes. (A PCL printer omits the document's last page if there is no trailing form-feed.) | Required for some applications. It can be set as the default in the **Print Processor** dialog box. |
| RAW [FF auto] | Check for a trailing form-feed and add one if it is not already there, but make no other changes. | Required for some applications. It can be set as the default in the **Print Processor** dialog box. |
| EMF 1.00x | Treat the document as an enhanced metafile (EMF) rather than the RAW data that the printer driver puts out. | EMF documents are created by products in the Windows Server 2003 family. |
| TEXT | Treat the entire job as ANSI text and add print specifications using the print device's factory defaults. | This is useful when the print job is simple text and the target print device cannot interpret simple text. |

# Choosing and configuring a port

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Choosing and configuring a port**

The term print monitor is used to describe two types of print monitors: language monitor and port monitor. (See the The printing process to see how the print monitor fits into the printing process.) A language monitor is needed if the printer supports bidirectional printing, a two-way communication between the printer and the spooler running on the print server. The spooler then can access configuration and status information from the printer. The more important monitor is the port monitor, which controls the I/O port to the printer. A printer port is an interface through which a printer can communicate with the computer. You can add printer ports using the Add Printer Wizard while adding a printer, from the **Ports** tab in the printer's property page, or through the print server property page. See Set Ports and Protocols for the complete procedures on ports.

The process of selecting a port and the subsequent options that are displayed depends on how your printer is connected to the server or network and what software (including protocols) you have installed.

If the printer is physically attached to the print server, select the appropriate local port. LPT1 through LPT3 represent parallel ports; COM1 through COM4 represent serial ports. When a client prints to a printer port denoted as FILE, the client is prompted for the file name, and the output file is stored on the client computer. If you decide to add a new local port, you can enter one of the following:

- A file name, such as **C:***dir**filename*. All jobs sent to this port are written to the named file, and each new job overwrites the last one.
- The share name of a printer, such as *****server**printer* (URLs are not accepted). Jobs sent to this port are transferred over the network to the named share by the network redirector.
- NUL. This specifies the null port, which you can use to test whether network clients can send jobs. Jobs sent to NUL are deleted without wasting paper or delaying real print jobs.
- IR. Use this port to connect to infrared-enabled printers meeting Infrared Data Association (IrDA) specifications. If your hardware does not support IR, it will not be listed on the **Ports** tab.

Certain ports are not listed in the **Ports** tab unless a printer that requires one of them is installed. Universal Serial Bus (USB) and IEEE 1394 printers are Plug and Play compatible; when you plug a printer into the correct physical port (and USB or IEEE 1394) enabled in BIOS, the correct port monitor is installed automatically. Your operating system detects the device, displays its settings on the screen, and prompts you to confirm. You might be required to insert a CD-ROM containing driver files, as described in Add a local port.

If the printer is attached directly to the network, add a port when prompted by the Add Printer Wizard for a port selection. The following table shows the port options available and explains under what conditions the port is available. You must have administrative credentials to add a port.

| Additional port | Enables clients to print to | Available |
|---|---|---|
| Local port | Printers connected to a parallel port, serial port, specific file name, universal naming convention (UNC) name, or the NUL port. | By default; see Add a local port. |
| Standard TCP/IP port | TCP/IP printers connected directly to the network. | By default; see Add a standard TCP/IP port. |
| AppleTalk printing devices | AppleTalk printers. | When AppleTalk protocol is installed; see Add an AppleTalk printing device port. |

| | | |
|---|---|---|
| LPR port | TCP/IP printers connected to a UNIX (or VAX) server. | When Print Services for Unix is installed; see Add an LPR port. |
| Port for NetWare | NetWare printing resources. | When NWLink protocol and Client Services for NetWare are installed. |

**Note**

- Print Server for Macintosh is not available on the 64-bit versions of the Windows operating systems.

The port you need might not appear in the wizard if its prerequisite network protocol or services are not installed. To add a network protocol or service, see Add a network component.

**Print Services for Unix**

With UNIX, a program on one computer can use a Line Printer Remote (LPR) service to send a document to a print spooler service on another computer. The receiving service is usually called a Line Printer Daemon (LPD).

Print Services for Unix provides both LPR and LPD services, which act independently on a print server computer running a Windows Server 2003 family operating system. LPD is run on the print server computer to allow the server to accept jobs from LPR clients such as UNIX systems. LPR is an option for computers running Windows XP Professional to submit jobs to UNIX servers running LPD.

- LPDSVC on the print server receives documents from native LPR utilities running on client UNIX computers.

- LPRMON on the print server sends print jobs to native LPD processes on UNIX computers to which printers are attached.

By default, the LPD service is set to start manually. To have it start automatically, change the startup options for the TCP/IP print server service in Services. You need a Windows Server 2003 family operating system compact disc to install Print Services for Unix on a computer running a Windows Server 2003 family operating system. You need the Windows XP Professional compact disk to install the services on a computer running Windows XP Professional.

# Installing printers with Plug and Play

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing printers with Plug and Play**
Plug and Play provides automatic detection and quick installation of many hardware devices, including printers. Nearly every printer on the market today is a Plug and Play printer. However, the way printers are detected and the level of user intervention required for the installation process differs, and depends on the way the printer is connected to the computer.

**Universal serial bus (USB) and IEEE 1394 printers**
Printers using the latest connector technology, such as printers with a universal serial bus (USB) port or IEEE 1394 port, are detected immediately. When you insert the jack into the port, your operating system detects the printer and starts the installation process without any user intervention. Note that a USB or 1394 port is installed automatically upon detection of such device. If no such device is connected to your computer, these ports are not listed in the existing port list.

**Parallel (LPT port) printers**
Printers that connect with a parallel port (LPT port) cannot be detected upon the physical connection. After you physically connect the parallel cable and verify that the printer is turned on and ready to print, you need to add the printer with the Add Printer Wizard, making sure that the **Automatically detect and install my Plug and Play printer** check box is selected. This starts the Plug and Play detection system. Or, you can restart your system to cause the startup process to detect the printer and start the New Found Hardware Wizard.

### Note

- If you add a parallel printer with the Add Printer Wizard while the **Automatically detect and install my Plug and Play printer** check box is cleared, the next time you restart your computer (even after several days or weeks working with that printer) Windows detects a new hardware device and starts the New Found Hardware Wizard to add that printer.

**Infrared-enabled (IR port) printers**
Infrared-enabled printers are detected in the same manner as printers with USB or IEEE 1394: automatically upon physical connection. You should place the printer approximately one yard (one meter) away from the infrared transceiver for it to be detected.

Note that the IR port, like a USB port, is not present unless Windows detects and installs it. However, if your system is not infrared-enabled and you add an infrared transceiver, you need to add the IR port manually.

**Printers that are not Plug and Play**
The following printers (as well as other devices that connect the same way) are not Plug and Play and are not detected or installed automatically. These printers must be installed using the Add Printer Wizard:

- Printers connected through a serial (COM) port.
- Printers that are connected directly to the network with a network adapter.

For more information on using the Add Printer Wizard, see Add a printer attached to your computer.

# Printer properties overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Printer properties overview**

You use a printer's properties pages, or tabs, to set and customize a printer's behavior, provided you have the appropriate printer permission. The printer's properties tabs include a standard set of tabs that always appear for all printers, and optional tabs that might appear based on the printer's driver. For example, color printers have an additional tab called **Color Management**.

The first table summarizes the standard set of the printer's properties tabs, which always appear. The second table shows some examples of optional printer's properties tabs that might appear.

| Tab | Use to |
|---|---|
| | |
| General | Change printer's name<br>Set printer's location and comment<br>Print a test page<br>Set personal printing preferences |
| Sharing | Share a printer, or stop sharing<br>Publish a printer in Active Directory<br>Install additional drivers |
| Ports | Add, delete, and configure a port<br>Enable printer pooling |
| Advanced | Schedule printer availability<br>Assign printer priority<br>Change printer's driver<br>Set spooling options<br>Set printer's default preferences<br>Set a separator page |
| Security | Assign permissions for a printer<br>Audit printer use<br>Take ownership of a printer |
| Device Settings | Set printer memory<br>Assign a print form to a tray<br>Choose font types<br>Set what optional features are installed |

Here are some examples of optional properties tabs that might appear depending on the type of printer (as indicated by its driver), the situations in which they appear, and what you use them to do. Other optional tabs not listed in the table might also appear.

| Tab | Appears with | Use to |
| --- | --- | --- |
| | | |
| Color Management | Color printers | Set color profile |
| About | Some drivers | Printer manufacturer information (when manufacturer assists with driver) |
| Utilities | Some drivers | Printer manufacturer utilities |
| User Information | Fax drivers | Information to be used on the fax cover page |
| Printer Commands | Generic printers (text only) | Set control codes for a generic printer |
| Font Selection | Generic printers (text only) | Set control codes for fonts |

# Assigning printer permissions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Assigning printer permissions**
When a printer is installed on a network, default printer permissions are assigned that allow all users to print, and allow select groups to manage the printer, the documents sent to it, or both. Because the printer is available to all users on the network, you might want to limit access for some users by assigning specific printer permissions. For example, you could give all nonadministrative users in a department the Print permission and give all managers the Print and Manage Documents permissions. In this way, all users and managers can print documents, but managers can also change the print status of any document sent to the printer.

Windowsprovides three levels of printing security permissions: Print, Manage Printers, and Manage Documents. When multiple permissions are assigned to a group of users, the least restrictive permissions apply. However, when Deny is applied, it takes precedence over any permission. The following is a brief explanation of the types of tasks a user can perform at each permission level.

**Print**
The user can connect to a printer and send documents to the printer. By default, the Print permission is assigned to all members of the Everyone group.

**Manage Printers**
The user can perform the tasks associated with the Print permission and has complete administrative control of the printer. The user can pause and restart the printer, change spooler settings, share a printer, adjust printer permissions, and change printer properties. By default, the Manage Printers permission is assigned to members of the Administrators and Power Users groups.

By default, members of the Administrators and Power Users groups have full access, which means that the users are assigned the Print, Manage Documents, and Manage Printers permissions.

**Manage Documents**
The user can pause, resume, restart, cancel, and rearrange the order of documents submitted by all other users. The user cannot, however, send documents to the printer or control the status of the printer. By default, the Manage Documents permission is assigned to members of the Creator Owner group.

When a user is assigned the Manage Documents permission, the user cannot access existing documents currently waiting to print. The permission will only apply to documents sent to the printer after the permission is assigned to the user.

**Deny**
All of the preceding permissions are denied for the printer. When access is denied, the user cannot use or manage the printer or adjust any of the permissions.

**Printing permissions assigned to groups**
Windowsassigns printer permissions to six groups of users. These groups include Administrators, Creator Owner, Everyone, Power Users, Print Operators, and Server Operators. By default, each group is assigned a combination of the Print, Manage Documents, and Manage Printers permissions as shown in the following table.

| Group | Print | Manage Documents | Manage Printers |
|---|---|---|---|
| Administrators | X | X | X |
| Creator Owner | | X | |
| Everyone | X | | |
| Power Users | X | X | X |
| Print Operators | X | X | X |
| Server Operators | X | X | X |

The Print Operators and Server Operators groups are located only on domain controllers.

| |
|---|
| Members of this group can manage, create, share, and delete printers and print queues. Members of this group can load and unload device drivers on the server. Users who can load and unload device drivers also have the ability to load malicious code on the server. As a security best practice, only add trusted users to this group. |

Each permission consists of a group of special rights that allow the user to perform specific tasks. The following table summarizes the level of access associated with each of the printing security permissions.

| **Tasks permitted** | **Print** | **Manage Documents (applies to documents only)** | **Manage Printers** |
|---|---|---|---|
| Print | X | | X |
| Manage Printers | | | X |
| Manage Documents | | X | |
| Read Permissions | X | X | X |
| Change Permissions | | X | X |
| Take Ownership | | X | X |

For more information, see Set Group Policy for printers.

# Enabling printer location tracking

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Enabling printer location tracking**

In network environments, most users do not need to know the physical location of files, databases, and Web sites. However, they do need to know the physical location of hardware devices such as printers, scanners, copiers, and facsimile (fax) machines. The printer location tracking feature helps users find hardware devices by storing their locations in Active Directory. When this feature is enabled, the location string is displayed automatically for each printer.

Your network environment must have the following to be able to use this feature:

- A working directory service with more than one site or more than one subnet.
- A network IP addressing scheme that corresponds roughly to the physical layout of your enterprise.
- Client computers that can query the directory service.
- A subnet object for each site. You can create them using Active Directory Sites and Services.
- Administrative credentials.

If these requirements are met, you need to do the following to enable this feature:

1. **Establish a naming convention for your organization.**

   For more information, see Establishing a naming convention for printer locations.

2. **Create a subnet object in the directory service.**

   For location tracking to work, you must have more than one subnet or site. You also need a subnet object for each subnet that a client computer might use. The naming of subnets is defined by the directory service. For more information, see Create a subnet.

   Note that to set and manage the directory service site and subnet you need to use Active Directory Sites and Services.

3. **Set the location attribute of the sites and subnets.**

   After you have created the site and subnet objects, you need to set the location string for each subnet. Use the **Location** tab of the subnet property page to set the location string. Note that the directory service site name does not have to be the same as the location name.

4. **Enable location tracking.**

   You need to use Group Policy to enable location tracking. For information on how to do this, see Enable printer location tracking.

5. **Set the location of each printer.**

   Add the location for each printer in each printer's property page. You can either type the location attribute, or you can click to browse for it.

   Consider adding more information about the location of the printer, such as its room number. For information on how to do this, see Enable printer location tracking.

6. **Test your settings.**

Always test your settings by trying them on several printers, and on different print servers from different locations.

**How an end user uses location tracking**

Location tracking is used whenever a user queries the directory service. To start the query, click **Start**, click **Search**, and then click **Find Printers**. You can also open the query screen from the Add Printer Wizard while connecting to a printer connection, by clicking **Find a printer in the Directory**. If location tracking is enabled, the system first determines where the client computer is physically located in the organization. While this is in progress, the location field of the query form displays **Checking**. After the location has been determined, it is entered into **Location**. If the location cannot be determined, **Location** is left blank.

When the user clicks **Find Now**, Active Directory lists all printers matching the user's query that are located in the user location. Users can change the location field by clicking **Browse** to search for printers in other locations. For example, suppose a company is located in a building with several floors, where each floor is configured as a subnet. If a user located in the first floor fails to locate a color printer in **Floor 1**, then the user can change the location to **Organization 1/Floor 2** or even to **Organization 1** to increase the scope of the search.

Note that the location field is not automatically available for users running Windows 95, Windows 98, or Windows NT 4.0 without a directory service client. However, they can still query the directory service for printers in a specific location, if they know the exact location attribute and type it in the location field.

# Group Policy and printing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group Policy and printing**

Administrators use Group Policy to define the computer environment that is provided to a group of users and computers, including the applications that are available to them, the applications that appear on their desktop and on the **Start** menu options, who can modify their desktop and who cannot, and so on. For more information about Group Policy see Group Policy overview.

Administrators can also use Group Policy to change the default behavior of the printing environment and to provide computers and users a standard set of preferences. For example, an administrator can restrict some groups or users from adding or deleting printers, or prevent everyone from using Internet printing or publishing their printers in Active Directory.

The following list shows examples of setting policies on printers.

- To disable Web-based printing for every client on the print server:

  Open Group Policy. Expand the following: Computer Configuration, Administrative Templates, Printers. Select **Disable Web-based Printing** to enable the policy.

- To enable Web-based printing for every client on the print server, except Client1:

  Select **Disable Web-based Printing** to disable the policy for everyone on the print server. Then, add the policy as a snap-in for Client1 as the Group Policy object. Here, clear **Disable Web-based Printing** to enable the policy.

Other usages of Group Policy for printing are as follows:

- Administrators can change the default behavior of the Add Printer Wizard. For more information, see Add a printer attached to your computer, or Add a printer attached directly to the network.

- Administrators can change the way printers are published in Active Directory. For more information, see Publish a printer in Active Directory, and Manually publish a printer in Active Directory

- Administrators can disable Internet printing. For more information, see Manage printers from a browser, and Connect to a printer with a browser

Several other Group Policy settings change the default behavior of printing. For information on these settings, click **Explain** on the setting's dialog box. For more information about Group Policy and printing, see Set Group Policy for printers

# Using Printing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using printing**

As with any other operating system, building an effective printing environment with the Windows Server 2003 family requires careful planning. Many variables can affect the performance of your printing resources and the satisfaction of users. The wide variety of printing equipment and strategies for deploying it add further considerations for decision-making.

This section describes a number of different printing scenarios and provides information on fine-tuning your printing performance.

- Planning for Printing
- Administering Printing

# Planning for Printing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning for printing**

As administrator of a computer running a member of the Windows Server 2003 family, you first need to examine your printing workload and estimate the capacity needed to satisfy demand under varying conditions. You also need to establish a naming convention that will ease installation, usage, and support of your printing environment.

Next, you need to determine how many print servers your network requires, and how many printers you need to allocate to each server. Finally, you must decide which printers to buy, which computers to use as print servers, where to locate printers, and how to manage printer traffic.

This section covers:

- Choosing a printer name
- Establishing a naming convention for printers
- Establishing a naming convention for printer locations
- Sizing and choosing printers
- Sizing and choosing print servers

# Choosing a printer name

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Choosing a printer name**

Windows XP and Windows Server 2003 family products support the use of long printer names. This allows you to create printer names that contain spaces and special characters. However, if you share a printer over a network, some clients will not recognize or correctly handle the long names, and users may experience problems printing. Also, some programs cannot print to printers with names longer than 32 characters.

For shared printers, the entire qualified name (including the server name, for example \\PRINTER2\PSCRIPT) must be 32 or fewer characters.

- If you share a printer with a variety of clients on a network, use 32 or fewer characters for printer names, and do not include spaces or special characters in these names.

- If you share a printer with MS-DOS computers, do not use more than eight characters for the printer's share name. You can lengthen the name by adding a period followed by no more than three characters, but you cannot use spaces in the name.

Several Windows version 3.*x* programs cannot print to a printer if its name contains more than the specified number of characters and will generate an Access Violation or other message if printing is attempted. Other programs may not print to any printer, even printers with short names, if the default printer's name is too long. To resolve these problems, rename the printers used by these programs with shorter names and make one of the renamed printers the default printer.

# Establishing a naming convention for printers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Establishing a naming convention for printers**

Setting a standard for printer names is a well-accepted practice, and many organizations establish it early in their printing planning. However, in the Windows Server 2003 family environment, the printer location tracking feature shifts the importance of naming standards from printer names to location names. When printer location tracking is enabled, setting a solid location name standard is imperative to its successful implementation. The feature also allows for much more liberty in naming printers. For more information about setting printer location names, see Establishing a naming convention for printer locations.

However, printer location tracking is not suited for every organization, and it is disabled by default. If you do not enable printer location tracking, then you should carefully plan your organization's naming standard for printers. You need to create a simple, easy-to-implement naming standard that fits your own printer deployment plan.

For example, if you have two identical printers in the mail room, your naming convention needs to provide a way to identify each of the printers, perhaps by adding a number at the end of each printer name. You also want a naming standard that provides users with information about the printer. Therefore, to continue with the previous example, you might name the printers Printer-01, and Printer-02. The naming standard might also tell users what kind of printed output to expect. You could call a color laser printer ColorLaser-01, and a color inkjet printer ColorInk-01.

If you do not enable printer location tracking, consider adding the printer location as part of your printer naming standard. However, remember that printers are likely to move, which will require you to change their names.

For other considerations and issues with setting printer names, see Choosing a printer name.

# Establishing a naming convention for printer locations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Establishing a naming convention for printer locations**

To use printer location tracking, described in Enable printer location tracking, you need to set a naming convention for printers' locations using the following rules:

- Location names are in the form *name***/***name***/***name***/***name***/**... (The slash (**/**) must be the dividing character.)
- A name can consist of any characters except for the slash (**/**).
- The number of levels to a name is limited to 256.
- The maximum length of *name* is 32 characters.
- The maximum length of an entire location name is 260 characters.

Because location names are used by end users, they should be simple and easy to recognize. Avoid using special names known only to facilities management. For better readability, avoid using special characters in a name, and keep names to a maximum of 32 characters to make sure that the whole name string is visible in the user interface.

**Example:**

Consider an organization with multiple locations in North America and Europe. The naming scheme for the organization might be as follows:

| **Top level** | **Level** | **Level** | **Level** |
|---|---|---|---|
| | | | |
| NorthAmerica | | | |
| | NewYork | | |
| | | HQ | |
| | | | Floor1 |
| | | | Floor2 |
| | | Buffalo | |
| | | | Design |
| | | | Plant |
| | | | Admin |
| | Vancouver | | |
| | | Building1 | |
| | | Building2 | |
| | Dallas | | |
| Europe | | | |
| | Paris | | |

| | | | |
|---|---|---|---|
| | | Design | |
| | London | | |
| | | ... | |
| | Madrid | | |

Note that the tree varies in depth depending on the complexity of the organization and the amount of detail available in the IP network. The naming convention for this example includes more levels than for a smaller organization located in a single city, or a single building. The full name of the design building in Buffalo, New York is NorthAmerica/NewYork/Buffalo/Design; for the design building in Paris, the full name is Europe/Paris/Design, and the smaller office in Dallas has the name as NorthAmerica/Dallas.

**Setting standards when printer location tracking is disabled**

As mentioned previously, you can add information to **Location** in the **General** tab of the printer property page even if printer location tracking is disabled. However, this has the potential to make printers difficult for users to locate. When users search for printers on the tenth floor, they need to know exactly what to type in the **Find Printers** property page when they click **Start**, then **Search**, and then **Find Printers**. When printer location tracking is enabled, the **Location** field in the **Find printer** property page is filled in automatically.

# Sizing and choosing printers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sizing and choosing printers**

When you plan the printing strategy for your organization, you need to estimate the number and type of printers you need both now and in the future. Consider the following:

- Determine how printing resources will be divided and allocated. High-volume printers generally have more features but affect more users if they break down.
- Consider the printer features you need, such as color, duplex printing, envelope feeders, multi-bin mailboxes, internal disks, and staples. Determine who needs these features and where these users are physically located.
- Although cost is a factor, laser printers might be a good choice for both black-and-white and color printing. However, many less expensive laser printers do not support larger page size, which you might require.
- Generally, you will experience fewer maintenance problems if you match printing volume with a printer's duty cycle (the number of pages the printer was designed to print per month).
- Consider what type of graphics your organization needs. Windows, TrueType, and other technologies make it possible to print complex and sophisticated graphics and fonts on most printers.
- Consider printing speed requirements. Generally, printers that attach directly to the network with network adapters offer faster throughput than printers attached with parallel buses. However, print throughput rates also depend on network traffic, the type of network adapter, and the protocol used, not just the type of the printer.
- To confirm that your printer is designed for this operating system, see the compatibility information in Support resources.

**Deciding where to locate printers**

You want to place printers close to the people who will be using them. However, you also need to determine printers' locations in relation to the location of the print server and users' computers within your network. Another goal should be to minimize the impact of printing on your network environment.

Check your network infrastructure and try to prevent print jobs from hopping through multiple internetwork devices. If you have a group of users with high-volume printing needs, you can isolate them with their own printer located on their segment of the network, minimizing the effect on other users.

# Sizing and choosing print servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sizing and choosing print servers**

Consider the following when sizing and choosing your print servers:

- A print server can be any computer running a product in the Windows Server 2003 family or Windows XP Professional.
- A print server running Windows XP Professional is limited to 10 concurrent connections from other computers and does not support printing from Macintosh and NetWare clients.
- The minimum requirements for a Windows Server 2003 family server for file and print services will be sufficient for a print server that manages just a few printers with low printing throughput. Managing a large number of printers or many large documents requires more memory, disk space, and potentially a more powerful computer.
- In situations where many large documents are submitted for printing at the same time, the print server must have enough disk space to spool all of the documents. If you need to keep a copy of everything you print, you must provide additional disk space.
- If you use the Windows Server 2003 family server for both file and print sharing, file operations have a higher priority, so printing will not slow access to files. That is especially true if the printers are connected directly to the server; parallel and serial ports are always the primary bottleneck.
- Printers that attach directly to the print server, typically through the parallel port, require more CPU time. It is always preferable to use printers that are attached directly to the network with a network adapter.
- To maximize print server throughput, and to manage many printers, or printing of many large documents, you should dedicate a Windows Server 2003 family server only for printing.
- To increase the throughput of a print server, you can change the location of the print spool folder. For best results, move the spool folder to a dedicated disk drive that does not share any files, including page files with the operating system.

# Administering Printing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering printing**
You can administer printers and print servers locally or over the network. Administrative tasks include managing documents in a print queue, managing individual printers on print servers, and managing the print servers themselves.

This section covers:

- Managing documents
- Managing printers
- Managing printer drivers
- Setting document printing defaults
- Connecting clients to a printer
- Setting device-specific properties
- Using separator pages
- Using plotters
- Printing extended or international characters
- Managing printing from the command line
- Managing Printing Traffic

# Managing documents

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing documents**

When managing a document, you can:

- Pause or resume printing.
- Restart the document from the beginning.
- Delete a document.
- View and change various document settings, such as the document priority and the person notified when the document is done. You can also view--but not change--the form type, paper source, page orientation, and number of copies. These options are available only to Windows XP and Windows 2000 clients using a printer on the network.

For information on managing the documents in a print queue, see Manage Documents.

# Managing printers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing printers**
When you manage printers, your actions affect the entire printer, not individual documents. Typical tasks include pausing, resuming, and purging the queue for a printer.

**Redirecting documents**
If a printer becomes faulty, you might need to send documents in its queue to another printer. This prevents users from having to resubmit print jobs that are already in the queue. You can redirect documents to a printer on the same print server or on a different print server. However, both printers must use the same printer driver.

To send documents to a different printer, see Transfer documents to another printer.

**Administering printers on the network**
Any network user can check the status of a printer from any computer across the network. However, only users who have Manage Printers or Manage Documents permission for the printer can manage documents other than their own. If you do not have the correct permission, certain options are unavailable. Also, when you attempt to view certain properties on computers running Windows NT 4.0 or earlier, an error message appears.

You can also manage printers from a Web browser, if Internet printing is enabled.

For more information about accessing a printer on the network, see Remotely manage printers. For more information about managing a printer from a Web browser, see Manage printers from a browser.

**Printers and Active Directory**
The easiest way to manage, locate, and connect to printers is through Active Directory. Users can also search for specific printers--for example, all color printers in building 10--and even save search results for future use. Administrators can create custom searches for different groups of users, and then save the result files on users' desktops, or at any other location. For more information on how to do custom searches for printers, see Create a custom printer search.

By default, all printers that are added to a computer running a Windows Server 2003 family operating system and shared are also published in Active Directory. Administrators can also manually publish printers, as described in Manually publish a printer in Active Directory.

**Auditing a printer**
To increase the level of security of some specific printers, or as a tool for troubleshooting, you can audit a printer's activity. For more information about auditing a printer, see Track printer usage.

**Taking ownership of a printer**
To change print administrators (for example, if the current print administrator left your organization) you would need to take ownership of the printer in order to manage it. For more information about taking ownership of a printer, see Take ownership of a printer.

**Setting Group Policy for printers**
If you want to define a standard printing environment for your organization, you can use a Group Policy setting for groups of users. Each new user that joins the organization has the same credentials as other users in that group without any intervention from the administrator. For more information on Group Policy settings, see Set Group Policy for printers.

# Managing printer drivers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing printer drivers**

If your network contains a mixture of Alpha-based and x86-based computers, you can install printer drivers for each one on each print server. This ensures that documents originating from Windows XP, Windows 2000, Windows NT 4.0, Windows 95, or Windows 98 clients running on any of the hardware platforms can use all printers.

For example, suppose your network contains the following: Windows 95 clients, x86-based clients running Windows XP or Windows 2000 and Windows NT 4.0, and Alpha-based clients running Windows NT Workstation 4.0 and 3.51. If you create a shared printer on an x86-based computer, you should install these four printer drivers in addition to the x86-based Windows Server 2003 family printer driver that is installed by default for the printer you have selected:

- Windows 95.
- Windows NT 4.0 x86-based.
- Windows NT 4.0 Alpha-based.
- Windows NT 3.5 or 3.51 Alpha-based.

When installed on a computer which is acting as a print server, the Windows Server 2003 family operating system determines whether incoming print requests are Alpha-based or x86-based and automatically sends the appropriate driver to the client.

# Setting document printing defaults

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting document printing defaults**
Device-specific properties such as resolution and memory specify a printer's hardware characteristics. Document printing defaults describe how that hardware can be used to perform a printing task. Unless you override them, a program uses the default document properties that are set for a printer.

Typical document default properties include:

- Page orientation
- One-sided or two-sided printing
- Paper source
- Type of form (paper size)

You can set other preferences as well. To view the document printing preferences, see Set Printing Preferences.

**Setting default printing preferences**
As administrator, you can set the initial defaults for a printer. When a user connects to the printer, the user's defaults are set to these global settings. For more information on setting the printing default preferences, see Set printing defaults.

**Setting personal printing preferences**
Individual users can change default document properties and set their own personal printing preferences. These preferences include the same options as the default printing preferences except that they apply only to that user instead of to the printer. As with Windows NT 4.0, a user can also change the printing defaults from the print dialog box of the application. In such a case, the new defaults apply when a program prints. Note that changes made by an administrator after a user has established a connection to a printer have no effect on that user. For more information on setting personal printing preferences, see Set personal printing preferences.

# Connecting clients to a printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connecting clients to a printer**
After you have added a printer to a computer running a Windows Server 2003 family operating system, you can set up clients to access it. The tasks that you perform to make sure users can print depend on the operating system used by the client computers on your network.

Windows XP**, Windows 2000, Windows NT, Windows 95, and Windows 98 clients**

For Windows XP, Windows 2000, Windows NT 4.0, Windows 95, and Windows 98 clients, you do not need to do anything further. The users connect to the shared printer by clicking **Connection to this printer** in the Add Printer Wizard. Or, if Active Directory is enabled, they can just search for the printer they want to add, right-click it, and then click **Connect**. In both cases, the printer driver is automatically copied to the client computer.

Windows 2000 and Windows NT 4.0 clients check the printer driver and printer configuration each time they connect. Windows NT 3.*x* clients check each time the spooler service on the client is started. If the driver is not current, a copy of the new driver is downloaded automatically. The printer driver for a client running Windows 95 or Windows 98 is not automatically kept current. If you update the driver on the print server, you must manually install the driver on clients running Windows 95 or Windows 98. However, administrators should update the drivers on the print server, making it easier for these clients to update their drivers manually from the print server instead of requiring floppy disks or CD-ROMs. For more information, see Connect to a printer on a network, or Connect Windows NT 4.0, Windows 95, and Windows 98 clients.

**Windows 3.*x* , Windows for Workgroups, and MS-DOS clients**

MS-DOS and all the different versions of previous Windows operating systems support printing from MS-DOS-based applications and Windows-based applications, by using 16-bit printer drivers that must be installed on each computer. Typically, they send jobs to the print server by using one of the following network client redirectors:

- LAN Manager
- Microsoft Network Client 3.0 for Windows
- Windows for Workgroups built-in redirector

The network redirector can send jobs using NWLink or TCP/IP. The print server receives the job through the server service, which typically does not alter the print job. For more information, see Connect MS-DOS, Windows 3.x, and OS/2 clients.

**NetWare Clients**

NetWare clients can install network client software on each client computer to provide direct access to NetWare servers, and to Windows Server 2003 family servers and printers. For example, on Windows 95 and Windows 98, clients that are connected only to the NetWare server need to add the Client for Microsoft Networks to add connectivity to computers running Windows Server 2003 operating systems.

**Note**

- The IPX/SPX protocol is not available on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.

**Macintosh Clients**

Macintosh clients send print jobs over AppleTalk to a print server computer running a Windows Server 2003 family operating system. Print Server for Macintosh must be installed on the print server.

**Note**

- Print Server for Macintosh is not available on the 64-bit versions of the Windows operating systems.

### UNIX Clients

UNIX clients can connect to a print server computer running a Windows Server 2003 family operating system, by using the Line Printer Remote (LPR) monitor. This might be problematic because not all UNIX systems support LPR specifications, and different versions of UNIX use different LPR command syntax. For more information, see Print from an LPR client to a printer.

# Setting device-specific properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting device-specific properties**
Device-specific properties describe the physical configuration of a printer, such as how much memory it has, which paper trays are loaded, and so on. When you add a new printer, make sure the device-specific properties match the settings of the printer. Although default settings work for many printing needs, some special options, such as those available with PostScript printer drivers, require specific settings.

**Setting installable options**
As an administrator, you have the ability to specify which options are actually installed on the printer. Many printers today support options such as duplex units (to allow printing on both sides of a paper), internal hard disks, envelope feeders, staplers, multi-bin mailbox trays, and others.

To set the options available to users, see Set installable options for a printer.

**Setting printer memory**
Because page printers must store an entire page in memory, they require relatively large amounts of memory. If you are using a page printer, such as a laser printer, make sure that the amount of memory available in the device matches the value shown in the **Device Settings** tab. If the printer has substantially more or less memory than what is shown in the **Device Settings** tab, print throughput can suffer. For example, your operating system might try to download more fonts to the printer than it can reasonably handle. (Running a printer self-test usually tells you how much RAM the printer contains.)

To change the amount of memory specified for a printer, see Set printer memory.

**Assigning forms to paper trays**
If a printer has multiple trays that hold different types of forms, you can assign a form to a specific paper tray. Users can then select the form from within the program that they are using. When they print a document, the print job is routed to the correct paper tray.

Windows-based programs can use different forms within a document. For example, a user might use Envelope for the first page, Letterhead for the second page, and Letter for the third and following pages.

The default form setting for a paper tray is Letter. To set forms to trays, see Match a form to a printer tray.

**Choosing font types**
Products in the Windows Server 2003 family support three types of fonts:

- Device fonts actually reside in the hardware of your printer. They can be built into the printer itself or can be provided by a font cartridge or font card.

- Screen fonts are fonts (including OpenType, TrueType, raster, and vector fonts) that can be translated for output to the printer. OpenType extends the TrueType font standard but is compatible with previous versions of Windows and any application that supports TrueType fonts.

- Downloadable or soft fonts are sets of characters stored on disk and sent to a printer's memory when needed for printing a document. Clients that use downloadable fonts and that print to computers running Windows Server 2003 family operating systems should install the fonts locally.

Required screen and downloadable fonts are sent to the printer for each document. To improve printing times, use device fonts, which are already present at the printer.

Not all printers can use all three types of printer fonts. Pen plotters, for example, usually cannot use downloadable or print raster screen fonts.

# Using separator pages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using separator pages**

A separator or banner page typically states who sent the document to the printer and gives the date and time of printing. You can use one of the standard separator pages or create a custom page. Windows provides three separator page files, which are located in the systemroot\System32 folder.

The following table shows the names of the separator page files, the type of printer with which it is compatible, and the purpose of each page. You can edit or customize any of these separator pages.

| File name | Printer language | Purpose |
|---|---|---|
| Pcl.sep | Printer Control Language | Switches the printer to PCL printing and prints a separator page before each document. Pcl.sep is compatible with PCL printers, but may not work unless the printer also supports PJL. |
| Pscript.sep | PostScript | Switches the printer to PostScript printing, but does not print a separator page before each document. Pscript.sep is compatible with PostScript printers that also support PJL. |
| Sysprint.sep | PostScript | Switches the printer to PostScript printing and prints a separator page before each document. Sysprint.sep is compatible with PostScript printers. |

For more information, see Choose a separator page.

**Note**

- The separator page files provided by Windows may not work with some printers.

# Using plotters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using plotters**

The following are some considerations when printing to a plotter:

- In this version of Windows, 7-bit serial connections to plotters are not supported, so you must use 8-bit connections.
- If you notice that some lines are not printing on a pen plotter, try setting the plotter's control panel so that installed pens are set at the minimum width supported by the hardware. Be aware, however, that some plotters will not print thin lines unless the thinnest pen is selected.
- Pen plotters can take longer to clear their buffers than other plotters, so you may want to increase the port time-out setting to avoid receiving error messages.
- Windows plotter printer driver for most HP DesignJet series plotters are designed for use with margins set to Normal, paper size set to Software, and autorotation set to Off. When troubleshooting problems, reset the plotter to the factory defaults and then change only the necessary settings.
- All plotters supported by this version of Windows use the HP-GL/2 language. Some plotters supported by Windows can be set to receive a choice of plotter languages; however, to work with Windows, HP-GL/2 must be selected. (This version of Windows does not support the HPGL language.)
- When printing to plotter models that offer a choice of roll or sheet media, the form to tray assignment must be set to the actual paper size available to the plotter. Since selecting a media size or type not featured on the plotter is not supported, doing so may result in misaligned output.

# Printing extended or international characters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Printing extended or international characters**

In addition to the 128 standard ASCII characters you can type using your keyboard, you can use extended or international characters by using the Character Map program.

When Windows prints a document using printer fonts, each character your program sends to the printer is translated to the appropriate resident font. If your printer supports that character, the character prints. Otherwise, another character prints instead. Check your printer manual and experiment with your printer to determine which extended characters your printer supports. This limitation applies only to the printer's built-in fonts. TrueType and OpenType fonts provided in Windows will print all extended characters, unless the font has been mapped to a resident font on the printer. In that case, the TrueType or OpenType font will print only the characters supported by the printer.

For information about changing fonts or using the Character Map program, see Printer fonts overview.

# Managing printing from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing printing from the command line**

You can manage your printers at the command line by using:

- Print to print a text file or to display the contents of a print queue.
- Net print to display or control print jobs and printer queues.
- Net start spooler to start the Spooler service.
- Lpr to print a file to a computer running an LPD server.
- Lpq to obtain status of a print queue on a computer running the LPD server.

You can obtain additional functionality through scripts by using:

- Prncnfg.vbs to get and set printer configurations, or to rename a printer.
- Prndrvr.vbs to add, delete, and list printer drivers.
- Prnjobs.vbs to pause, resume, cancel, and list print jobs.
- Prnqctl.vbs to print a test page, pause or resume a printer, and clear a printer queue.
- Prnmngr.vbs to add, delete, and list printer connections. Prnmngr.vbs can also be used for obtaining and setting the default printer.
- Prnport.vbs to add, delete, and list standard TCP/IP ports. Prnport.vbs can also be used to obtain and set the port configuration.

For information about other command-line utilities, see Command-line reference A-Z. For more information about manageability, see Management Strategies and Tools. For more information about printing, see Printing.

# Managing Printing Traffic

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing printing traffic**

With a computer running a member of the Windows Server 2003 family, you can use several methods to improve the efficiency of your printing operations and manage your printing traffic:

- Scheduling alternate printing times
- Assigning different priority levels
- Setting print spooler options
- Creating a printing pool
- Setting the location of the spool folder
- Monitoring print queue performance

# Scheduling alternate printing times

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Scheduling alternate printing times**

One way to maximize the use of printers is to schedule alternate printing times for long documents or certain types of documents. For example, if printer traffic is heavy during the day, you can postpone printing of long documents by routing them to a printer that prints only during off-hours. The print spooler continues to accept documents, but it does not send them to the destination printer until the designated start time.

Instead of dedicating an actual print device for only off-hour printing, which is not an efficient use of resources, you can set different logical printers for the same print device and configure each with different available times. One printer might be available from 6:00 PM to 6:00 AM, while the other is available 24 hours a day. You can then tell users to send long documents to the printer available only during off-hours, and all other documents to the printer available all the time. To set up printer availability times, see Schedule alternate printing times.

You can also differentiate the two printers with different priority levels to print certain types of documents before any other types, regardless of time of day. To set priority levels, see Set different print priority to different groups.

# Assigning different priority levels

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Assigning different priority levels**

You can expedite documents that need to be printed immediately. Documents sent by users with high priority levels can bypass a queue of lower priority documents waiting to be printed. If two logical printers are associated with the same printer, the Windows Server 2003 family operating system routes documents with the highest priority level to the printer first.

To take advantage of this print priority system, create multiple logical printers for the same printer. Assign each a different priority level, and then create a group of users that corresponds to each printer. For example, users in Group1 might have access rights to a priority 1 printer, users in Group2 might have access rights to a printer with priority 2, and so on.

For a complete procedure on how to set different priority levels using multiple logical printers, see Set different print priority to different groups.

# Setting print spooler options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting print spooler options**

Although you can control whether to use spooling or not, you'll typically want to spool documents you send to printing. Spooling documents expedites the printing process, and allows the application that sent the document to release control back to the user much faster. All the spooling options are set through the **Advanced** tab of the printer's property page. The following table shows other options you can set to affect how the spooler operates.

| Option | Description |
|---|---|
| | |
| Spool print documents so program finishes printing faster | Either select this option or the **Print directly to the printer** option. If you choose this option, the documents spool. This option has two related options that you must choose between (see the next two options). |
| Start printing after last page is spooled | The printer does not print a document until it is completely spooled. This is useful for documents that are assigned a low priority. Documents that are assigned a higher priority start printing immediately. |
| Start printing immediately | The printer starts printing a document before it is completely spooled, which means it is printed sooner, and the application you are printing from releases control back to you faster. |
| Print directly to the printer | The document does not spool, which decreases printing time. Select this option only for a nonshared printer. This might be useful for other programs that use their own spooling process. |
| Hold mismatched documents | Documents that do not match the configuration of the printer are not printed. This prevents errors resulting from documents that use paper sizes different from letter size. |
| Print spooled documents first | A spooled document is printed before a partially spooled document. |
| Keep documents after they are printed | Documents remain in the print spooler after they are printed, and can be quickly resubmitted for printing. You must carefully watch for disk space if you choose this option. |
| Enable advanced printing features | When enabled, the document is rendered using metafile datatype (EMF) and advanced features such as Page Order, Booklet Printing, and Pages Per Sheet are available. If compatibility problems occur, try to disable this option. |

For more information, see Set printer properties.

If you choose to set different spooling options on the same printer for different groups of users, you need to set multiple logical printers for the same physical printer.

# Creating a printing pool

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating a printing pool**

You can create a printing pool to automatically distribute print jobs to the next available printer. A printing pool is one logical printer connected to multiple printers through multiple ports of the print server. The printer that is idle receives the next document sent to the logical printer. This is useful in a network with a high volume of printing because it decreases the time users wait for their documents. A printing pool also simplifies administration because multiple printers can be managed from the same logical printer on a server.

With a printing pool created, the user prints a document without having to find out which printer is available. The logical printer checks for an available port and sends documents to ports in the order that they are added. Adding the port connected to the fastest printer first ensures that documents are sent to the printer that can print the fastest before they are routed to slower printers in the printing pool.

Before setting a printing pool, consider the following:

- All printers in a pool must use the same driver.
- Because users will not know which printer in the pool prints a given document, make sure all printers in the pool are located in the same place.

For procedures on how to set a printing pool, see Set up a printer to print to multiple devices.

# Setting the location of the spool folder

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting the location of the spool folder**

By default the spool folder is located at systemroot**\System32\Spool\Printers**. However, this drive also holds the Windows system files. Because these files are frequently accessed by the operating system, performance of both Windows and the printing functions might be slowed.

If your print server serves only one or two printers with low traffic volumes, the default location of the spool folder is sufficient. However, for high-volume printing requirements, to support large numbers of printers, or to support large print jobs, you should relocate the spool folder. For best results, move the spool folder to a drive that has its own controller, which reduces printing's impact on the rest of the operating system.

For information on relocating the print server spool folder, see Change the spool folder location.

For more information on changing the spool folder location for a single printer, see the Windows Server 2003 Resource Kit.

# Monitoring print queue performance

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring print queue performance**

You can monitor the performance and operation of printers across the network using System Monitor. Counters can be set up for a variety of performance criteria such as Bytes Printed/sec, Job Errors, and Total Pages Printed.

When you select **Print Queue** in the **Performance object** text box, you are provided with a list of all available performance counters for that object. The one you will probably use most is the **Jobs** counter, which is selected by default.

Other counters help you determine the current load on the print server or provide you with statistics and accumulative printing performance since the last time the system was started.

In System Monitor, click the plus sign (**+**) to add counters, and then click **Explain** to see an explanation of the counter.

For information on how to use System Monitor to monitor print queues, see Monitor print queue performance.

# Printing Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

- Windows Catalog at Support resources
- Microsoft TechNet at Microsoft TechNet
- Microsoft TechNet compact disks
- Microsoft Product Support Services at the Microsoft Web site
- Request for Comments Web site

**Note**

- Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

# Printing Troubleshooting

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**

Products in the Windows Server 2003 family have a modular printing architecture with each module responsible for different types of tasks. This modularity provides a great deal of flexibility, allowing you to support different clients on different operating systems and submit print jobs from different environments and applications. However, that flexibility and variety of options can make troubleshooting more challenging.

This section contains information on solving printing problems.

- General troubleshooting information
- Troubleshooting common printing problems

# General troubleshooting information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**General troubleshooting information**

Successful troubleshooting depends on your ability to identify the source of the problem. Printing problems occur because of trouble with:

- The printing device.
- The connection between the printer and the network.
- Other printing components in the Windows Server 2003 family products.
- The network, protocols, and other communication components.

When solving printing problems, a good first step is to identify the process creating the problem. You can often determine this by testing different scenarios. For example, if a network client cannot print to a certain printer and other users can, then you know that the problem is not with the physical printer and its connection to the network.

**Troubleshooting printing problems: quick list**

A quick way to solve most problems associated with printing is to follow these four steps:

- Verify the physical printer is operational. If other users can print, it is probably not a problem with the printer, or with the print server.
- Verify that the printer on the print server is using the correct printer driver. If print clients are using other operating systems, make sure you installed all necessary drivers for the other platforms.
- Verify the print server is operational, make sure there is enough disk space for spooling, and make sure the print spool service is running.
- If print clients are using operating systems other than Windows XP , verify the client computer has the correct printer driver.

**Troubleshooting physical problems**

- Check the physical printer and make sure it is in the ready state (ready to print). With most printers, you can print a test page from the printer console itself to verify correct operation.
- Check the cable connecting the printer and make sure it is connected properly. If the printer is connected directly to the network with a network adapter, check the light on the card, which indicates network connectivity.

**Troubleshooting communication problems**

- Make sure you can communicate with the printer over the network. As an example, if a printer communicates over the TCP/IP protocol, you can use the **ping** command to verify connectivity.
- Verify communication to the print server from other computers.
- Check that any service required for the printer and the client submitting the print job is working properly. For example, for a Macintosh client, verify that the AppleTalk protocol is working.
- Make sure the print spool service is running on the print server.

**Troubleshooting Windows Server 2003 family printing**

The modularity of the printing architecture makes diagnosing problems fairly easy. Windows Server 2003 family printing across a network consists of seven processes that always occur. By testing each process, you can generally identify the problem.

1. The administrator adds a printer and shares it.

    - Check the property of the logical printer; make sure the driver is correct for that printer.
    - Using the Add Printer Wizard, you can add another logical printer for the same physical printer to quickly identify whether the problem is with the logical printer.
    - If you cannot browse printer connections, or cannot find the printer port, you might have a network problem.
    - Verify you are logged on as administrator, or as a member of the Administrator group.

2. A network client connects to that share.

    - Check the property of the logical printer on the client computer; make sure the driver is correct for that printer.
    - Using the Add Printer Wizard, you can add another logical printer for the same physical printer to quickly identify whether the problem is with the logical printer.
    - Check the users permissions to print to that printer, and check which Group Policy settings for printers are enabled.
    - If you cannot browse printer connections, you might have a network problem.

3. The client application creates a print job.

    - Check whether the document the client is trying to print consists of text only or includes graphics. Check the printer driver and the fonts settings.
    - Check whether there is a problem with the separator page selection.
    - Try to reproduce the same print job from another client; if it prints properly, the problem is most likely not caused by this process.

4. The client system sends the print job to the printer share on the print server.

    - Check the network transport; for example, TCP/IP, NWLink, or AppleTalk.
    - Check other network components that are required to print; for example Print Server for Macintosh or Print Services for Unix.

    **Note**

Print Server for Macintosh is not available on the 64-bit versions of the Windows operating systems.

- Make sure the network is working properly for the client. Check the network adapter and intermediate network devices.
- Make sure the print spool folder on the print server has not run out of disk space.
- Try to send the print job to the spooler in another way, or from another application.

1. The print server receives, spools, and--if necessary--alters the print job.

    - Check disk space for spooling.
    - Make sure the problem does not involve an incorrect data type, such as RAW or PScript1.
    - Try to change an EMF print job to RAW to see whether it solves the problem.

2. The print server sends the print jobs to the printer.

    - Check network transport (such as TCP/IP or NWLink) and other network devices.
    - Check the physical printer connection to the network.
    - Make sure the printer is ready to print.
    - Try to print from other network clients.

3. The printer interprets the job and produces hardcopy output.

    - Make sure the printer is ready to print.
    - Try to print a test page from the printer console.

# Troubleshooting common printing problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting common printing problems**
What problem are you having?

- A printer connected to a computer does not print.
- A printer connected to the network does not print.
- Printing from an Outlook client with multiple languages is slow.
- Users on Windows 95 or Windows 98 cannot connect to a printer.
- Users get an Access Denied message when trying to configure a printer from within an application.
- The document does not print completely, or comes out garbled.
- Hard disk problems occur, and the document does not reach the print server.
- Documents on the print server will not print and cannot be deleted.
- An application on a 16-bit version of Windows (such as Windows for Workgroups) gives an out-of-memory error on startup.
- A document sent to the printer from an MS-DOS–based program on a Windows XP, Windows 2000, or Windows NT 4.0 client does not print.
- A driver is not listed.
- A new print driver downloaded from the Internet needs to be installed.
- Microsoft does not have the printer driver for the printer.
- With printer location tracking enabled, some printers cannot be located.
- The company has changed its organization, and as a result the naming scheme has to change.
- My organization has a small network without any subnets.

**A printer connected to a computer does not print.**
**Cause:** A problem might exist with the physical printer, the print driver, a print server, or the application you are trying to print from.

**Solution:** Try the following steps to identify and solve the problem.

- Verify the physical printer is in ready state, and that the correct default printer is set.
- Try to print a test page.
- Try printing from the command line (on non-PostScript printers only). Type **Dir > LPT1** at the command prompt.

- Try printing from Notepad. This verifies that the printer driver is correct, and confirms that the problem lies with the application. If you cannot print from Notepad, the problem lies with the printer driver.

- Check the available disk space on the system drive. If there is not enough room to spool the job, larger jobs might fail where smaller jobs do not.

**A printer connected to the network does not print.**
**Cause:** A problem might exist with the physical printer, the logical printer setting on the client computer, the application you are trying to print from, network protocols, or hardware.

**Solution:** Try the following to isolate and solve the problem:

- Verify basic network connectivity. Check user rights, protocols, share names, and so on to determine whether you can see the server. Try to copy a file to the server; if you cannot access the server, you might not be able to access the printer.

- On the **Advanced** tab, make sure the printer availability time is correct.

- Create a local printer and redirect the port to the network server. Using the Add Printer Wizard, click Local, and then type the server and printer name for the printer (*****servername******printername*). This determines whether you can copy files from the print server.

- Check the available disk space on the print server. If there is not enough room to spool the job, larger jobs might fail where smaller jobs do not.

**Printing from an Outlook client with multiple languages is slow.**
**Cause:** Multiple languages are installed on the client computer, but not on the print server computer.

**Solution:** If clients use additional languages on their computers, you need to add these languages to print server.

Users on Windows 95 or Windows 98 cannot connect to a printer.

**Cause:** Print drivers for Windows 95 and Windows 98 are not the same as for the Windows Server 2003 family, and are not installed on the print server.

**Solution:** Make sure the user has Print permission, and make sure the proper printer driver is installed on the print server for that operating system.

**Users on Windows 95 or Windows 98 cannot connect to a printer.**
**Cause:** Print drivers for Windows 95 and Windows 98 are not the same as for the Windows Server 2003 family, and are not installed on the print server.

**Solution:** Make sure the user has Print permission, and make sure the proper printer driver is installed on the print server for that operating system.

**Users get an Access Denied message when trying to configure a printer from within an application.**
**Cause:** You do not have the appropriate permission to change printer configuration.

**Solution:** You need Manage Printer permission to change the printer's setup.

**The document does not print completely, or comes out garbled.**
**Cause:** The printer's driver is either corrupted or incorrect.

**Solution:** Verify or reinstall the correct printer driver on the client computer.

**Hard disk problems occur, and the document does not reach the print server.**
**Cause:** The hard disk might not have enough space for spooling the document.

**Solution:** Make sure the hard disk has enough disk space, or relocate the spool folder to another volume.

**Documents on the print server will not print and cannot be deleted.**
**Cause:** The print spooler might be stalled.

**Solution:** On the print server, try to stop and restart the Print Spooler service.

**An application on a 16-bit version of Windows (such as Windows for Workgroups) gives an out-of-memory error on startup.**

**Cause:** A default printer is not selected.

**Solution:** Add a printer and set it as the default printer.

**A document sent to the printer from an MS-DOS–based program on a Windows XP, Windows 2000, or Windows NT 4.0 client does not print.**
**Cause:** Some MS-DOS programs will not print until you close the program.

**Solution:** Close the application you tried to print from. In addition, make sure the correct printer driver is installed on the client computer.

**A driver is not listed.**
**Cause:** The printer was not on the market when the Windows Server 2003 family was released, or a newer version of the print driver has only recently become available.

**Solution:** Windows printer drivers are developed through cooperation between Microsoft and the independent hardware vendor (IHV) that manufactures the print device. A product in the Windows Server 2003 family supports all print devices listed in the Windows Catalog; see Support resources.

For new and updated print drivers, see Microsoft printing support at the Microsoft Web site. You should also check Windows Update.

**A new print driver downloaded from the Internet needs to be installed.**
**Cause:** The print driver is not listed in the Add Printer Wizard's list of printers, but instead was downloaded from the Internet.

**Solution:**

1. Download the printer driver to an empty folder.

2. Expand the files by typing the name of the executable followed by the **-d** switch. For example, if the name of the file is Nt4prn.exe, type the following at a command prompt:

   **nt4prn -d**

3. Read the Readme.txt and the License.txt files.

4. Click **Start**, point to **Settings**, and then click **Printers and Faxes**.

5. Double-click **Add Printer** to start the Add Printer Wizard, click **Next**, click **Local printer attached to this computer**, and then click **Next**.

6. Click the port where your printer is attached, and then click **Next**.

7. Click **Have Disk**, enter the path from Step 1, and then click **OK**.

8. Click the appropriate printer, click **Next**, and then continue with the Add Printer Wizard.

**Microsoft does not have the printer driver for the printer.**
**Cause:** The printer might be too new, and Microsoft does not have the driver ready on its Web site.

**Solution:** Find a printer driver emulation that can provide the correct output. Check with the printer manufacturer to see if they have a Windows Server 2003 family printer driver.

**With printer location tracking enabled, some printers cannot be located.**
**Cause:** After printer location tracking is enabled, the default behavior is that the user will find only those printers whose location attribute matches the naming convention.

**Solution:** You need to set the location string again for this printer. For information on how to do this, see Enable printer location tracking.

**The company has changed its organization, and as a result the naming scheme has to change.**
**Solution:** First, use Active Directory Sites and Services to update the sites and subnets. Next, you need to update all the printer location fields for the affected printers in the organization. You can create an ADSI script to expedite the updates.

**My organization has a small network without any subnets.**

**Solution:** Active Directory cannot locate a node in the tree of your directory without having a subnet associated with it. If your organization is small enough, then this is not a problem, and users can search for any printer in the organization. But for larger organizations, or ones with many printers, you can still allow users to browse the location hierarchy as an aid to locate a printer. To do this, you need to create artificial subnets in Active Directory to correspond to the hierarchy you want to create.

# Availability and Scalability

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Availability and scalability**
This section covers:

- Windows Clustering
- Enterprise Memory Architecture

**Information about other technologies that enhance availability**
For information about other operating system technologies that enhance availability for servers running Microsoft® Windows® Server 2003, see the following:

- For information about using an Uninterruptible Power Supply (UPS) that connects to your computer using a serial cable, see Using an Uninterruptible Power Supply.
- For information about dynamic volumes, including RAID-5 volumes which provide disk fault tolerance, see Disk Management.
- For information about monitoring tools, see Monitoring and Status Tools.
- For information about backup tools, see Backup.
- For information about troubleshooting tools and strategies, see Troubleshooting Strategies.
- For information about preparing for recovery of a system, see Disaster Recovery.
- For detailed information about setting system recovery options, see Specify what happens when the system stops unexpectedly.

**Information about practices that enhance availability**
Maintaining highly available systems requires not only good choices in technology, but careful attention to design and operational practices. For more information about practices that enhance availability, see the following:

- By following best practices for the technologies you use, you can prevent problems before they start, increasing system availability. For information about best practices for specific technologies, see the list in Best practices: pointers to recommendations and tips.
- By following best practices for security, you protect against attacks that could decrease system availability. For more information, see Best practices for security.
- By understanding the deployment and management practices described in the Windows Resource Kits, you can design, test, and operate systems in ways that maximize availability. For more information, see the following:
    - For information about browsing or obtaining the Windows Resource Kits, see Using the Windows Deployment and Resource Kits.
    - For information about deploying Windows, see "Planning for Deployment" at the Microsoft Windows Resource Kits Web site.
    - For information about planning for high availability, see "Planning Server Deployments" at the Microsoft Windows Resource Kits Web site.

- For detailed information about disks and volumes, server clusters, and network load balancing clusters, see the "Server Management Guide" at the Microsoft Windows Resource Kits Web site.

# Windows Clustering

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Clustering**

Windows Clustering provides three different, but complementary, clustering technologies. The clustering technologies, which ship in a number of different products, can be used separately or combined to provide scalable and highly-available services.

| **Clustering Technology** | **Network Load Balancing (NLB) clusters** | **Component Load Balancing (CLB) clusters** | **Server clusters** |
|---|---|---|---|
| Available in ... | Microsoft® Windows Server™ 2003, Web Edition; Microsoft® Windows Server® 2003, Standard Edition; Microsoft® Windows Server™ 2003, Enterprise Edition; and Microsoft® Windows Server™ 2003, Datacenter Edition | Microsoft Application Center 2000 | Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition |
| Maximum number of nodes | 32 | 12 | 8 |
| Application | Load balancing Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) traffic | Single point of management and configuration for Web farms | Failover and failback of applications |
| Specialized hardware required? | No<br>**Note**<br>• If you use teaming network adapters, you must select network adapters listed in the Windows Catalog. For more information, see Network Load Balancing system requirements and the compatibility information in Support resources. | No | Yes<br>To confirm that your server cluster hardware is designed for Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition, see the compatibility information in Support resources. |
| Typical deployments | Web servers, Microsoft Internet Security and Acceleration (ISA) server, virtual private networks, Windows Media™ servers, Mobile Information servers, Terminal Services | Web farms | MS SQL Server, MS Exchange Server, file and print servers, Message Queuing |
| Stateful or stateless? | Stateless | Stateless | Stateful |

**Important**

- Microsoft will not support the configuration of server clusters and Network Load Balancing clusters on the same server. For more information about how the Windows Clustering technologies can be combined in a multitiered approach to provide highly available services, see "Planning for High Availability" in the *Microsoft Windows Server 2003 Deployment Kit* at the Microsoft Windows Resource Kits Web site. In addition, see "Server Clusters and Network Load Balancing" in the *Microsoft Windows Server 2003 Resource Kit* at the Microsoft Windows Resource Kits Web site.

1. **Network Load Balancing clusters.** Network Load Balancing clusters provide scalability and high availability for TCP- and UDP-based services and applications by combining up to 32 servers running Windows Server 2003, Web Edition; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition, into a single cluster. By using Network Load Balancing to build a group of cloned, or identical, clustered computers, you can enhance the availability of these servers: Web and File Transfer Protocol (FTP) servers, ISA servers (for proxy servers and firewall services), virtual private network (VPN) servers, Windows Media servers, Terminal Services over your corporate LAN.

   You can install Network Load Balancing clusters through Network Connections or by using the Network Load Balancing Manager. For more information about Network Load Balancing clusters, see Network Load Balancing Overview.

2. **Component Load Balancing clusters.** Component Load Balancing clusters provide high scalability and availability by enabling COM+ applications (for example, a shopping cart application on an e-commerce Web site) to be distributed across multiple servers. For more information, see the documentation for Microsoft Application Center 2000 in Microsoft TechNet at the Microsoft Web site.

   **Important**

   - Component Load Balancing clusters is a feature of Microsoft Application Center 2000. It is not a feature of Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition.

3. **server clusters.** server clusters provide high availability for applications through the failover of resources. server clusters focus on preserving client access to applications and system services, such as Microsoft Exchange for messaging, Microsoft SQL Server for database applications, and file and print services.

   Server clusters can combine up to eight nodes. In addition, a cluster cannot be made up of nodes running both Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition. In server clusters with more than two nodes, all nodes must run Windows Server 2003, Datacenter Edition, or Windows Server 2003, Enterprise Edition, but not both.

   By default, all clustering and administration software files are automatically installed on your computer when you install any operating system in the Windows Server 2003 family. For more information about server clusters, see Understanding Server Clusters.

For more information about Network Load Balancing clusters and server clusters, see the following topics:

- For conceptual and procedural information on Network Load Balancing clusters, see Network Load Balancing Clusters.
- For conceptual and procedural information on server clusters, see Server Clusters.
- For guidelines on securing a Network Load Balancing cluster, see Network Load Balancing Best practices.
- For guidelines on securing a server cluster, see Best practices for securing server clusters.

# Network Load Balancing Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Load Balancing clusters**
This section of Windows Clustering covers Network Load Balancing (NLB), one of two clustering technologies offered as part of Windows. For a general overview of this subject, see Windows Clustering. You can use Network Load Balancing to enhance the scalability and availability of server applications. Applications that can take advantage of Network Load Balancing include Web services like HTTP and File Transfer Protocol (FTP) (using Internet Information Services (IIS)), firewall and proxy (using ISA 2000), virtual private networking, Windows Media Services, Mobile Information Server, and Terminal Services. Network Load Balancing can also help you scale your server's performance to keep up with the increasing demands of your Internet-based clients.

A new Network Load Balancing feature is Network Load Balancing Manager. Network Load Balancing Manager allows you to create, configure, and manage all hosts of a Network Load Balancing cluster from a single computer. For more information, see Network Load Balancing key features.

- Before you enable and configure Network Load Balancing, it is vital that you review the checklist, including the sections on cluster parameters, host parameters and port rules. It is highly recommended that you read through these three topics before configuring Network Load Balancing.

  Checklist: Enabling and configuring Network Load Balancing

- To find features that have been changed in the Windows Server 2003 family of products, see New ways to do familiar Network Load Balancing tasks.

- For tips about using Network Load Balancing, see Network Load Balancing Best practices.

- For help with specific tasks, see Network Load Balancing How To....

- For general background information, see Network Load Balancing Concepts.

- For troubleshooting information, see Network Load Balancing Troubleshooting.

# Checklist: Enabling and configuring Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Enabling and configuring Network Load Balancing**

| Step | Reference |
|---|---|
| Read "Best practices." | Network Load Balancing Best practices |
| Read "Network Load Balancing system requirements." | Network Load Balancing system requirements |
| Read "Planning your Network Load Balancing cluster." | Planning Your Network Load Balancing Cluster |
| (Optional) Install a second network adapter. | Single network adapter limitations |
| Have ready the cluster's full Internet name. | See Full internet name in Network Load Balancing parameters |
| Have ready the cluster's primary IP address. | See IP address on the Cluster Parameters tab in Network Load Balancing parameters;<br>Single network adapter;<br>Multiple network adapters |
| Have ready the subnet mask for the cluster. | See Subnet mark in Network Load Balancing parameters |
| Have ready the current IP address for each host in the cluster. | See IP address on the Host Parameters tab in Network Load Balancing parameters;<br>Single network adapter;<br>Multiple network adapters |
| Have ready the subnet mask for each host in the cluster. | See Subnet mark in Network Load Balancing parameters |
| Read "Cluster parameters." | See Cluster parameters in Network Load Balancing parameters |
| Carefully consider how to configure the following:<br>• **multicast support**<br>• **remote password**<br>• **confirm password**<br>• **remote control** | See Cluster Operation Mode, Remote password, Confirm password, and Remote control in Network Load Balancing parameters. |
| Read "Host parameters." | See Host parameters in Network Load Balancing parameters |

| | |
|---|---|
| Carefully consider how to configure the following:<br>• **priority (ID)**<br>• **initial state** | See Priority ID and Initial host state in Network Load Balancing parameters |
| Read "Port rules." | See Port rules in Network Load Balancing parameters |
| Carefully consider how to configure the following:<br>• **port range**<br>• **protocols**<br>• **Filtering mode**<br>• **Affinity**<br>• **load weight**<br>• **handling priority** | See Port range, Protocols, Filtering mode, Affinity, Load weight, and Handling priority in Network Load Balancing parameters |
| Enable and configure Network Load Balancing. | Enable Network Load Balancing |

# New ways to do familiar Network Load Balancing tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar Network Load Balancing tasks**

The following table lists common tasks for configuring and managing Network Load Balancing. The user interface for performing these tasks is different in the Windows Server 2003 family of products from the way it was in Windows 2000. Although the Windows 2000 procedures are still valid, in most cases the new procedures are the recommended methods.

| **If you want to** | **In Windows 2000 use** | **In the Windows Server 2003 family of products use** |
|---|---|---|
| Enable Network Load Balancing | Network and Dial-up Connections on each host. | Network Load Balancing Manager. For more information, see Enable Network Load Balancing. |
| Configure cluster parameters | Network and Dial-up Connections on each host. | Network Load Balancing Manager. For more information, see Configure cluster parameters. |
| Add a host | Network and Dial-up Connections on each host. | Network Load Balancing Manager. For more information, see Add a host. |
| Configure host parameters | Network and Dial-up Connections on each host. | Network Load Balancing Manager. For more information, see Configure host parameters. |
| Create, edit, or remove a port rule | Network and Dial-up Connections on each host. | Network Load Balancing Manager. For more information, see Create a new port rule, Edit an existing port rule, and Remove a port rule. |
| Perform basic Network Load Balancing commands: Stop, Start, Suspend, Resume, Drain, Drainstop | **Wlbs.exe**. | either Network Load Balancing Manager, **nlb.exe**, or **wlbs.exe**. For more information, see Perform Basic Network Load Balancing Operations and Nlb. |
| Disable Network Load Balancing | Network and Dial-up Connections on each host. | Network Load Balancing Manager. For more information, see Remove a host from a Network Load Balancing cluster and Remove all hosts from a Network Load Balancing cluster. |

# Network Load Balancing Best practices

Updated: December 21, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Note**

- The general security and configuration guidance in this topic also applies to Network Load Balancing (NLB) clusters in Windows Server 2008, Windows Server 2008 R2, or Windows Server 2012. However, for detailed operational guidance about NLB in Windows Server 2008 or Windows Server 2008 R2, see Network Load Balancing.
- The NLB functionality in Windows Server 2012 is generally the same as in Windows Server 2008 R2. However, some task details are changed in Windows Server 2012. For information on new ways to do tasks, see Common Management Tasks and Navigation.

**Best practices**

**Properly secure the Network Load Balancing hosts and the load balanced applications.**

- Network Load Balancing does not provide additional security for the load balanced hosts and cannot be used as a firewall. It is therefore important to properly secure the load balanced applications and hosts. Security procedures can typically be found in the documentation for each particular application. For example, if you are using Network Load Balancing to load balance a cluster of Internet Information Services (IIS) servers, you should follow the procedures and guidelines for securing IIS. To view the IIS 6.0 product documentation, install IIS and then see Microsoft Internet Information Services, or install IIS and then open the IIS User Interface (the IIS snap-in) and click **Help**.
- The Network Load Balancing subnet must be physically protected from intrusion by unauthorized computers and devices in order to avoid interference from unauthorized heartbeat packets.
- If you use the optional host list with Network Load Balancing Manager, ensure that only users in the local Administrators group have access to the host list file.

  For other general information on best practices for securing servers, see Best practices for security and the Microsoft Windows Resource Kits Web site. For tips about installing IIS, see Installing IIS.

**Use two or more network adapters in each cluster host whenever possible. Two network adapters, however, are not required.**

- If the cluster is operating in unicast mode (the default), Network Load Balancing cannot distinguish between single adapters on each host. Therefore, any communication among cluster hosts is not possible unless each cluster host has at least two network adapters.
- You can configure Network Load Balancing on more than one network adapter. However, if you use a second network adapter to address this best practice, make sure that you install Network Load Balancing on only one adapter (called the cluster adapter).

  For more information, see Multiple network adapters.

**Use only the TCP/IP network protocol on the cluster adapter.**

- Do not add any other protocols (for example, IPX) to this adapter.

**Use Network Load Balancing Manager.**

- You can configure many Network Load Balancing options through either Network Load Balancing Manager or the **Network Load Balancing Properties** dialog box accessed through **Network Connections**. However, Network Load

Balancing Manager is the preferred method. Using both Network Load Balancing Manager and **Network Connections** together to change Network Load Balancing properties can lead to unpredictable results.

**Do not enable Network Load Balancing remote control.**

- The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. It is highly recommended that you do not enable remote control and instead use Network Load Balancing Manager or other remote management tools such as Windows Management Instrumentation (WMI).

If you choose to enable remote control, it is vital that you restrict access by specifying a strong remote control password. It is also imperative that you use a firewall to protect the Network Load Balancing UDP control ports (the ports that receive remote control commands) in order to shield them from outside intrusion. By default, these are ports 1717 and 2504 at the cluster IP address. Use remote control only from a secure, trusted computer within your firewall.

For more information on the remote control parameter, see Remote control in Network Load Balancing parameters. For more information about strong passwords, see Strong passwords.

**Enable Network Load Balancing Manager logging.**

- You can configure Network Load Balancing manager to log each Network Load Balancing Manager event. This log can be very useful in troubleshooting problems or errors when using Network Load Balancing Manager. Enable Network Load Balancing Manager logging by clicking **Log Settings** in the Network Load Balancing Manager **Options** menu. Check the **Enable logging** box and specify a name and location for the log file.

  The Network Load Balancing Manager log file contains potentially sensitive information about the Network Load Balancing cluster and hosts, so it must be properly secured. By default, the log file inherits the security settings of the directory in which it is created, so you might have to change the explicit permissions on the file to restrict read and write access to those individuals who don't need full control of the file. Be aware that the individual using Network Load Balancing Manager does require full control of the log file. For more information, see Access Control How To....

**Verify that the following is true for cluster parameters, port rules and host parameters:**

- Cluster parameters and port rules for each unique virtual IP address are identical across all hosts.

  Each unique virtual IP address must be configured with the same port rules across all hosts that service that Virtual IP address. However, if you have multiple virtual IP addresses configured on a host, each of those virtual IP addresses can have a different set of port rules.

- Port rules are set for all ports used by the load-balanced application. For example, FTP uses port 20, port 21, and ports 1024-65535).

  Always click **Add** after setting a port rule. Otherwise, the port rule will not appear in the list of rules, and the rule will not take effect.

- The dedicated IP address is unique and the cluster IP address is added to each cluster host.

- Affinity is set to **Single** or **Class C** when you are using **UDP** or **Both** for your protocol setting.

For more information, see Cluster parameters, Host parameters, and Port rules in Network Load Balancing parameters.

**Verify that any given load-balanced application is started on all cluster hosts on which the application is installed.**

- Network Load Balancing does not start or stop applications.

**Verify that the following is true for the dedicated IP address and the cluster IP address:**

- Except in the case of a virtual private network (VPN),both the dedicated IP address and the cluster IP address must be entered during setup in the **Network Load Balancing Properties** dialog box and also in the **Internet Protocol (TCP/IP) Properties** dialog box.Make sure that the addresses are the same in both places. However, if you are configuring a VPN load balancing cluster, you should not configure the dedicated IP address. On a VPN, only the cluster IP address should be present on each of the cluster hosts because clients running Windows 95, Windows 98, or Windows NT 4.0 may be unable to connect to the cluster if the dedicated IP address is configured on the Network Load Balancing cluster hosts.

  If you omit this step, the cluster will converge and appear to be working properly, but the cluster host will not accept and handle cluster traffic.

- The dedicated IP address is always listed first (before the cluster IP address) in the **Internet Protocol (TCP/IP) Properties** dialog box. This will ensure that responses to connections originating from a host will return to the same host. For more information, see Set up TCP/IP for Network Load Balancing.

- Both the dedicated IP address and the cluster IP address must be static IP addresses. They cannot be DHCP addresses.

**Ensure that all hosts in a cluster belong to the same subnet and that the cluster's clients are able to access this subnet.**

- No cluster interconnect is used by Network Load Balancing other than the subnet in which the cluster is located. You should therefore not connect two network adapters in an effort to create a system area network (SAN) for which there is no need.

**Perform moves of a cluster host according to the following guidelines:**

- If you move a cluster host from one cluster to another on the same subnet by changing the cluster IP address, first remove Network Load Balancing as described in Remove a host from a Network Load Balancing cluster, and then reenable Network Load Balancing after changing the IP address.

  This will prevent you from experiencing an IP address conflict.

**Verify that all cluster hosts are operating in either unicast or multicast mode, one or the other, but not both.**

**Always begin Network Load Balancing command-line commands with "nlb.exe".**
For more information, see Nlb.

**Do not enable Network Load Balancing on a computer that is part of a server cluster.**

- Network Load Balancing can interfere with server cluster's use of network adapters and Microsoft does not support this configuration. Instead, use separate Network Load Balancing and server clusters.

For more information on server clusters, see Windows Clustering.

**Avoid uninstalling Network Load Balancing.**

- There is typically no need to uninstall this feature. Network Load Balancing is an integral part of the products in the Windows Server 2003 family and does not need to be installed or uninstalled separately.

# Network Load Balancing How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

- Create and Manage Network Load Balancing Clusters
- Configure Network Load Balancing Parameters
- Perform Basic Network Load Balancing Operations
- Perform Advanced Network Load Balancing Procedures

# Create and Manage Network Load Balancing Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Create and Manage Network Load Balancing clusters**

- Enable Network Load Balancing
- Set up TCP/IP for Network Load Balancing
- Add a host
- Connect to existing clusters from Network Load Balancing Manager using a single host
- Connect to existing clusters from Network Load Balancing Manager using a host list
- Enable Network Load Balancing Manager logging
- Remove a host from a Network Load Balancing cluster
- Remove all hosts from a Network Load Balancing cluster
- Stop managing a cluster from Network Load Balancing Manager

# Enable Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Network Load Balancing**

1. Open Network Load Balancing Manager.

2. Right-click **Network Load Balancing Clusters**, and then click **New Cluster**.

3. Enter the cluster's IP address and other cluster information and click **Next**.

4. If necessary, add additional virtual IP addresses that will be used by this cluster by clicking **Add**, entering the virtual IP address and Subnet mask information, then clicking **OK**. Repeat this process for each additional virtual IP address, then click **Next**.

5. If necessary, add appropriate port rules and then click **Next**.

6. Type the name of a host that will be a member of your cluster and click **Connect**. After you click **Connect** the network adapters that are available on the host that you typed will be listed at the bottom of the dialog box. Click the network adapter that you want to use for Network Load Balancing and then click **Next**. The IP address configured on this network adapter will be the dedicated IP address for this host.

   **Important**

   - To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

7. Configure the remaining host parameters as appropriate, then click **Finish**.

8. Add additional hosts as appropriate.

**Important**

- To ensure that Network Load Balancing Manager is displaying the most recent host information, right-click the cluster and click **Refresh**. This step is necessary because the host properties that Network Load Balancing Manager displays are a copy of the host properties that were configured the last time Network Load Balancing Manager connected to that host. When you click **Refresh**, Network Load Balancing Manager reconnects to the cluster and displays updated information.

**Notes**

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

- If Network Load Balancing Manager is not used to enable Network Load Balancing, you must manually add the cluster's IP address to the TCP/IP settings on each host. For more information, see "Set up TCP/IP for Network Load Balancing" in Related Topics below.

- To install and configure Network Load Balancing, you must use an account that is in the Administrators group on each host. As you install and configure each host, if you are not using an account in the Administrators group, you will be prompted to provide the logon credentials for such an account. You can set up an account that Network Load Balancing Manager will use by default by clicking **Credentials** in the Network Load Balancing Manager **Options** menu. It is recommended that this account is an account not used for any other purpose. Be sure to keep the password from expiring on the account (follow your organization's policies for password renewal).

- When you add additional hosts, they will automatically inherit the cluster port rules from the initial host.

- If Network Load Balancing clients are accessing a cluster through a router, be sure that the router meets the following requirements:

    - Accepts a dynamic Address Resolution Protocol (ARP) reply that maps the unicast IP address to its unicast media access control (MAC) address

    - In multicast mode, accepts an ARP reply that has a MAC address in the payload of the ARP structure. If your router does not meet these requirements, you can also create a static ARP entry in the router. Certain routers require a static ARP entry because they do not support the resolution of unicast IP addresses to multicast MAC addresses.

- The parameters set in this procedure are recorded in the registry on each host.

- Network Load Balancing also supports unattended setup. For information about unattended setup, see "Planning for unattended setup" in Related Topics.

- When installing Network Load Balancing, you might expect to find a setup application (such as Setup.exe). There is no such application. The Network Load Balancing driver is installed as a standard Windows networking driver.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set up TCP/IP for Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set up TCP/IP for Network Load Balancing**

1. Open Network Connections.

   **Important**

   - These steps should be used to configure TCP/IP only if you choose not to use Network Load Balancing Manager to create your cluster. When configuring Network Load Balancing, you can use either Network Load Balancing Manager, or you can access the Network Load Balancing Properties dialog box through Network Connections as described in this procedure. Using Network Load Balancing Manager is the preferred method. For more information on using Network Load Balancing Manager to create a cluster, see "Enable Network Load Balancing" in Related Topics.

2. Right-click **Local Area Connection**, and then click **Properties**.

3. In the **Local Area Connection Properties** dialog box, click **Internet Protocol (TCP/IP)**, and then click **Properties**.

4. Click **Use the following IP address**, and then enter the host's dedicated IP address in the space for **IP address**.

5. Enter subnet mask and default gateway information for your TCP/IP network.

6. Save your settings by clicking **OK**.

7. On the host you just added, return to Network Connections.

8. Right-click the network adapter that is using Network Load Balancing and then click **Properties**.

9. In the **Local Area Connection Properties** dialog box, click **Internet Protocol (TCP/IP)**, and then click **Properties**.

10. Click **Advanced**, and then, under **IP addresses**, click **Add**.

11. Enter the cluster IP address in the space for the IP address, followed by the appropriate subnet mask, and then click **Add**.

    This IP address corresponds to the cluster's primary IP address that you entered in the **Network Load Balancing Properties** dialog box under **Cluster parameters** when first enabling Network Load Balancing.

12. If you need to configure additional default gateways or virtual IP addresses for your cluster, you can do so here, in the **Advanced TCP/IP Settings** dialog box.

**Important**

- It is essential that you enter the dedicated IP address first, in the **Internet Protocol (TCP/IP) Properties** dialog box (not in the **Advanced TCP/IP Settings** dialog box), so that all outbound connections made from this host (for example, Telnet or FTP) are initiated with this address.

- TCP/IP is the only network protocol that should be present on the cluster adapter. You must not add any other protocols (for example, IPX) to this adapter.

- Be aware that if you are using Network Load Balancing to load balance Point-to-Point Tunneling Protocol (PPTP) servers,

you must use two network adapters on each cluster host (although Network Load Balancing does not need to be installed on both adapters). When load balancing PPTP, the hosts can not have a dedicated IP addresses configured.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.
- You should repeat this procedure for each network adapter on which you want to install Network Load Balancing.
- Both the dedicated IP address and the cluster's primary IP address must be static IP addresses. They cannot be DHCP (Dynamic Host Configuration Protocol) addresses.
- Regardless of the mode in which Network Load Balancing is operating (unicast or multicast), the steps described previously are the same.
- Although unicast mode is preferable in many situations, the dedicated IP address, will not be addressable by the other cluster hosts unless multicast support has been enabled in the **Network Load Balancing Properties** dialog box under **Cluster parameters**.
- If only one **Local Area Connection** icon is displayed in **Network Connections**, it means that you have only one network adapter installed on your computer. Additional network adapters are represented by additional **Local Area Connection** icons.
- If you use two network adapters you should supply an IP address for the default gateway for only one of the adapters (the one with a route to the largest network, for example to the internet).

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

How Network Load Balancing works
Enable Network Load Balancing

# Add a host

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a host**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.

   **Important**

   - To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

3. Right-click the cluster where you want to add the host and choose **Add Host To Cluster**.
4. Enter the host's name and click **Connect**.
5. After you click **Connect** the network adapters that are available on the host that you typed will be listed at the bottom of the dialog box. Click the network adapter that you want to use for Network Load Balancing and then click **Next**. The IP address configured on this network adapter will be the dedicated IP address for this host.
6. Configure the remaining host parameters as appropriate, then click **Finish**.

**Important**

- To ensure that Network Load Balancing Manager is displaying the most recent host information, right-click the cluster and click **Refresh**. This step is necessary because the host properties that Network Load Balancing Manager displays are a copy of the host properties that were configured the last time Network Load Balancing Manager connected to that host. When you click **Refresh**, Network Load Balancing Manager reconnects to the cluster and displays updated information.

  Similarly, if a host is added to a cluster through the host's local **Network Connections** rather than through Network Load Balancing Manager, the host will not be visible by Network Load Balancing Manager until you **Refresh** the connection as described.

**Notes**

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- When you add additional hosts after the first host is added, the subsequent hosts will automatically inherit the cluster port rules from the initial host.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your

account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to existing clusters from Network Load Balancing Manager using a single host

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to existing clusters from Network Load Balancing Manager using a single host**

1. Open Network Load Balancing Manager.
2. Right-click **Network Load Balancing Clusters** and click **Connect to Existing**.
3. Enter the name of one of the cluster hosts and then click **Connect**.
4. After you click **Connect** the Network Load Balancing clusters that exist on that host will be listed at the bottom of the dialog box. Click the cluster name that you want to manage from Network Load Balancing Manager and then click **Finish**.

   **Important**

   - To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

## Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as. If you attempt to connect to an existing Network Load Balancing cluster, either using a single host or using a host list, and are not a member of the Administrators group on any of the cluster's hosts, those hosts will not be displayed in Network Load Balancing Manager.

  If the Network Load Balancing Manager log displays "Access denied, error connecting to "*host*"" you must reconnect to the cluster using a logon name that is a member of the Administrators group on all hosts. You can do this by logging on with a different logon name, using Run as, or providing an alternate logon name for Network Load Balancing Manager to use by clicking **Credentials** in the Network Load Balancing Manager **Options** menu.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- This procedure allows you to connect to a cluster by entering the name of a single host. After you select a particular cluster, that cluster and all hosts in the cluster will be displayed in Network Load Balancing Manager.
- When using this procedure, certain network problems can prevent Network Load Balancing Manager from connecting to one or more of the other hosts in the cluster. Similarly, if you have misconfigured the cluster by using duplicate priorities on multiple hosts, Network Load Balancing Manager will not be able to connect to those misconfigured hosts. In these cases, some hosts will not appear in Network Load Balancing Manager. If all of the hosts do not appear in Network Load Balancing Manager, try using a host list instead. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect to existing clusters from Network Load Balancing Manager using a host list

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to existing clusters from Network Load Balancing Manager using a host list**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Network Load Balancing Manager.
2. In the **File** menu, click **Load Host List**.
3. Navigate to and select your host list text file and click **Open**.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- For security reasons, ensure that only users in the local Administrators group have access to the host list file.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.

  If you attempt to connect to an existing Network Load Balancing cluster, either using a single host or using a host list, and are not a member of the Administrators group on any of the cluster's hosts, those hosts will not be displayed in Network Load Balancing Manager.

  If the Network Load Balancing Manager log displays "Access denied, error connecting to "*host*"" you must reconnect to the cluster using a logon name that is a member of the Administrators group on all hosts. You can do this by logging on with a different logon name, using Run as, or providing an alternate logon name for Network Load Balancing Manager to use by clicking **Credentials** in the Network Load Balancing Manager **Options** menu.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- The host list text file is a text file that you create using Notepad or any other similar application. The file should list the name of each host. Each host name should be separated by a line break. You can include comments in the host list by preceding the comment with a ";".
- This procedure allows you to connect to multiple hosts and all Network Load Balancing clusters on those hosts. The clusters and hosts will then be displayed in Network Load Balancing Manager. This is particularly useful when a host's Network Load Balancing network adapter is having connectivity problems, but another network adapter is available on that host. You can also use this procedure to detect and diagnose problems such as cluster hosts converging separately.

**Using a command line**

1. Open Command Prompt.

2. Type:

   **nlbmgr /hostlist** *host-list*

| Value | Description |
|---|---|
| host-list | The fully qualified path to a text file that you create using Notepad or any other similar application. The file should list the name of each host. Each host name should be separated by a line break. |

**Important**

- For security reasons, ensure that only users in the local Administrators group have access to the host list file.

**Notes**

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

  If you attempt to connect to an existing Network Load Balancing cluster, either using a single host or using a host list, and are not a member of the Administrators group on any of the cluster's hosts, those hosts will not be displayed in Network Load Balancing Manager.

  If the Network Load Balancing Manager log displays "Access denied, error connecting to "*host*"" you must reconnect to the cluster using a logon name that is a member of the Administrators group on all hosts. You can do this by logging on with a different logon name, using Run as, or providing an alternate logon name for Network Load Balancing Manager to use by clicking **Credentials** in the Network Load Balancing Manager **Options** menu.

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

- To view the complete syntax for this command, at a command prompt, type:

  **nlbmgr /help**

- Ensure that only users in the local Administrators group have access to the host list file.

- You can include comments in the host list by preceding the comment with a ";".

- This procedure allows you to connect to multiple hosts and all Network Load Balancing clusters on those hosts. The clusters and hosts will then be displayed in Network Load Balancing Manager. This is particularly useful when a host's Network Load Balancing network adapter is having connectivity problems, but another network adapter is available on

that host. You can also use this procedure to detect and diagnose problems such as cluster hosts converging separately.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable Network Load Balancing Manager logging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Network Load Balancing Manager logging**

1. Open Network Load Balancing Manager.
2. Click **Log Settings** in the **Options** menu.
3. Check **Enable logging** and specify a name and location for the log file.

## Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- Network Load Balancing Manager logging is different from the logging of events generated by the Network Load Balancing service. Network Load Balancing Manager logging records only events related to the use of Network Load Balancing Manager. To view events related to the Network Load Balancing service, you must use Event Viewer. For more information, see Related Topics below.
- You should always manage a Network Load Balancing cluster from a trusted and secure computer, particularly when logging is enabled. The Network Load Balancing Manager log file contains potentially sensitive information about the Network Load Balancing cluster and hosts, so it must be properly secured. By default, the log file inherits the security settings of the directory in which it is created, so you might have to change the explicit permissions on the file to restrict read and write access to those individuals who do not need full control of the file. Be aware that the individual using Network Load Balancing Manager does require full control of the log file. For more information, see Related Topics below.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove a host from a Network Load Balancing cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove a host from a Network Load Balancing cluster**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the host on which you want to disable Network Load Balancing and choose **Delete Host**.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

  If you can not use Network Load Balancing Manager, you can disable Network Load Balancing through **Network Connections Properties** on each host.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**. Right-click the **Local Area Connection** on which Network Load Balancing is installed, and then click **Properties**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove all hosts from a Network Load Balancing cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove all hosts from a Network Load Balancing cluster**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the cluster on which you want to disable Network Load Balancing and choose **Delete Cluster**.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

  If you can not use Network Load Balancing Manager, you can disable Network Load Balancing through **Network Connections Properties** on each host.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**. Right-click the **Local Area Connection** on which Network Load Balancing is installed, and then click **Properties**.
- After performing this procedure, all existing connections to the hosts will be lost and the cluster will no longer exist.
- When Network Load Balancing is enabled for use with a network adapter in multicast mode, a manually configured media access control (MAC) address, which may have been optionally assigned to the adapter, will be removed after Network Load Balancing is later disabled. When the adapter is subsequently reinitialized (typically when the computer is restarted), the network adapter will revert to its factory-assigned MAC address. To avoid this problem, be sure to reassign the adapter's manually configured MAC address after disabling Network Load Balancing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Stop managing a cluster from Network Load Balancing Manager

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To stop managing a cluster from Network Load Balancing Manager**

1. Open Network Load Balancing Manager.
2. Right-click the cluster that you want to remove from Network Load Balancing Manager and choose **Remove from view**.

## Notes

- Performing this task does not require you to have administrative credentials. Therefore, as a security best practice, consider performing this task as a user without administrative credentials.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To ensure that Network Load Balancing Manager is displaying the most recent host information, right-click the cluster and click **Refresh**. This step is necessary because the host properties that Network Load Balancing Manager displays are a copy of the host properties that were configured the last time Network Load Balancing Manager connected to that host. When you click **Refresh**, Network Load Balancing Manager reconnects to the cluster and displays updated information.
- This procedure only removes visibility to the cluster from Network Load Balancing Manager. The cluster still exists and the Network Load Balancing service on each of the cluster's hosts is unaffected.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Network Load Balancing Parameters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure Network Load Balancing parameters**

- Configure cluster parameters
- Enable multicast support
- Enable Internet Group Management Protocol (IGMP) support
- Configure host parameters
- Configure Port Rules

# Configure cluster parameters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure cluster parameters**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the cluster and choose **Cluster Properties**.
4. Click the **Cluster Parameters** tab.
5. On the **Cluster Parameters** tab, specify values for **IP address**, **Subnet mask**, **Full Internet name**, **Cluster Operation Mode**, **Remote control**, **Remote password** and **Confirm password** using information from the enabling and configuring checklist.

**Important**

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To ensure that Network Load Balancing Manager is displaying the most recent host information, right-click the cluster and click **Refresh**. This step is necessary because the host properties that Network Load Balancing Manager displays are a copy of the host properties that were configured the last time Network Load Balancing Manager connected to that host. When you click **Refresh**, Network Load Balancing Manager reconnects to the cluster and displays updated information.
- The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. It is highly recommended that you do not enable remote control and instead use Network Load Balancing Manager or other remote management tools such as Windows Management Instrumentation (WMI).

If you choose to enable remote control, it is vital that you restrict access by specifying a strong remote control password. It is also imperative that you use a firewall to protect the Network Load Balancing UDP control ports (the ports receiving remote control commands) in order to shield them from outside intrusion. By default, these are ports 1717 and 2504 at the cluster IP address. Use remote control only from a secure, trusted computer within your firewall. For more information on the remote control parameter, see Remote control in Network Load Balancing parameters. For more information about strong passwords, see Strong passwords.

**Notes**

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

- You only need to perform this procedure on a single host. All hosts will automatically inherit the cluster configuration from the initial host.

- The parameters set in the properties dialog box are recorded in the registry on each host.

- Changes to Network Load Balancing parameters are applied when you click **OK** in the properties dialog box. Clicking **OK** stops Network Load Balancing (if it is running), reloads the parameters, and then restarts cluster operations.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Checklist: Enabling and configuring Network Load Balancing

# Enable multicast support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable multicast support**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the cluster, and then click **Cluster Properties**.
4. On the **Cluster Parameters** tab, in **Cluster operation mode**, select **Multicast**. If appropriate, you can also enable Internet Group Management Protocol (IGMP) support by clicking the **IGMP multicast** check box.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- You can only enable IGMP support when your cluster is configured for multicast mode.
- If you enable IGMP support, the allowed multicast IP address is restricted to the standard class D range; that is, 224.0.0.0 to 239.255.255.255.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable Internet Group Management Protocol (IGMP) support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Internet Group Management Protocol (IGMP) support**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the cluster, and then click **Cluster Properties**.
4. On the **Cluster Parameters** tab, click the **IGMP multicast** check box to enable IGMP support on all hosts in the cluster.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. # Configure host parameters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure host parameters**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the host that you want to configure, and then click **Host Properties**.
4. Click the **Host Parameters** tab.
5. Specify values for **Priority (unique host identifier)**, **IP address**, and **Subnet mask**, and select an initial host state.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To ensure that Network Load Balancing Manager is displaying the most recent host information, right-click the cluster and click **Refresh**. This step is necessary because the host properties that Network Load Balancing Manager displays are a copy of the host properties that were configured the last time Network Load Balancing Manager connected to that host. When you click **Refresh**, Network Load Balancing Manager reconnects to the cluster and displays updated information.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

Checklist: Enabling and configuring Network Load Balancing

# Configure Port Rules

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure port rules**

Before you proceed, it is vital that you review the port rules section of Checklist: Enabling and configuring Network Load Balancing. It is highly recommended that you read through this section before configuring Network Load Balancing.

- Create a new port rule
- Edit an existing port rule
- Remove a port rule

# Create a new port rule

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a new port rule**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the cluster, and then click **Cluster Properties**.
4. Click the **Port Rules** tab.
5. Click **Add**.
6. Using information from the enabling and configuring checklist, specify values for the following:
   - **Cluster IP address**, which is the virtual IP address that you want this rule to apply to. Enter a specific virtual IP address to create a virtual cluster, or check **All** to apply the rule to all virtual IP addresses.
   - **Port range**
   - **Protocols**
   - **Filtering mode** and as appropriate, values for **Affinity**, and **Load weight**, and then click **OK**.

**Important**

- The number and type of rules must be exactly the same for each host in the cluster. This is best achieved by using Network Load Balancing Manager to configure port rules (see second note below). If you are using Network Load Balancing Manager, when you add additional hosts, they will automatically inherit the cluster port rules from the initial host.

  If a host attempts to join the cluster with a different number of rules, or with different rules from the other hosts, it is not accepted as part of the cluster. The rest of the cluster then continues to handle the traffic as before. At the same time, a message is entered into the Windows event log. When this happens, consult the event log to determine which host is in conflict with the other cluster hosts, resolve the conflict, and then restart Network Load Balancing on that host.

- In order to allow Network Load Balancing to properly handle IP fragments, you should avoid using **None** when selecting UDP or Both for your protocol setting.

- You cannot add more than 32 port rules to a Network Load Balancing cluster.

**Notes**

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

- If all of your hosts are running a product in the Windows Server 2003 family, you can specify port rules to apply to only specific IP addresses. This is useful when creating virtual clusters. If you are not running a Windows Server 2003 family product, you must apply the port rules to all IP addresses. For more information about virtual clusters, see "Understanding Virtual Clusters."

- The list of all currently installed port rules is sorted by port range.

- The parameters set in the properties dialog box are recorded in the registry on each host.

- Changes to Network Load Balancing parameters are applied when you click **OK** in the properties dialog box. Clicking **OK** stops Network Load Balancing (if it is running), reloads the parameters, and then restarts cluster operations.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

- To ensure that Network Load Balancing Manager is displaying the most recent host information, right-click the cluster and click **Refresh**. This step is necessary because the host properties that Network Load Balancing Manager displays are a copy of the host properties that were configured the last time Network Load Balancing Manager connected to that host. When you click **Refresh**, Network Load Balancing Manager reconnects to the cluster and displays updated information.

**Information about functional differences**

# Edit an existing port rule

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To edit an existing port rule**

1. Open Network Load Balancing Manager.
2. Right-click the cluster and then click **Cluster Properties**.
3. Click the **Port Rules** tab.
4. In the Defined port rules list, click a rule then click **Edit**.
5. Modify the cluster IP address that you want this rule to apply to, the port range, protocols and filtering mode parameters as required, and then click **OK**.

   For more information, see See Also.

### Important

- The number and type of rules must be exactly the same for each host in the cluster. This is best achieved by using Network Load Balancing Manager to configure port rules (see second note below). If you are using Network Load Balancing Manager, when you add additional hosts, they will automatically inherit the cluster port rules from the initial host.

  If a host attempts to join the cluster with a different number of rules, or with different rules from the other hosts, it is not accepted as part of the cluster. The rest of the cluster then continues to handle the traffic as before. At the same time, a message is entered into the Windows event log. When this happens, consult the event log to determine which host is in conflict with the other cluster hosts, resolve the conflict, and then restart Network Load Balancing on that host.

- You cannot add more than 32 port rules to a Network Load Balancing cluster.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To ensure that Network Load Balancing Manager is displaying the most recent host information, right-click the cluster and click **Refresh**. This step is necessary because the host properties that Network Load Balancing Manager displays are a copy of the host properties that were configured the last time Network Load Balancing Manager connected to that host. # Remove a port rule

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove a port rule**

1. Open Network Load Balancing Manager.
2. Right-click the cluster, and then click **Cluster Properties**.
3. Click the **Port Rules** tab.
4. Click the rule you want to remove, and then click **Remove**.

**Important**

- The number and type of rules must be exactly the same for each host in the cluster. This is best achieved by using Network Load Balancing Manager to configure port rules (see second note below). If you are using Network Load Balancing Manager, when you add additional hosts, they will automatically inherit the cluster port rules from the initial host.

  If a host attempts to join the cluster with a different number of rules, or with different rules from the other hosts, it is not accepted as part of the cluster. The rest of the cluster then continues to handle the traffic as before. At the same time, a message is entered into the Windows event log. When this happens, consult the event log to determine which host is in conflict with the other cluster hosts, resolve the conflict, and then restart Network Load Balancing on that host.

- You cannot add more than 32 port rules to a Network Load Balancing cluster.

# Perform Basic Network Load Balancing Operations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Perform basic Network Load Balancing operations**

- Immediately stop handling all Network Load Balancing cluster traffic
- Restart handling Network Load Balancing cluster traffic
- Suspend Network Load Balancing
- Resume Network Load Balancing
- Disable and block all Network Load Balancing traffic handling for specific ports
- Enable Network Load Balancing traffic handling for specific ports
- Disable new traffic handling for specific ports
- Disable new traffic handling for specific ports and stop Network Load Balancing

# Immediately stop handling all Network Load Balancing cluster traffic

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To immediately stop handling all Network Load Balancing cluster traffic**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. If you want to stop cluster operations on all cluster hosts, right-click the cluster, and then point to **Control Hosts**.

   Or, if you want to stop the cluster service on only a particular host, right-click the host, and then point to **Control Host**.
4. Click **Stop**

Cluster operations are immediately stopped and all existing connections are immediately closed.

**Important**

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

**Notes**

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- When you use the **stop** command, either through Network Load Balancing Manager or the command prompt, any client connections already in progress are interrupted. To avoid interrupting active connections, consider using the **drainstop** cluster-control command, which allows the host to continue servicing active connections, but disables all new traffic to that host. For more information, see "Disable new traffic handling and stop Network Load Balancing" in Related Topics.
- For information on how to restart cluster operations, see "To start Network Load Balancing" in Related Topics.
- The **stop** command differs from the **suspend** command in that **suspend** stops Network Load Balancing on the host and also suspends all Network Load Balancing cluster-control commands on the host, except for the **resume** and **query** commands. **Stop** only stops Network Load Balancing on the host, but does not affect the other Network Load Balancing cluster-control commands. For more information on the **suspend** command, see "To suspend Network Load Balancing".

**Using a command line**

1. Open Command Prompt.

2. Type:

   **nlb.exe stop**

   Cluster operations are immediately stopped on the local cluster host and all existing connections are immediately closed.

   Or, if you want to stop cluster operations on all cluster hosts, type:

   **nlb.exe stop***cluster IP address* | *cluster name*

### Notes

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

- When you use the **stop** command, either through Network Load Balancing Manager or the command prompt, any client connections already in progress are interrupted. To avoid interrupting active connections, consider using the **drainstop** cluster-control command, which allows the host to continue servicing active connections, but disables all new traffic to that host. For more information, see "Disable new traffic handling and stop Network Load Balancing" in Related Topics.

- For information on how to restart cluster operations, see "To start Network Load Balancing" in Related Topics.

- The **stop** command differs from the **suspend** command in that **suspend** stops Network Load Balancing on the host and also suspends all Network Load Balancing cluster-control commands on the host, except for the **resume** and **query** commands. **Stop** only stops Network Load Balancing on the host, but does not affect the other Network Load Balancing cluster-control commands. For more information on the **suspend** command, see "To suspend Network Load Balancing" in Related Topics.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Restart handling Network Load Balancing cluster traffic

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restart handling Network Load Balancing cluster traffic**

Using the Windows interface

Using a command line

**Using the Windows interface**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. If you want to start cluster operations on all cluster hosts, right-click the cluster, and then point to **Control Hosts**.

   Or, if you want to start the cluster service on only a particular host, right-click the host, and then point to **Control Host**.
4. Click **Start**

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- This command can be used after a previous **stop** or **suspend** command. It restarts cluster operations. It does not reenable the use of cluster-control commands, including remote control commands, which have been disabled by a previous **suspend** command. For information on how to reenable cluster-control commands, see "To resume Network Load Balancing" in Related Topics.
- You should not use the **start** command to form a new cluster. For more information, see "Enable Network Load Balancing".

**Using a command line**

1. Open Command Prompt.
2. Type:

   **nlb.exe start**

   Or, if you want to start cluster operations on all cluster hosts, type:

   **nlb.exe start***cluster IP address* | *cluster name*

## Notes

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. # Suspend Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To suspend Network Load Balancing**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. If you want to suspend cluster operations on all cluster hosts, right-click the cluster and then point to **Control Hosts**.

   Or, if you want to suspend the cluster service on only a particular host, right-click the host, and then point to **Control Host**.
4. Click **Suspend**

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- The **suspend** command suspends all cluster operations until the **resume** and **start** commands are issued.

  The purpose of the **suspend** command is to override any remote control commands that might be issued. All subsequent cluster-control commands except **resume** and **query** are ignored.
- This command can be performed on the whole cluster or remotely to a single host.
- The **stop** command differs from the **suspend** command in that **suspend** stops Network Load Balancing on the host and also suspends all Network Load Balancing cluster-control commands on the host, except for the **resume** and **query** commands. **Stop** only stops Network Load Balancing on the host, but does not affect the other Network Load Balancing cluster-control commands. For more information on the **stop** command, see "Immediately stop handling all Network Load Balancing cluster traffic" in Related Topics.

**Using a command line**

1. Open Command Prompt.

2. Type:

   **nlb.exe suspend**

   Or, if you want to suspend cluster operations on all cluster hosts, type:

   **nlb.exe suspend***cluster IP address* | *cluster name*

### Notes

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

# Resume Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To resume Network Load Balancing

- Using the Windows interface
- Using a command line

#### Using the Windows interface

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click a host or a cluster, and then point to **Control Host** or **Control Hosts**.
4. Click **Resume**

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- Performing this command at the cluster level resumes Network Load Balancing on all hosts within the cluster. Performing this command at the host level resumes Network Load Balancing on the specific host only.
- This command can be used after a previous **suspend** command. It reenables the use of cluster-control commands, including remote control commands. It does not restart cluster operations. For information on how to restart cluster operations, see "Restart handling Network Load Balancing cluster traffic" in Related Topics.
- This command can be performed on the whole cluster or remotely to a single host.

#### Using a command line

1. Open Command Prompt.
2. Type:

   **nlb.exe resume**

   Or, if you want to reenable cluster-control commands on all cluster hosts, type:

**nlb.exe resume***cluster IP address* | *cluster name*

## Notes

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

# Disable and block all Network Load Balancing traffic handling for specific ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable and block all Network Load Balancing traffic handling for specific ports**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click a host or a cluster, and then click **Control Ports**.
4. Select the port rule that contains the ports that you want to disable and then click **Disable**.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- This command disables and immediately blocks all traffic handling for the rule whose port range contains the specified port. All ports specified by the port rule are affected.
- All active connections on the specified hosts are blocked. To maintain active connections, use the drain function instead.
- This has no effect if the specified hosts have not started cluster operations.
- For information on how to enable specific ports, see "Enable Network Load Balancing traffic handling for specific ports" in Related Topics.

**Using a command line**

1. Open Command Prompt.
2. Type:

**nlb.exe disable***vip*[:*port*|:all] | all[:*port*|:all] *cluster*[:*host*]| all [*local*|*global*]

For more information about the parameters that you can use with this command, see "Nlb" in Related Topics.

## Notes

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

# Disable new traffic handling for specific ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable new traffic handling for specific ports**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click a host or a cluster, and then click **Control Ports**.
4. Select the port rule that contains the ports that you want to drain and then click **Drain**.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open Command Prompt. From the command window, type **NLBMgr.exe**, and then press **ENTER**.
- Draining disables new traffic handling for the rule whose port range contains the specified port. New connections to the specified hosts are not allowed, but all active connections are maintained. To disable active connections, use the disable command instead.
- Performing this command at the cluster level drains the specified ports on all hosts within the cluster. Performing this command at the host level drains the ports on the specific host only.
- This command has no effect if the specified hosts have not started cluster operations.

**Using a command line**

1. Open Command Prompt.
2. Type:

   **nlb.exe drain***vip*[:*port*|:all] | all[:*port*|:all] *cluster*[:*host*]| all [*local*|*global*]

   For more information about the parameters that you can use with this command, see "Nlb" in Related Topics.

**Notes**

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. # Disable new traffic handling for specific ports and stop Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable new traffic handling for specific ports and stop Network Load Balancing**

- Using the Windows interface
- Using a command line

**Using the Windows interface**

1. Open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster. For more information, see "Manage existing clusters from Network Load Balancing Manager" in Related Topics.
3. Right-click a host or a cluster, and then point to **Control Host** or **Control Hosts**.
4. Click **Drainstop**

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open Command Prompt. From the command window, type **nlbmgr.exe**, and then press **ENTER**.
- Performing this command at the cluster level performs the command on all hosts within the cluster. Performing this command at the host level performs the command on the specific host only.
- This command disables all new traffic handling on the specified hosts. While draining, hosts continue to service opened connections and stop their cluster operations when there are no more active connections. Draining mode can be terminated by explicitly stopping cluster mode with the stop command or by restarting new traffic handling with the start command
- While draining, hosts remain in the cluster and stop their cluster operations when there are no more active connections. To stop draining mode, explicitly stop cluster mode with the **stop** command, or restart new traffic handling with the **start** command.

**Using a command line**

1. Open Command Prompt.

2. Type **nlb.exe drainstop**.

   For more information about the parameters that you can use with this command, see "Nlb" in Related Topics.

## Notes

- To run nlb.exe from a remote computer, you must enable remote control on the host that is running Network Load Balancing. The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. Only use remote control on a secure computer within your firewall. Because of the many security risks remote control presents, it is recommended that you do not enable the remote control feature. Instead, use other remote management tools such as Network Load Balancing Manager or Windows Management Instrumentation (WMI).

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To uninstall Network Load Balancing**

1. Log on as an administrator on the local computer.

   **Important**

   - If possible, you should avoid uninstalling Network Load Balancing. There is typically no need to uninstall this feature, and doing so might adversely affect the operation of other system components. Removing Network Load Balancing from the network adapter, as described in "Remove a host from a Network Load Balancing cluster" in Related Topics below is all that is needed to ensure that Network Load Balancing is not being used by the host.
   - If you do not follow these steps in the exact order shown, your network will experience IP address conflicts.

2. Open Network Connections.
3. Right-click the **Local Area Connection** on which Network Load Balancing is installed, and then click **Properties**.
4. Click **Internet Protocol (TCP/IP)**, and then click **Properties**.
5. In the **Internet Protocol (TCP/IP) Properties** dialog box, remove the cluster's primary IP address. If the cluster's primary IP address is in the **Advanced TCP/IP Settings** dialog box, click **Advanced**.
6. In the **Advanced TCP/IP Settings** dialog box, remove the cluster's primary IP address and any other cluster IP addresses that you might have entered here, and then click **OK**.
7. In the **Internet Protocol (TCP/IP) Properties** dialog box, click **OK**.
8. In the **Local Area Connection Properties** dialog box, click **OK**.
9. Right-click the **Local Area Connection** on which Network Load Balancing is installed, and then click **Properties**.
10. Click **Network Load Balancing**, and then click **Uninstall**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Enable Network Load Balancing

# Install Network Load Balancing if it was previously uninstalled

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install Network Load Balancing if it was previously uninstalled**

1. Open Network Connections.

   **Important**

   - To avoid networking problems, follow these steps in the exact order shown.

2. Right-click the **Local Area Connection** on which Network Load Balancing is to be installed, and then click **Properties**.

3. Click **Install**.

4. In the **Select Network Component Type** dialog box, click **Service**, and then click **Add**.

5. In the **Select Network Service** dialog box, click **Network Load Balancing**, and then click **OK**.

   **Important**

   - Do not select the check box for Network Load Balancing at this point. When you configure the cluster using Network Load Balancing Manager (in the next step), Network Load Balancing Manager will automatically enable this service.

6. Use Network Load Balancing Manager to configure the cluster. For more information, see "Enable Network Load Balancing" in Related Topics.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Network Connections, click **Start**, click **Control Panel**, and then double-click **Network Connections**.

- If Network Load Balancing clients are accessing a cluster through a router, be sure that the router meets the following requirements:

  - Accepts a dynamic Address Resolution Protocol (ARP) reply mapping the unicast IP address to its unicast media access control (MAC) address

  - In multicast mode, accepts an ARP reply that has a MAC address in the payload of the ARP structure. If your router does not meet these requirements, you can also create a static ARP entry in the router. Cisco routers require a static ARP entry because they do not support the resolution of unicast IP addresses to multicast MAC addresses.

- If only one **Local Area Connection** icon is displayed in **Network Connections**, you have only one network adapter installed on your computer. Additional network adapters are represented by additional **Local Area Connection** icons.

- When installing Network Load Balancing, you might expect to find a setup application (such as Setup.exe). There is no

such application. The Network Load Balancing driver is installed as a standard Windows networking driver.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Adjust convergence parameters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To adjust convergence parameters**

1. Click **Start**, click **Run**, and then, in **Open**, type **regedit**.
2. Click the registry key:

   HKEY_LOCAL_MACHINE\System\CurrentControlSet

   \Services\WLBS\Parameters\Interface*Network adapter ID*
3. Edit the **AliveMsgPeriod** or **AliveMsgTolerance** parameters as necessary.
4. Restart the computer.

### Caution

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- The purpose of this procedure is to allow you to control both the message exchange period and the number of missed messages required to initiate convergence. For more information, see Related Topics.
- The **AliveMsgPeriod** value holds the message exchange period in milliseconds, and the **AliveMsgTolerance** value specifies how many exchanged messages from a host can be missed before the cluster initiates convergence.

  These numbers should reflect your installation's requirements. A longer message exchange period reduces the heartbeat traffic needed to maintain fault tolerance, but it increases the time that it takes for Network Load Balancing to stop sending network messages to an offline host. Likewise, increasing the number of message exchanges prior to convergence reduces the number of unnecessary convergence initiations due to network congestion, but it too increases the time for an offline host to stop receiving network traffic.

  Using the default values, 5 seconds are needed to discover a missing host, and another 5 seconds are needed for the cluster to redistribute the load. A total of 10 seconds to stop sending network traffic to an offline host should be acceptable for most TCP/IP applications. This configuration incurs very low networking overhead.
- WLBS stands for Windows NT Load Balancing Service, the former name of Network Load Balancing in Windows NT 4.0. For reasons of backward compatibility, WLBS continues to be used in certain instances.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Limit switch port flooding

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To limit switch port flooding**

1. If multicast support has been enabled during setup, open Network Load Balancing Manager.
2. If Network Load Balancing Manager does not already list the cluster, connect to the cluster.
3. Right-click the cluster, and then click **Cluster Properties**.
4. On the **Cluster Parameters** tab, click the **IGMP multicast** check box to enable Internet Group Management Protocol (IGMP) support on all hosts in the cluster.

### Important

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

### Notes

- When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring, or you must have been delegated the appropriate authority. As a security best practice, consider using Run as to perform this procedure. If you are configuring a cluster or host by running Network Load Balancing Manager from a computer that is not part of the cluster, you do not need to be a member of the Administrators group on that computer. For more information, see Default local groups, Default groups, and Using Run as.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.
- If the cluster hosts are directly connected to a hub to receive client requests and IGMP support is not enabled, incoming client traffic is automatically sent to all switch ports, and may produce switch flooding.
- You can only enable IGMP support when your cluster is configured for multicast mode. To enable multicast mode, see "Enable multicast support" in Related Topics below.
- Windows NT Load Balancing Service (WLBS) is the former name of Network Load Balancing in Windows NT 4.0. For backward compatibility reasons, WLBS continues to be used in certain instances.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Introduction to Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Introduction to Network Load Balancing**

The Network Load Balancing (NLB) service enhances the availability and scalability of Internet server applications such as those used on Web, FTP, firewall, proxy, VPN, and other mission-critical servers. A single computer running Windows can provide a limited level of server reliability and scalable performance. However, by combining the resources of two or more computers running one of the products in the Windows Server 2003 family into a single cluster, Network Load Balancing can deliver the reliability and performance that Web servers and other mission-critical servers need. The following diagram depicts two connected Network Load Balancing clusters. The first cluster consists of two hosts and the second cluster consists of four hosts:

Each host runs separate copies of the desired server applications, such as that for a Web, FTP, and Telnet server. Network Load Balancing distributes incoming client requests across the hosts in the cluster. The load weight to be handled by each host can be configured as necessary. You can also add hosts dynamically to the cluster to handle increased load. In addition, Network Load Balancing can direct all traffic to a designated single host, called the default host.

Network Load Balancing allows all of the computers in the cluster to be addressed by the same set of cluster IP addresses (but also maintains their existing unique, dedicated IP addresses).

For load-balanced applications, when a host fails or goes offline, the load is automatically redistributed among the computers still operating. Applications with a single server have their traffic redirected to a specific host. When a computer fails or goes offline unexpectedly, active connections to the failed or offline server are lost. However, if you bring a host down intentionally, you can use the drainstop command to service all active connections prior to bringing the computer offline. In either case, when ready, the offline computer can transparently rejoin the cluster and regain its share of the workload.

**Note** If you plan to use Network Load Balancing in a 64-bit environment, you must use the 64-bit Network Load Balancing version. If you do not, the cluster will fail to form.

**Overview of Network Load Balancing configuration**

Network Load Balancing runs as a Windows networking driver. Its operations are transparent to the TCP/IP networking stack. The following diagram shows the relationship between Network Load Balancing and other software components in a typical configuration of a Network Load Balancing host:

**Database access from load-balanced server applications**

Some server applications access a database that is updated by client requests. When these applications are load balanced in

the cluster, these updates need to be properly synchronized. Each host can use local, independent copies of databases that are merged offline as necessary. Alternatively, the clustered hosts can share access to a separate, networked database server. A combination of these approaches can also be used. For example, static Web pages can be replicated among all clustered servers to ensure fast access and complete fault tolerance. However, database requests would be forwarded to a common database server that handles updates for multiple Web servers.

Some mission-critical applications might require the use of highly available database engines to ensure complete fault tolerance for the service. It is recommended that you deploy cluster-aware database software to deliver highly available and scalable database access within an overall clustering scheme. One such example of this is Microsoft SQL Server, which can be deployed with the Cluster service in a server cluster. The Cluster service ensures that if one node fails, a remaining node assumes the responsibilities of the failed computer, thus providing almost continuous service to Microsoft SQL Server clients. It is able to do this because the computers in the server cluster make use of a cluster storage device. For more information on the Cluster service and how it works with Network Load Balancing, see Updated technical information.

**Notes**

- It is important to distinguish between the two cluster solutions under discussion. The first, Network Load Balancing, is intended primarily to load balance incoming TCP/IP traffic. The computers participating in this solution form one type of cluster. The second, the Cluster service, is intended primarily to provide failover service from one computer to another. The computers participating in this solution form a different type of cluster. Moreover, the Network Load Balancing cluster would most commonly be running Web server applications. In contrast, the Cluster service would most commonly be running database applications (when used in conjunction with Network Load Balancing). Network Load Balancing and the Cluster service can not both be active on the same computer, but by joining the two cluster solutions together to function in a complementary fashion, the user creates an overall clustering scheme, as shown in the following diagram:

- For more information on how Network Load Balancing achieves fault tolerance and scalability, see How Network Load Balancing works.

# Network Load Balancing key features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Load Balancing key features**

**Scalability**

- Load balances requests for individual TCP/IP services across the cluster.
- Supports up to 32 computers in a single cluster.
- Load balances multiple server requests, from either the same client, or from several clients, across multiple hosts in the cluster.
- Fully pipe-lined implementation ensures high performance and low overhead.

  **Note**

  - During packet reception, the Network Load Balancing fully pipe-lined implementation overlaps the delivery of incoming packets to TCP/IP and the reception of other packets by the NDIS driver. This increases the overall processing speed and reduces latency because TCP/IP can process a packet while the NDIS driver receives a subsequent packet. It also reduces the overhead required for TCP/IP and the NDIS driver to coordinate their actions, and in many cases it eliminates an extra memory copy of packet data. During packet sending, Network Load Balancing also enhances throughput and reduces latency and overhead by increasing the number of packets that TCP/IP can send with one NDIS call. To achieve these performance enhancements, Network Load Balancing allocates and manages a pool of packet buffers and descriptors, that it uses to overlap the actions of TCP/IP and the NDIS driver.

**High Availability**

- Automatically detects and recovers from a failed or offline computer.
- Automatically balances the network load when hosts are added or removed.
- Recovers and redistributes the workload within 10 seconds.

**Manageability**

- You can manage and configure multiple Network Load Balancing clusters and the cluster hosts from a single computer using Network Load Balancing Manager.
- You can specify the load balancing behavior for a single IP port or group of ports using port management rules.
- If you use the same set of load balanced servers for multiple applications or Web sites, by using virtual clusters you can define different port rules for each Web site based on the destination virtual IP address.
- Using optional single-host rules, you can direct all client requests to a single host, in effect using Network Load Balancing to route client requests to a particular host running specific applications.
- You can block undesired network access to certain IP ports.
- You can enable Internet Group Management Protocol (IGMP) support on the cluster hosts to control switch flooding when operating in multicast mode.

- Network Load Balancing logs all actions and cluster changes in the Windows event log.

- Using shell commands or scripts, you can remotely start, stop, and control Network Load Balancing actions from any networked computer that is running Windows.

**Ease of use**

- Network Load Balancing is installed as a standard Windows networking driver component.

- Network Load Balancing requires no hardware changes to enable and run.

- Network Load Balancing Manager allows you to create new Network Load Balancing clusters and configure and manage clusters and all of the cluster's hosts from a single remote or local computer. Ideally you should use a second network adapter when managing the cluster from a local computer.

- Network Load Balancing lets clients access the cluster with a single logical Internet name and virtual IP address (also know as the cluster IP address) while retaining individual names for each computer. Network Load Balancing allows multiple virtual IP addresses for multihomed servers (although in the case of virtual clusters, the servers do not need to be multihomed in order to have multiple virtual IP addresses).

- Network Load Balancing can be bound to multiple network adapters allowing you to configure multiple independent clusters on each host. Support for multiple network adapters is different from virtual clusters in that virtual clusters allow you to configure multiple clusters on a single network adapter.

- You do not have to modify server applications to run in a Network Load Balancing cluster.

- If a cluster host fails and then is subsequently brought back online, Network Load Balancing can be configured to automatically add that host to the cluster. The added host will then be able to start handling new server requests from clients.

- You can take computers offline for preventive maintenance without disturbing cluster operations on the other hosts.

# Network Load Balancing system requirements

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Load Balancing system requirements**

Network Load Balancing is designed to work as a standard networking device driver in the Microsoft® Windows Server 2003 family of products. Because Network Load Balancing provides clustering support for TCP/IP-based server applications, TCP/IP must be installed in order to take advantage of Network Load Balancing functionality. The current version of Network Load Balancing is designed for use with Ethernet network adapters. It is not compatible with asynchronous transfer mode (ATM), ATM local area network (LAN) emulation, or token ring. It has been tested on 10 megabits per second (Mbps), 100 Mbps, and gigabit Ethernet networks with a wide variety of network adapters, including teaming network adapters listed as compatible with the Windows Server 2003 family of products. For information regarding compatible hardware, click the appropriate link in Support resources.

On x86-based computers, Network Load Balancing uses between 750 kilobytes (KB) and 27 MB of RAM per network adapter during operation, using the default parameters and depending on the network load. The parameters can be modified to allow up to 84 MB memory to be used. Typical memory usage ranges between 750 KB and 2 MB.

On x64-based computers, Network Load Balancing uses between 825 KB and 32.3 MB of RAM per network adapter during operation, using the default parameters and depending on the network load. The parameters can be modified to allow up to 102 MB memory to be used. Typical memory usage for x64-based computers ranges between 825 KB and 2.5 MB.

For optimum cluster performance, you should install a second network adapter on each Network Load Balancing host. In this configuration, the first network adapter handles the network traffic addressed to the server as part of cluster, while the second network adapter is used for intra-host communication.

It is important to understand that it is possible to use Network Load Balancing with only a single network adapter. For more details, see Single network adapter limitations.

**Note**

- Network Load Balancing can operate in two modes: unicast and multicast. Unicast support is enabled by default. To enable multicast support, see Enable multicast support.

**Using a router**

If Network Load Balancing clients are accessing a cluster through a router when the cluster has been configured to operate in multicast mode, be sure that the router meets the following requirements:

- Accepts an Address Resolution Protocol (ARP) reply that has one media access control (MAC) address in the payload of the ARP structure, but appears to arrive from a station with another MAC address, as determined by the Ethernet header

- Accepts an ARP reply for a unicast IP address with a multicast MAC address in the payload of its ARP structure

These conditions allow the router to map the cluster IP addresses to the corresponding MAC address. If your router does not meet these requirements, you can also create a static ARP entry in the router. Cisco routers require a static ARP entry because they do not support the resolution of unicast IP addresses to multicast MAC addresses.

# How Network Load Balancing works

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How Network Load Balancing works**

Network Load Balancing provides high availability and scalability of servers using a cluster of two or more host computers working together. Internet clients access the cluster using a either a IP address or a set of addresses. The clients are unable to distinguish the cluster from a single server. Server applications do not identify that they are running in a cluster. However, a Network Load Balancing cluster differs significantly from a single host running a single server application because it can provide uninterrupted service even if a cluster host fails. The cluster can also respond more quickly to client requests than a single host.

Network Load Balancing delivers high availability by redirecting incoming network traffic to working cluster hosts if a host fails or is offline. Existing connections to an offline host are lost, but the Internet services remain available. In most cases (for example, with Web servers), client software automatically retries the failed connections, and the clients experience a delay of only a few seconds in receiving a response.

Network Load Balancing delivers scaled performance by distributing the incoming network traffic among one or more virtual IP addresses (the cluster IP addresses) assigned to the Network Load Balancing cluster. The hosts in the cluster then concurrently respond to different client requests, even multiple requests from the same client. For example, a Web browser might obtain each of the multiple images in a single Web page from different hosts within a Network Load Balancing cluster. This speeds up processing and shortens the response time to clients.

Network Load Balancing enables all cluster hosts on a single subnet to concurrently detect incoming network traffic for the cluster IP addresses. On each cluster host, the Network Load Balancing driver acts as a filter between the cluster adapter driver and the TCP/IP stack in order to distribute the traffic across the hosts.

Network Load Balancing employs a fully distributed algorithm to statistically map incoming clients to the cluster hosts based on their IP address and port. No communication between the hosts is necessary for this process to occur. When inspecting an arriving packet, all hosts simultaneously perform this mapping to quickly determine which host should handle the packet. The mapping remains invariant unless the number of cluster hosts changes. The Network Load Balancing filtering algorithm is much more efficient in its packet handling than centralized load-balancing applications, which must modify and retransmit packets.

**Distribution of cluster traffic**

Network Load Balancing controls the distribution of TCP and UDP traffic from the Internet clients to selected hosts within a cluster as follows: After Network Load Balancing has been configured, incoming client requests to the cluster IP addresses are received by all hosts within the cluster. Network Load Balancing filters incoming datagrams to specified TCP and UDP ports before these datagrams reach the TCP/IP protocol software. Network Load Balancing manages the TCP and UDP protocols within TCP/IP, controlling their actions on a per-port basis.

In multicast mode, Network Load Balancing can limit switch flooding by providing Internet Group Management Protocol (IGMP) support. Network Load Balancing does not control any incoming IP traffic other than TCP and UDP traffic for specified ports and IGMP traffic in multicast mode. It does not filter other IP protocols (for example, ICMP or ARP), except as described below. Be aware that you should expect to see duplicate responses from certain point-to-point TCP/IP applications (such as ping) when the cluster IP address is used. If required, these applications can use the dedicated IP address for each host to avoid this behavior.

**Convergence**

To coordinate their actions, Network Load Balancing hosts periodically exchange heartbeats within the cluster (for more information, see Internet Group Management Protocol (IGMP)). IP multicasting allows the hosts to monitor the status of the cluster. When the state of the cluster changes (such as when hosts fail, leave, or join the cluster), Network Load Balancing invokes a process known as convergence, in which the hosts exchange a limited number of messages to determine a new, consistent state of the cluster and to designate the host with the highest host priority as the new default host. When all cluster hosts have reached consensus on the correct new state of the cluster, they record the completion of convergence in the Windows event log. This process typically takes less than 10 seconds to complete.

During convergence, the remaining hosts continue to handle incoming network traffic. Client requests to working hosts are unaffected. At the completion of convergence, the traffic destined for a failed host is redistributed to the remaining hosts. Load-balanced traffic is repartitioned among the remaining hosts to achieve the best possible new load balance for specific TCP or UDP ports.

If a host is added to the cluster, convergence allows this host to receive its share of the load-balanced traffic. Expansion of the cluster does not affect ongoing cluster operations and is achieved transparently to both Internet clients and to server applications. However, it might affect client sessions that span multiple TCP connections when client affinity is selected, because clients might be remapped to different cluster hosts between connections. For more information on affinity, see Network Load Balancing and stateful connections.

Network Load Balancing assumes that a host is functioning properly within the cluster as long as it exchanges heartbeats with other cluster hosts. If other hosts do not receive a response from any member for several heartbeat exchanges, they initiate convergence to redistribute the load that would have been handled by the failed host.

You can control both the message exchange period and the number of missed messages required to initiate convergence. The default values are respectively set to 1,000 milliseconds (1 second) and 5 missed message exchange periods. Because these parameters are not usually modified, they are not configurable through the **Network Load Balancing Properties** dialog box. They can be adjusted manually in the registry as necessary. The procedures for this are described in Adjust convergence parameters.

# Understanding virtual clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding virtual clusters**

It is becoming increasingly common to host multiple applications or Web sites on a single Network Load Balancing (NLB) cluster. When doing so, you may require independent load balancing policies, defined through port rules, applied to each of these applications or sites.

In the Windows Server 2003 family of products you can configure multiple Network Load Balancing clusters on the same network adapter and then apply specific port rules to each of those IP addresses. These are referred to as "virtual clusters."

You can also use virtual clusters to block network traffic to a specific host for a specific application, without affecting traffic for other applications on that host. You can also use virtual clusters to limit each application, Web site, or virtual IP address to a specific subset of computers within your primary cluster. See the diagram below for an example of this use of virtual clusters.

This diagram depicts a four host Network Load Balancing cluster. Through the use of virtual clusters and IP address-specific load weight, Network Load Balancing directs network traffic as follows:

- Users accessing Web Site A (IP address *nnn.nnn.nnn*.1) are directed to any of the four hosts
- Users accessing Web site B (IP address *nnn.nnn.nnn*.2), which is a virtual cluster, are directed to hosts 1 and 2
- Users accessing Web site C (IP address *nnn.nnn.nnn*.3), which is a virtual cluster, are directed to hosts 3 and 4

For more information on how this is configured, see Virtual clusters and Create a new port rule.

# Planning Your Network Load Balancing Cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning your Network Load Balancing cluster**

This section covers the issues you must consider as you plan how to set up Network Load Balancing in your organization.

- Identifying Your Risks
- Choosing a Network Load Balancing Model
- Capacity Planning
- Optimizing Network Load Balancing Clusters

# Identifying Your Risks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Identifying your risks**

When you identify network risks, you identify the possible failures that can interrupt access to network resources. A single point of failure is any component in your environment that would block data or applications if it failed. Single points of failure can be hardware, software, or external dependencies, such as power supplied by a utility company and dedicated wide area network (WAN) lines.

In general, you provide maximum reliability when you:

- Minimize the number of single points of failure in your environment.
- Provide mechanisms that maintain service when a failure occurs.

In the case of Network Load Balancing, you also provide maximum reliability when you:

- Load balance only applications appropriate to Network Load Balancing.
- Make sure that the application servers are properly configured for the applications they are running.

This section covers the following areas:

- Addressing your risks
- Determining which applications to use with Network Load Balancing

For more information about monitoring recommendations for high-availability systems, see the "System Performance and Troubleshooting Guide" at the Microsoft Windows Resource Kits Web site. For more information about maximizing the availability of a Network Load Balancing cluster, see the "Server Management Guide" at the Microsoft Windows Resource Kits Web site.

# Addressing your risks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Addressing your risks**

A principal goal of Network Load Balancing is to provide increased reliability. A cluster of two or more computers ensures that if one computer fails, another computer is available to continue processing client requests.

However, Network Load Balancing is not designed to protect all aspects of your workflow in all circumstances. For example, Network Load Balancing is not an alternative to backing up data. Network Load Balancing protects only the availability of data, not the data itself. Also, it does not guard against a power outage that would disable the entire cluster.

Windows Server 2003, Standard Edition ; Windows Server 2003, Enterprise Edition ; and Windows Server 2003, Datacenter Edition , have built-in features that protect certain computer and network processes during failure. These features include disk mirroring (RAID Level 1) and disk striping [AMC25A] with parity (RAID Level 5). When planning your Network Load Balancing environment, look for places where these features can help you in ways that Network Load Balancing cannot.

The following table lists common points of failure in a Windows Server 2003, Standard Edition ; Windows Server 2003, Enterprise Edition ; or Windows Server 2003, Datacenter Edition , environment, and describes whether the point of failure can be protected, either by Network Load Balancing or by other means.

These features include RAID-1, disk mirroring, RAID-5, and disk striping with parity.

| **Failure point** | **Network Load Balancing solution** | **Other solutions** |
|---|---|---|
| Network hub | n/a | Redundant networks |
| Power outage | n/a | • Uninterruptable power supply (UPS)<br>• Generator |
| server connection | Failover | n/a |
| Disk | Failover | Hardware or software RAID, to ensure against the loss of data on a specific computer and to provide uninterrupted service |
| Other server hardware, such as CPU or memory | Failover | Spare components, such as motherboards and SCSI controllers (any spare components should exactly match the original components, including network and SCSI components) |
| server software, such as the operating system or specific applications | n/a | server clusters (only computers running Windows Server 2003, Enterprise Edition , or Windows Server 2003, Datacenter Edition ) |
| IP-level failures, such as IIS service interruptions | Failover | n/a |
| WAN links, such as routers and dedicated lines | n/a | Redundant links, to provide secondary access to remote connections |
| Dial-up connection | n/a | Multiple modems |
| Application or Service failure | n/a | Microsoft Application Center, available as a separate product, contains tools to monitor specific applications and services. |

# Determining which applications to use with Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Determining which applications to use with Network Load Balancing**

Many applications work with Network Load Balancing. This section offers guidelines for determining which applications might be suitable.

In general, Network Load Balancing can load balance any application or service that uses TCP/IP as its network protocol and is associated with a specific Transmission Control Protocol (TCP) or User Datagram Protocol (UDP) port. For more information, see Transmission Control Protocol (TCP) and User Datagram Protocol (UDP).

Some examples are:

| Protocol | Examples |
|---|---|
| HTTP over TCP/IP | Web servers, such as Microsoft Internet Information Services: Port 80. |
| HTTPS over TCP/IP | HTTP over SSL (Secure Sockets Layer), for encrypting Web traffic: Port 443. |
| FTP over TCP/IP | FTP (File Transfer Protocol): Port 20, port 21, and ports 1024-65535. |
| TFTP over TCP/IP | TFTP servers (used by such applications as BOOTP): port 69. |
| SMTP over TCP/IP | SMTP (Simple Mail Transfer Protocol), used by such applications as Microsoft Exchange: Port 25. |
| RDP over TCP/IP | RDP (Remote Datagram Protocol), used by Terminal Services: Port 3389. |

In addition, Network Load Balancing is in common use with:

- Web servers using round-robin DNS.
- Virtual private network (VPN) servers.
- Streaming media servers.
- Print Services.
- Microsoft Internet Security and Acceleration Server (ISA).

# Choosing a Network Load Balancing Model

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Choosing a Network Load Balancing model**
Network Load Balancing can be configured using one of four different models. This section describes the models, and sets forth the advantages and disadvantages of each.

- Single network adapter in unicast mode
- Multiple network adapters in unicast mode
- Single network adapter in multicast mode
- Multiple network adapters in multicast mode

# Single network adapter in unicast mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Single network adapter in unicast mode**
This model is suitable for a cluster in which ordinary network communication among cluster hosts is not required and in which there is limited dedicated traffic from outside the cluster subnet to specific cluster hosts.

**Advantages**

- Only one network adapter is required. It is not necessary to install a second adapter.
- This is the most straightforward configuration because unicast mode is the default.
- This model works with all routers.

**Disadvantages**

- Ordinary network communication among cluster hosts is not possible.
- Network Load Balancing itself does not affect network performance and a second network adapter is not a requirement. However, under certain conditions, a second adapter can improve overall network performance. For more information, see Multiple network adapters.

Regardless of the number of network adapters you use and how the adapters are configured, the cluster heartbeat traffic always originates from the network load balancing network adapter.

**Important**

- Network Load Balancing does not support a mixed unicast/multicast environment within a single cluster. Within each cluster, all network adapters in that cluster must be either multicast or unicast; otherwise, the cluster will not function properly.

  There is no restriction on the number of network adapters that can be bound to network load balancing on each computer: Different hosts can have a different number of adapters, but you can never have more than one adapter on a computer be part of the same cluster.

  Different adapters on each computer can be part of different clusters, and they can all reside on the same subnet. You can also host multiple clusters on the same network adapter. For more information, see Understanding virtual clusters.

- Before you install Network Load Balancing, it is vital that you review Checklist: Enabling and configuring Network Load Balancing, including the sections on cluster parameters, host parameters, and port rules. It is highly recommended that you read through these sections before configuring Network Load Balancing.

For more information, see also Single network adapter and Single network adapter limitations.

# Multiple network adapters in unicast mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multiple network adapters in unicast mode**
This model is suitable for a cluster in which ordinary network communication among cluster hosts is necessary or desirable. It is also appropriate when you want to separate the traffic used to manage the cluster from the traffic occurring between the cluster and client computers.

**Advantages**

- Ordinary network communication among cluster hosts is permitted.
- This model works with all routers.

**Disadvantages**

- This model requires a second network adapter.

Regardless of the number of network adapters you use and how the adapters are configured, the cluster heartbeat traffic always originates from the network load balancing network adapter.

**Important**

- Network Load Balancing does not support a mixed unicast/multicast environment within a single cluster. Within each cluster, all network adapters in that cluster must be either multicast or unicast; otherwise, the cluster will not function properly.

  There is no restriction on the number of network adapters that can be bound to network load balancing on each computer: Different hosts can have a different number of adapters, but you can never have more than one adapter on a computer be part of the same cluster.

  Different adapters on each computer can be part of different clusters, and they can all reside on the same subnet. You can also host multiple clusters on the same network adapter. For more information, see Understanding virtual clusters.

- Before you install Network Load Balancing, it is vital that you review Checklist: Enabling and configuring Network Load Balancing, including the sections on cluster parameters, host parameters, and port rules. It is highly recommended that you read through these sections before configuring Network Load Balancing.

For more information, see Multiple network adapters.

# Single network adapter in multicast mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Single network adapter in multicast mode**
This model is suitable for a cluster in which ordinary network communication among cluster hosts is necessary or desirable but in which there is limited dedicated traffic from outside the cluster subnet to specific cluster hosts.

**Advantages**

- Only one network adapter is required. It is not necessary to install a second adapter.
- This model permits ordinary network communication among cluster hosts.
- You can enable Internet Group Management Protocol (IGMP) support on the cluster hosts to control switch flooding when operating in multicast mode. For more information, see Limit switch port flooding.

**Disadvantages**

- Network Load Balancing itself does not affect network performance and a second network adapter is not a requirement. However, under certain conditions, a second adapter can improve overall network performance.
- Some routers might not support the use of a multicast media access control (MAC)address. This only affects the Network Load Balancing/MAC address (not all MAC addresses) and only when dynamic ARP replies are sent by the cluster to the router, not all MAC addresses.

In this model, the computer can also handle traffic from inside the subnet if the IP datagram does not carry the same MAC address as on the cluster adapter. For more information, see Address Resolution Protocol (ARP).

Regardless of the number of network adapters you use and how the adapters are configured, the cluster heartbeat traffic always originates from the network load balancing network adapter.

**Important**

- Network Load Balancing does not support a mixed unicast/multicast environment within a single cluster. Within each cluster, all network adapters in that cluster must be either multicast or unicast; otherwise, the cluster will not function properly.

  There is no restriction on the number of network adapters that can be bound to network load balancing on each computer: Different hosts can have a different number of adapters, but you can never have more than one adapter on a computer be part of the same cluster.

  Different adapters on each computer can be part of different clusters, and they can all reside on the same subnet. You can also host multiple clusters on the same network adapter. For more information, see Understanding virtual clusters.

- Before you install Network Load Balancing, it is vital that you review Checklist: Enabling and configuring Network Load Balancing, including the sections on cluster parameters, host parameters, and port rules. It is highly recommended that you read through these sections before configuring Network Load Balancing.

For more information, see Single network adapter, Single network adapter limitations, and Using a router in Network Load Balancing system requirements.

# Multiple network adapters in multicast mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multiple network adapters in multicast mode**
This model is suitable for a cluster in which ordinary network communication among cluster hosts is necessary and in which there is heavy dedicated traffic from outside the cluster subnet to specific cluster hosts.

**Advantages**

- Because there are at least two network adapters, overall network performance is typically enhanced.
- Ordinary network communication among cluster hosts is permitted.

**Disadvantages**

- This model requires a second network adapter.
- Some routers might not support the use of a multicast media access control (MAC)address. This only affects the Network Load Balancing/MAC address (not all MAC addresses) and only when dynamic ARP replies are sent by the cluster to the router. not all MAC addresses.

For more information, see Multiple network adapters and Using a router in Network Load Balancing system requirements.

**Important**

- Network Load Balancing does not support a mixed unicast/multicast environment within a single cluster. Within each cluster, all network adapters in that cluster must be either multicast or unicast; otherwise, the cluster will not function properly.

  There is no restriction on the number of network adapters that can be bound to network load balancing on each computer: Different hosts can have a different number of adapters, but you can never have more than one adapter on a computer be part of the same cluster.

  Different adapters on each computer can be part of different clusters, and they can all reside on the same subnet. You can also host multiple clusters on the same network adapter. For more information, see Understanding virtual clusters.

- Before you install Network Load Balancing, it is vital that you review Checklist: Enabling and configuring Network Load Balancing, including the sections on cluster parameters, host parameters, and port rules. It is highly recommended that you read through these sections before configuring Network Load Balancing.

# Capacity Planning

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Capacity planning**
This section helps you determine the number of servers you need and how they should be configured. Your planning should be based on the Network Load Balancing model you choose to implement. For more information, see Choosing a Network Load Balancing Model.

- Sizing Network Load Balancing clusters
- Determining server capacity requirements

# Sizing Network Load Balancing clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sizing Network Load Balancing clusters**

Cluster size, defined as the number of cluster hosts participating in the cluster (up to 32), is based on the number of computers required to meet the anticipated client load for a given application.

If, for example, you determine that you need six computers running Microsoft Internet Information Services to meet the anticipated client demand for Web services, then Network Load Balancing will run on all six computers, and your cluster will consist of six cluster hosts.

As a general rule, add servers until the servers can comfortably meet their demands without saturating the network. The exact number depends on the nature of the application. When the cluster subnet approaches saturation, add clusters using round-robin DNS. The maximum cluster size is determined by network capacity. The minimum cluster size is determined by server capacity. For example, if two extremely powerful servers can take the place of six less powerful servers, your entire cluster will consist of only two cluster hosts. In addition, you should always make sure that there is enough extra server capacity so that if one server fails, the server next in line will not fail, which would create a cascading series of server failures.

### Notes

- If you deploy two or more clusters, consider putting them on individual switches so that incoming cluster traffic is handled separately. For more information on using Network Load Balancing hosts on switches, see article Q238219, "How Network Load Balancing Hosts Converge When Connected to a Layer 2 Switch," and article Q193602, "Configuration Options for WLBS Hosts Connected to a Layer 2 Switch," in the Microsoft Knowledge Base.

- Before load balancing an application in a Network Load Balancing cluster, review the application license, or check with the application vendor. Each application vendor sets its own licensing policies for applications running on clusters.

# Determining server capacity requirements

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Determining server capacity requirements**

After you determine the size of your cluster, you are ready to determine how individual cluster hosts should be configured. In general, this is based on the applications being load balanced and the anticipated client demand on those applications.

Some server applications (such as file and print servers) are extremely disk intensive and require very large disk capacities and fast I/O. Some applications (such as Microsoft Exchange) are CPU intensive and require very fast processers to work at maximum efficiency. Other applications (such as Microsoft SQL Server) require large amounts of memory. You should consult the documentation for each application that you will be running to determine how the servers in your cluster should be configured.

You should also bear in mind that while it might be possible to substitute two or three very powerful servers for a larger number of less powerful computers, deploying the larger number might actually be a better approach. With more servers, the client load can be more widely distributed, so that if one or more servers fail, the impact on clients is reduced.

# Optimizing Network Load Balancing Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Optimizing Network Load Balancing clusters**

Because Windows uses an adaptable architecture, it is largely self-tuning. It is able to allocate resources as needed to meet changing usage requirements. However, you can make certain hardware and configuration choices to improve cluster performance. These choices are explained in the following sections:

- Focusing on the right hardware resources
- Optimizing the paging file size and location
- Optimizing network performance
- Using additional TCP/IP services

# Focusing on the right hardware resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Focusing on the right hardware resources**

The goal in tuning Network Load Balancing and the applications it load balances is to determine which hardware resource will experience the greatest demand, and then to adjust the configuration to relieve that demand and maximize total throughput.

For example, if the primary role of the cluster is to provide high availability of file and print services, high disk use will be incurred due to the large number of files being opened and closed. File and print services also cause a heavy load on network adapters because of the large amount of data that is being transferred. It is important to make sure that your network adapter and cluster subnet can handle the load. In this scenario, RAM typically does not carry a heavy load (although memory usage can be heavy if a large amount of RAM is allocated to a file system cache). Processor use is also typically low in this environment. In such cases, memory and processor use usually do not need the optimizing that other components need.

In contrast, a server-application environment (such as e-commerce sites running COM+ applications) is much more processor and RAM intensive than a typical file or print server environment because much more processing is taking place at the server. In these cases, it is best to use high-end multiprocessor computers. The disk and network loads tend to be used less because the amount of data being sent is smaller. Network Load Balancing uses few system resources either for host-to-host communication or for the operation of the cluster itself.

# Optimizing the paging file size and location

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Optimizing the paging file size and location**

The location and size of the paging file can greatly affect performance. Putting the paging file on a separate, fast, low-use drive can boost performance. The size setting of the paging file is also critical to performance. A paging file that must constantly expand and shrink requires additional processor and I/O overhead. Usually, you should set the size of your paging file at two or two-and-a-half times the amount of installed physical memory if applications such as Microsoft SQL Server or Microsoft Exchange Server are present. If you set the same value for the minimum and maximum size of your paging file, the amount of disk defragmentation is reduced.

# Optimizing network performance

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Optimizing network performance**

If the cluster hosts are directly connected to a hub in order to receive client requests, incoming client traffic is automatically sent to all ports.

To limit switch port flooding (for example, when computers outside the cluster also share the hub), see Limit switch port flooding. The steps outlined make all incoming client traffic flow through one switch port and thereby conserve switch bandwidth. In this configuration, you are advised to consider adding a second, dedicated network adapter for each host connected to an individual switch port. The use of two network adapters per host on the cluster subnet helps to direct network traffic through the cluster hosts. Incoming client traffic flows through the hub for simultaneous delivery to all hosts, while outgoing traffic flows directly to the switch ports. Be sure to enter a gateway IP address in the **Internet Protocol (TCP/IP) Properties** dialog box in **Network Connections** for the dedicated network adapter, to cause outgoing network traffic to flow through that network adapter. At the same time, be sure to remove the default gateway for the cluster adapter, if one has been configured. It is essential that the default gateway be configured for either the cluster adapter or the dedicated adapter but not both.

# Using additional TCP/IP services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using additional TCP/IP services**

WINS, DHCP, and DNS Services use additional server resources, which must be considered before implementing any of these services on a server also operating as a cluster host. It is highly recommended that you do not run WINS, DHCP, or DNS Services on cluster hosts. In particular, WINS can require substantial overhead during peak logon times in large networks. In such cases, make sure that your server has the necessary capacity to perform adequately.

# Using Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Network Load Balancing**
This section covers:

- Network Load Balancing Manager
- Single network adapter
- Single network adapter limitations
- Multiple network adapters
- Network Load Balancing parameters
- Virtual clusters
- Upgrading Network Load Balancing
- Adjusting multicast parameters
- Handling LAN failures
- Error detection and handling
- Event logging
- Network Load Balancing and stateful connections
- Managing Network Load Balancing from the command line

# Network Load Balancing Manager

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Load Balancing Manager**
Network Load Balancing (NLB) Manager allows you to create and manage Network Load Balancing clusters from a single computer. By centralizing Network Load Balancing administration tasks, Network Load Balancing Manager helps eliminate many common configuration errors.

Using Network Load Balancing Manager, you can configure and manage your clusters and all cluster hosts from a single computer, and you can also replicate the cluster configuration to other hosts.

You can perform the following procedures with Network Load Balancing Manager:

- Create new clusters
- Add hosts to an existing cluster and, by doing so, automatically enable Network Load Balancing on that host and and automatically configure cluster parameters on that host
- Remove hosts from a cluster and, by doing so, automatically disable Network Load Balancing on that host
- Configure all host and cluster properties
- Replicate the cluster configuration to other hosts
- Diagnose problems with existing Network Load Balancing clusters.

As part of the Windows Server 2003 Administration Tools Pack, Network Load Balancing Manager can also be installed and used on Windows XP Professional. You can use Network Load Balancing Manager on Windows XP Professional only to manage Network Load Balancing clusters on remote computers running the Windows Server 2003 family of products. You can not install the Network Load Balancing service itself on Windows XP Professional.

Network Load Balancing Manager uses Windows Management Instrumentation (WMI) which in turn has a dependency on remote procedure call (RPC) and Distributed Component Object Model (DCOM). To understand how to enable DCOM across a firewall, refer to Using Distributed COM with Firewalls .

When using Network Load Balancing Manager, you must be a member of the Administrators group on the host that you are configuring. However, you do not have to me a member of the Administrators group on the computer from which you are running Network Load Balancing Manager.

For more information on Network Load Balancing, see Network Load Balancing Clusters, and Network Load Balancing Overview.

**Important**

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

**Network Load Balancing Manager compared to other deployment and management tools**
Network Load Balancing Manager is similar to other application management tools, such as Microsoft Application Center 2000, but Network Load Balancing Manager does not completely replace these other tools. Although you can use either Network Load Balancing Manager or a similar tool to manage Network Load Balancing clusters, you can not use Network Load Balancing Manager to perform additional tasks that are often available through these other tools.

Network Load Balancing Manager is used to centrally create and manage the configuration of Network Load Balancing clusters only. It is not used to administer and deploy applications. In contrast, other management tools are designed to create, deploy, and manage large scale Web applications. These tools typically include advanced monitoring, logging, and scripting capabilities which are not included with Network Load Balancing Manager.

For example:

- Network Load Balancing Manager provides limited monitoring of the status of the Network Load Balancing hosts, but does not provide any alerts or notifications. Other management tools often provide real-time monitoring, notification and alert capabilities allowing you to view the health, performance and availability of clusters and other applications.

- Scripting is not supported in Network Load Balancing Manager but is often used by other management tools for monitoring and automating various administrative tasks.

- Network Load Balancing Manager can log general Network Load Balancing cluster information to a text-based log file, while other tools often can provide detailed logging on a variety of applications.

Network Load Balancing Manager is a tool targeted at very specific tasks related to Network Load Balancing clusters and you should not attempt to use Network Load Balancing Manager for other administrative purposes.

# Single network adapter

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Single network adapter**

Network Load Balancing can operate in two modes: unicast and multicast.

In unicast mode, the cluster's media access control (MAC) address is assigned to the computer's network adapter, and the network adapter's built-in MAC address is not used.

In multicast mode, the cluster's MAC address is assigned to the computer's network adapter, but the network adapter's built-in address is retained so that both addresses are used, the first for client-to-cluster traffic and the second for network traffic specific to the computer.

The following describes the principal characteristics of each mode when a single network adapter is used.

**Single network adapter in unicast mode**

- The adapter's own, unique MAC address is disabled.

  The cluster MAC address (which Network Load Balancing automatically generates) replaces this address.

- The adapter becomes, in effect, the cluster adapter.

- Both the dedicated IP address and the cluster IP address resolve to the cluster MAC address.

- Because all cluster hosts share the same MAC address, and because the original MAC address is not used, ordinary network communication between this host and the other cluster hosts is not possible. However, the computer can still handle traffic originating from outside the subnet in which the cluster is located, and from inside the subnet if the IP datagram does not carry the same MAC address as on the cluster adapter. For more information, see Address Resolution Protocol (ARP).

**Single network adapter in multicast mode**

- Network Load Balancing automatically generates a cluster MAC address for the network adapter.

- The adapter's own, unique MAC address is retained.

- The cluster IP address resolves to the cluster MAC address.

- The dedicated IP address resolves to the original MAC address.

**Important**

- Network Load Balancing does not support a mixed unicast/multicast environment within a single cluster. Within each cluster, all network adapters in that cluster must be either multicast or unicast; otherwise, the cluster will not function properly.

  However, there is no restriction on the number of network adapters: Different hosts can have a different number of adapters.

- To start Network Load Balancing Manager, open a Command prompt. From the command window, type **NLBMgr**, and then press ENTER.

Unicast support is enabled by default. To enable multicast support, see Enable multicast support.

If multicast support is enabled, a single network adapter can handle both client-to-cluster traffic and dedicated traffic without difficulty. However, the use of a second network adapter might improve performance by handling dedicated traffic concurrently with the original network adapter.

Multicast support, with or without multiple network adapters, has several advantages, such as eliminating the inherent limitations of a single network adapter, as described in Single network adapter limitations. Network Load Balancing handles the resolution of the cluster's primary IP address to its associated multicast cluster MAC address within the ARP on your router. In rare cases, the use of a multicast MAC address might not be supported by the ARP implementation on a given router. If this problem arises, the cluster will not be accessible from outside the local subnet. To correct this problem, you must create a static ARP entry within the router. Refer to the documentation for your router to determine how to create a static ARP entry. For more information, see Network Load Balancing system requirements.

If you disable multicast support (causing the host to revert to unicast mode), Network Load Balancing automatically instructs the driver belonging to the cluster adapter to override the adapter's unique, built-in network address and to change its MAC address to the cluster's MAC address. This is the address used on all cluster hosts. You do not need to manually configure the network adapter to recognize this address. (Note that some network adapters do not support changing their MAC addresses. If you experience this problem, you must install a network adapter that does.)

If you are using multiple network adapters, see Multiple network adapters.

# Single network adapter limitations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Single network adapter limitations**

The limitations described in this topic apply only when multicast support is not enabled.

If you do not enable multicast support, you should consider installing a dedicated network adapter to achieve optimal performance and the full range of networking functionality. Although a successful cluster can be implemented with only one network adapter and without activating multicast support, this approach has two limitations:

- Ordinary network communication among cluster hosts is not possible.
- Network traffic intended for any individual computer within the cluster generates additional networking overhead for all computers in the cluster.

Further, if you are working from a computer that has a single network adapter that is bound to Network Load Balancing in unicast mode, you can not use Network Load Balancing Manager on this computer to configure and manage other hosts.

These limitations might not be important for many installations. If the cluster hosts are accessed only from outside the cluster (because host-to-host communication cannot take place) and noncluster communications are infrequent (for example, short nightly updates of the Web server content to individual computers in the cluster), the use of a single network adapter should be sufficient. Also, it is always possible to test and demonstrate Network Load Balancing using a single network adapter prior to installing additional network adapters for operational purposes.

# Multiple network adapters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multiple network adapters**
Network Load balancing can use multiple network adapters in two different and distinct ways. The first use is to create multiple Network Load Balancing clusters; achieved by binding Network Load Balancing to each of the multiple adapters.

The second use for multiple network adapters is to use one or more adapters for handling cluster traffic, but also configure at least one adapter to be used for server management. The management adapter does not handle cluster traffic. Further information on this this second use of multiple network adapters is described below.

**Multiple network adapters in unicast mode**
In unicast mode, the cluster's media access control (MAC) address is assigned to the network adapter that is functioning as the cluster adapter, and the cluster adapter's built-in MAC address is not used. Because of this, host to host communication (other than Network Load Balancing heartbeat-related traffic) is not possible on the cluster adapter.

The following characteristics apply:

- Adapters used as cluster adapters
    - The cluster IP address resolves to the adapter's cluster MAC address (which Network Load Balancing automatically generates).
    - If the cluster adapter's dedicated IP address is used, this IP address also resolves to the cluster MAC address.
    - The cluster adapter handles client-to-cluster traffic using the virtual IP address. However host-to-host traffic within the same cluster is not possible on this adapter because the MAC address for each host in a particular cluster is the same. For more information, see Address Resolution Protocol (ARP).
- Adapter used as the management adapter
    - Network Load Balancing in not bound to this adapter.
    - This adapter's IP address resolves to the adapter's built-in MAC address.
    - This adapter handles network traffic specific to the computer, including traffic from both inside and outside the subnet in which the computer is located.

**Multiple network adapters in multicast mode**
In multicast mode, the cluster's MAC address is assigned to network adapters that are functioning as cluster adapters, but the cluster adapters' built-in address is retained so that both addresses are used, the first for client-to-cluster traffic and the second for network traffic specific to the computer.

This following characteristics apply:

- Adapters used as cluster adapters
    - The cluster IP address resolves to the adapter's cluster MAC address (which Network Load Balancing automatically generates).
    - If the cluster adapter's dedicated IP address is used, this IP address resolves to the adapter's original, built-in MAC address.
    - In multicast mode, the cluster adapters can handle both client-to-cluster traffic and traffic specific to the computer, including all traffic from both inside and outside the subnet in which the computer is located.

- Adapter used as the management adapter
    - Network Load Balancing in not bound to this adapter.
    - This adapter's IP address resolves to the adapter's built-in MAC address.
    - This adapter can be used to handle the network traffic specific to the computer, including traffic from both inside and outside the subnet in which the computer is located.

**Important**

- Network Load Balancing does not support a mixed unicast/multicast environment within a single cluster. Within each cluster, all network adapters in that cluster must be either multicast or unicast; otherwise, the cluster will not function properly.

  However, there is no restriction on the number of network adapters: Different hosts can have a different number of adapters.

Network Load Balancing handles the resolution of the cluster's IP address to its associated multicast cluster media access control address within the Address Resolution Protocol (ARP) on your router. In rare cases, the use of a multicast MAC address might not be supported by the ARP implementation on a given router. If this problem arises, the cluster will not be accessible from outside the local subnet. To correct this problem, you must create a static ARP entry within the router. Refer to the documentation for your router to determine how to create a static ARP entry. For more information, see Using a router in Network Load Balancing system requirements.

If you disable multicast support (causing the host to revert to unicast mode), Network Load Balancing automatically instructs the driver belonging to the cluster adapter to override the adapter's unique, built-in network address and to change its media access control address to the cluster's media access control address. This is the address used on all cluster hosts. You do not need to manually configure the network adapter to recognize this address. (Note that some network adapters do not support changing their media access control addresses. If you experience this problem, you must install a network adapter that does.)

**Notes**

- Multicast support is not enabled by default. To enable it, see Enable multicast support. However, even if you do not enable multicast support, you are advised to consider using at least two network adapters (with one network adapter dedicated to handling client-to-cluster traffic) in order to achieve optimum performance and the full range of networking functionality. For more information, see Optimizing network performance.
- If you are using single network adapter, see Single network adapter and Single network adapter limitations.

# Network Load Balancing parameters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Load Balancing parameters**

This topic describes the parameters that are specific to each host in a Network Load Balancing cluster and the parameters for a Network Load Balancing cluster as a whole. It also describes the parameters that control how the cluster functions. These are called port rules. Values entered for the entire cluster must be the same for all host computers in the cluster. You enter parameters in the **Network Load Balancing Properties** dialog box and they are recorded in the registry.

The parameters are contained in the following tabs on the **Network Load Balancing Properties** dialog box:

| Tab | These parameters |
|---|---|
| Cluster parameters | Apply to the entire cluster. |
| Host parameters | Apply to a specific host. |
| Port rules | Control how the cluster functions. |

**Cluster parameters**

| Parameter | Description |
|---|---|
| **IP address** on the **Cluster Parameters** tab | This parameter specifies the cluster's primary IP address in standard Internet dotted notation (for example, w.x.y.z). The address is a virtual IP address and must be set identically for all hosts in the cluster. This IP address is used to address the cluster as a whole, and it should be the IP address that maps to the full Internet name that you specify for the cluster. This should be the primary IP address and subnet mask for the cluster. If you want to add multiple IP addresses to the cluster, you enter the additional IP addresses in the TCP/IP properties dialog box or in the Cluster IP Addresses dialog box in Network Load Balancing Manager.<br><br>**Important**<br><br>• Typically, both the dedicated IP address and the cluster IP address, entered during setup in the **Network Load Balancing Properties** dialog box, must also be entered in the **Internet Protocol (TCP/IP) Properties** dialog box. Make sure that the addresses are the same in both places. However, if you are configuring a virtual private network (VPN) load balancing cluster, you should not configure the dedicated IP address. On a VPN, only the cluster IP address should be present on each of the cluster hosts. |
| **Subnet mask** on the **Cluster Parameters** tab | This parameter denotes the subnet mask for the IP address specified. The mask is entered in standard Internet dotted notation (for example, 255.255.255.0). |
| **Full Internet name** on the **Cluster Parameters** tab | This parameter specifies a full Internet name for the Network Load Balancing cluster (for example, cluster.microsoft.com). This name is used for the cluster as a whole and should be the same for all hosts in the cluster. If you alias several names for the cluster, the primary (main) name should be entered here. In any case, this name should be resolvable to the cluster's primary IP address through your DNS server or Hosts file. |

| | |
|---|---|
| **Network address** on the **Cluster Parameters** tab | This parameter specifies the network address (media access control [MAC] address) for the network adapter to be used for handling client-to-cluster traffic.<br><br>If multicast support is disabled (causing the host to revert to unicast mode), Network Load Balancing automatically instructs the driver belonging to the cluster adapter to override the adapter's unique, built-in network address and to change its MAC address to the cluster's MAC address. This is the address used on all cluster hosts. You do not need to manually configure the network adapter to recognize this address.<br><br>**Note**<br><br>• Some network adapters might not allow the built-in network address to be modified. If you experience this problem, you must obtain and install a different network adapter that supports this functionality.<br><br>If you have other Network Load Balancing clusters on one local subnet, each cluster needs to use a different network address. When you select a different primary IP address for each cluster, Network Load Balancing automatically ensures that the clusters use unique network addresses. |
| **Cluster Operation Mode** on the **Cluster Parameters** tab | These parameters specify whether or not a multicast MAC address should be used for cluster operations. If multicast is enabled, Network Load Balancing converts the cluster MAC address belonging to the cluster adapter into a multicast address. It also ensures that the cluster's primary IP address resolves to this multicast address as part of the ARP protocol. At the same time, the adapter can now use its original, built-in MAC address that, in unicast mode, was disabled.<br><br>**Note**<br><br>• If Network Load Balancing clients are accessing a cluster through a router when the cluster has been configured to operate in multicast mode, be sure that the router meets the following requirements:<br><br>  • Accepts an ARP reply that has one MAC address in the payload of the ARP structure but appears to arrive from a station with another MAC address, as identified by the Ethernet header.<br><br>  • In multicast mode, accepts an ARP reply that has a multicast MAC address in the payload of the ARP structure.<br><br>  This allows the router to map the cluster's primary IP address and other multihomed addresses to the corresponding MAC address. If your router does not meet these requirements, you can also create a static ARP entry in the router. Cisco routers require a static ARP entry because they do not support the resolution of unicast IP addresses to multicast MAC addresses.<br><br>In multicast mode, the IGMP multicast check box enables Internet Group Management Protocol (IGMP) support for limiting switch flooding by limiting traffic to "Network Load Balancing ports" only. That is, enabling IGMP support ensures that traffic intended for a Network Load Balancing cluster passes through only those ports serving the cluster hosts and not all switch ports.<br><br>**Notes**<br><br>• You must first enable multicast support before enabling IGMP support.<br><br>• You must enable IGMP support on the network adapter also.<br><br>• IGMP support is not enabled by default. To enable it, see Enable Internet Group Management Protocol (IGMP) support.<br><br>• To avoid switch flooding in multicast mode, see Limit switch port flooding.<br><br>If you do not select multicast support (causing the host to revert to unicast mode), Network Load Balancing automatically instructs the driver belonging to the cluster adapter to override the adapter's unique, built-in network address and to change its MAC address to the cluster's MAC address. This is the address used on all cluster hosts. You do not need to manually configure the network adapter to recognize this address. (Note that some network adapters do not support changing their MAC addresses. If you experience this problem, you must |

| | |
|---|---|
| | install a network adapter that does.)<br><br>**Important**<br><br>• Network Load Balancing does not support a mixed unicast/multicast environment within a single cluster. Within each cluster, all network adapters in that cluster must be either multicast or unicast; otherwise, the cluster will not function properly.<br><br>However, there is no restriction on the number of network adapters: Different hosts can have a different number of adapters.<br><br>**Note**<br><br>• Multicast support is not enabled by default. To enable it, see Enable multicast support. However, if you do not enable multicast support, you are advised to consider using at least two network adapters (with one network adapter dedicated to handling client-to-cluster traffic) in order to achieve optimum performance and the full range of networking functionality. For more information, see Multiple network adapters and Optimizing network performance. |
| **Remote Control** on the **Cluster Parameters** tab | This parameter specifies whether remote control operations are enabled. When enabled, remote, networked computers can control cluster operations by using the NLB.exe cluster-control application. Remote control is disabled by default.<br>Once remote control has been enabled, remote access can be restricted by specifying a remote control password.<br><br>Network Load Balancing remote control commands will not work correctly if they are sent from a computer that has Internet Protocol security (IPSec) configured such that the remote control traffic is encrypted by IPSec. For more information, see Internet Protocol Security (IPSec).<br><br>**Caution**<br><br>• The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. It is highly recommended that you do not enable remote control and instead use Network Load Balancing Manager or other remote management tools such as Windows Management Instrumentation (WMI).<br><br>  <br><br>If you choose to enable remote control, it is vital that you restrict access by specifying a strong remote control password. It is also imperative that you use a firewall to protect the Network Load Balancing UDP control ports (the ports that receive remote control commands) in order to shield them from outside intrusion. By default, these are ports 1717 and 2504 at the cluster IP address. Use remote control only from a secure, trusted computer within your firewall. For more information about strong passwords, see Strong passwords. |

| | |
|---|---|
| **Remote password** on the **Cluster Parameters** tab | This parameter specifies a password used for restricting access to the cluster from remote, networked computers that use the NLB.exe cluster-control application. The password consists of a string of alphanumeric characters. The password must be entered as the value of this parameter and also a second time for confirmation in the **Confirm password** parameter.<br><br>After a password has been accepted, subsequent NLB.exe remote control operations must use the **/PASSW** command-line parameter and submit the password. Clearing both fields disables use of the remote control password.<br><br>If you choose to enable remote control it is vital that you restrict access by specifying a strong remote control password. It is also imperative that you use a firewall to protect the Network Load Balancing UDP control ports (the ports receiving remote control commands) in order to shield them from outside intrusion. By default, these are ports 1717 and 2504 at the cluster IP address. For more information about strong passwords, see Strong passwords.<br><br>The remote control password is not used to restrict control operations from a cluster host. |
| **Confirm password** on the **Cluster Parameters** tab | This parameter specifies the password entered in the **Remote password** field. It is used to confirm proper entry of this password. Clearing both fields disables use of a remote control password. |

**Host parameters**

| Parameter | Description |
|---|---|
| **Interface** on the **Host Parameters** tab | This parameter only appears when using Network Load Balancing Manager and is configured when you add the host to the cluster. The parameter specifies the host's network adapter that will use network load balancing in context of the current cluster. |
| **Priority (Unique host ID)** on the **Host Parameters** tab | This parameter specifies a unique ID for each host.<br><br>The host with the lowest numerical priority among the current members of the cluster handles all of the cluster's network traffic that is not covered by a port rule. You can override these priorities or provide load balancing for specific ranges of ports by specifying rules in the **Port rules** tab of the **Network Load Balancing Properties** dialog box.<br><br>If a new host joins the cluster and its priority conflicts with another host in the cluster, the host is not accepted as part of the cluster. The rest of the cluster will continue to handle the traffic as before. A message describing the problem is written to the Windows event log. For more information on error logging and cluster operations, see How Network Load Balancing works, Event logging, and Error detection and handling. |

| | |
|---|---|
| **IP address** on the **Host Parameters** tab | This parameter specifies this host's unique IP address used for network traffic not associated with the cluster (for example, Telnet access to a specific host within the cluster). It should be entered in standard Internet dotted notation (for example, w.x.y.z). This IP address is used to individually address each host in the cluster and hence should be unique for each host. The dedicated IP address should always be entered first in TCP/IP properties.<br><br>Network Load Balancing references the dedicated IP address only when a single network adapter is used to handle both client-to-cluster traffic and other network traffic that must go specifically to the dedicated IP address. Network Load Balancing ensures that all traffic to the dedicated IP address is unaffected by the Network Load Balancing current configuration, including:<br><br>• When this host is running as part of the cluster<br><br>• When Network Load Balancing is disabled due to parameter errors in the registry<br><br>**Important**<br><br>• Typically, both the dedicated IP address and the cluster IP address, entered during setup in the **Network Load Balancing Properties** dialog box, must also be entered in the **Internet Protocol (TCP/IP) Properties** dialog box. Make sure that the addresses are the same in both places. However, if you are configuring a virtual private network (VPN) load balancing cluster, you should not configure the dedicated IP address. On a VPN, only the cluster IP address should be present on each of the cluster hosts.<br><br>• The dedicated IP address must be a static IP address. It cannot be a DHCP address. |
| **Subnet mask** on the **Host Parameters** tab | This parameter denotes the subnet mask for the IP address specified. The mask is entered in standard Internet dotted notation (for example, 255.255.255.0). |
| **Initial host state** on the **Host Parameters** tab | This parameter specifies whether Network Load Balancing will start and whether the host will immediately join the cluster when the operating system is started. For example, you might want to start other services manually and in a specific order before starting Network Load Balancing. Hosts can be commanded to join and leave the cluster dynamically by using the **start** and **stop** commands in Network Load Balancing command-line control. If the **Retain suspended state after computer starts** check box is selected, when the host is shut down while in a suspended state, the host will remain suspended when Windows is started.<br><br>For more information on command-line control, see Managing Network Load Balancing from the command line. |

**Port rules**

To maximize control of various types of TCP/IP traffic, you can set up port rules to control how each port's cluster network traffic is handled. The method by which a port's network traffic is handled is called its filtering mode. There are three possible filtering modes: **Multiple hosts**, **Single host**, and **Disabled**.

You can also specify that a filtering mode apply to a numerical range of ports. You do this by defining a port rule with a set of configuration parameters that define the filtering mode. Each rule consists of the following configuration parameters:

- The virtual IP address that the rule should be applied.
- The TCP or UDP port range for which this rule should be applied.
- The protocols for which this rule should apply, including TCP, UDP, or both.
- The filtering mode that specifies how the cluster handles traffic described by the port range and protocols.

In addition, you can select one of three options for client affinity: None, Single, and Class C. Single and Class C are used to ensure that all network traffic from a particular client be directed to the same cluster host. In order to allow Network Load Balancing to properly handle IP fragments, you should avoid using **None** when selecting **UDP** or **Both** for your protocol setting.

**Important**

- The number and type of rules must be exactly the same for each host in the cluster.
- You cannot add more than 32 port rules to a Network Load Balancing cluster.
- If a host attempts to join the cluster with a different number of rules from the other hosts, it is not accepted as part of the cluster and the rest of the cluster continues to handle the traffic as before. At the same time, a message is entered into the Windows event log. When this happens, consult the event log to determine which host has a conflicting number of rules, resolve the conflict, and restart Network Load Balancing on this host.
- The rules entered on each host in the cluster must have matching cluster IP addresses, port ranges, protocol types, and filtering modes.

  If Network Load Balancing detects an inconsistent rule among the hosts in the cluster, it records a message in the Windows event log. When this happens, consult the event log to determine the host in question and which rule is responsible for the problem, fix it, and restart Network Load Balancing on this host.

  For more information on error logging and cluster operations, see Error detection and handling and Event logging.
- When using Network Load Balancing to load balance VPN traffic such as PPTP/GRE and IPSEC/L2TP, you must configure the port rules that govern the ports handling the VPN traffic (TCP port 1723 for PPTP and UDP port 500 for IPSEC) to use either Single or Class C affinity.

**Note**

- By default, all cluster network traffic not governed by port rules is handled by the host with the highest host priority among the current members of the cluster. This single host handles all of the cluster network traffic, with another host taking over the traffic in the event that the highest priority host fails or goes offline. This default behavior ensures that Network Load Balancing does not affect cluster network traffic for ports that you do not specifically manage with the Network Load Balancing load-balancing mechanisms. It also provides high availability in the handling of your cluster network traffic.

The **Port Rules** tab shows only the summary of existing port rules. If you click **Add** or **Edit**, the following parameters will be available:

| Parameter | Description |
|---|---|
| **Cluster IP address** on the **Add/Edit Port Rules** dialog box | This parameter specifies the cluster IP address that the port rule should cover. If this parameter is left blank and **All** is selected instead, the port rule is a global port rule and will cover all cluster IP addresses associated with that particular Network Load Balancing cluster.<br>**Note**<br>• If a cluster IP address is specified, the port rule overrides any conflicting global port rule for that particular cluster IP address. |
| **Port range** on the **Add/Edit Port Rules** dialog box | This parameter specifies the TCP/UDP port range that a port rule should cover. Port numbers in a range of 0 to 65,535 are currently supported. The default port range is 0 to 65,535.<br>**Note**<br>• Rules for a single port are encoded as a range having the same starting and ending port numbers. |

| | |
|---|---|
| **Protocols** on the **Add/Edit Port Rules** dialog box | This parameter lets you choose the specific TCP/IP protocol that a port rule should cover: TCP, UDP, or both. Only the network traffic for the specified protocol is affected by the rule. Traffic not affected by the port rule is handled by the default host. |
| **Filtering mode** on the **Add/Edit Port Rules** dialog box | • **Multiple hosts.** This parameter specifies that multiple hosts in the cluster handle network traffic for the associated port rule. This filtering mode provides scaled performance in addition to fault tolerance by distributing the network load among multiple hosts. You can specify that the load be equally distributed among the hosts or that each host handle a specified load weight.<br><br>• **Single host.** This parameter specifies that network traffic for the associated port rule be handled by a single host in the cluster according to the specified handling priority. This filtering mode provides port specific fault tolerance for the handling of network traffic.<br><br>• **Disable this port range.** This parameter specifies that all network traffic for the associated port rule be blocked. In this case, the Network Load Balancing driver filters all corresponding network packets or datagrams. This filtering mode lets you block network traffic addressed to a specific range of ports. |

| | |
|---|---|
| **Affinity** on the **Add/Edit Port Rules** dialog box | This parameter is applicable only for Multiple host filtering mode.<br><br>• The **None** option specifies that multiple connections from the same client IP address can be handled by different cluster hosts (no client affinity). In order to allow Network Load Balancing to properly handle IP fragments, you should avoid using **None** when selecting **UDP** or **Both** for your protocol setting.<br><br>• The **Single** option specifies that Network Load Balancing should direct multiple requests from the same client IP address to the same cluster host. This is the default setting for affinity.<br><br>You can optionally modify Network Load Balancing client affinity to direct all client requests from a TCP/IP Class C address range (instead of a single IP address) to a single cluster host by enabling the **Class C** option instead of the **Single** option. This feature ensures that clients that use multiple proxy servers to access the cluster can have their TCP connections directed to the same cluster host. The use of multiple proxy servers at the client's site causes requests from a single client to appear to originate from different computers. Assuming that all of the client's proxy servers are located within the same Class C address range, enabling the **Class C** option ensures that client sessions are properly handled. If you do not need this capability, use the **Single** option instead to maximize scaled performance when using client affinity.<br><br>• **Class C** affinity specifies that Network Load Balancing direct multiple requests from the same TCP/IP Class C address range to the same cluster host.<br><br>Enabling **Class C** affinity instead of **Single** affinity ensures that clients that use multiple proxy servers to access the cluster have their TCP connections directed to the same cluster host. The use of multiple proxy servers at the client's site causes requests from a single client to appear to originate from different computers. Assuming that all of the client's proxy servers are located within the same Class C address range, **Class C** affinity ensures that client sessions are properly handled. If you do not need this capability, use **Single** affinity instead to maximize scaled performance.<br><br>Enabling either **Single** or **Class C** affinity ensures that only one cluster host handles all connections that are part of the same client session. This is important if the server application running on the cluster host maintains session state (such as "server cookies") between connections.<br><br>At the same time, it is important to realize that this does not preserve session state with back-end databases in which many different transactions are occurring involving many different computers. Once the connection is ended, session state also ends.<br><br>Disabling affinity allows for improved load balancing because it allows multiple connections from the same client to be handled concurrently by different cluster hosts. To maximize scaled performance, disable client affinity (using the **None** option) when it is not needed. However, in order to allow Network Load Balancing to properly handle IP fragments, you should avoid using **None** when selecting **UDP** or **Both** for your protocol setting.<br><br>**Important**<br><br>• When using Network Load Balancing to load balance VPN traffic such as PPTP/GRE and IPSEC/L2TP, you must configure the port rules that govern the ports handling the VPN traffic (TCP port 1723 for PPTP and UDP port 500 for IPSEC) to use either Single or Class C affinity. |

| | |
|---|---|
| **Load Weight** on the **Add/Edit Port Rules** dialog box | This parameter is applicable only for Multiple host filtering mode. You can configure this parameter only when you open the port rules dialog box through **Host Properties**. This parameter is not configurable when you open the port rules dialog box through **Cluster Properties**.<br><br>When using Multiple hosts filtering mode, this parameter specifies the relative amount of load-balanced network traffic that this host should handle for the associated port rule. Allowed values range from 0 (zero) to 100. To prevent a host from handling any network traffic, set the load weight to 0 (zero).<br><br>The actual fraction of traffic handled by each host is computed as the local load weight divided by the sum of all load weights across the cluster.<br><br>You can specify different load weights for each host in the cluster by using the **Load weight** parameter. You can specify that all hosts distribute the network load equally by using the Equal load distribution parameter instead of the **Load weight** parameter. |
| **Handling priority** on the **Add/Edit Port Rules** dialog box | This parameter is applicable only for Single host filtering mode. You can configure this parameter only when you open the port rules dialog box through **Host Properties**. This parameter is not available when you open the port rules dialog box through **Cluster Properties**<br><br>When Single host filtering mode is being used, this parameter specifies the local host's priority for handling the networking traffic for the associated port rule. The host with the highest handling priority (lowest numerical value) for this rule among the current members of the cluster will handle all of the traffic for this rule. The allowed values range from 1, the highest priority, to the maximum number of hosts allowed (32). This value must be unique for all hosts in the cluster.<br><br>Although this parameter is displayed in the **Defined port rules** list, you configure this parameter on the **Host Parameters** tab. |

**Notes**

- The parameters set in the **Network Load Balancing Properties** dialog box are recorded in the registry.
- Changes to Network Load Balancing parameters are applied when you click **OK** in the **Network Load Balancing Properties** dialog box. Clicking **OK** stops Network Load Balancing (if it is running), reloads the parameters, and then restarts cluster operations.
- WLBS stands for Windows NT Load Balancing Service, the former name of Network Load Balancing in Windows NT 4.0. For reasons of backward compatibility, WLBS continues to be used in certain instances.

# Virtual clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual clusters**

You create a virtual cluster by configuring multiple virtual IP addresses (where each IP address typically corresponds to different Web sites or applications hosted on the cluster) on a single network adapter and then configuring different port rules for each virtual IP address. In this way, on each host you are able to have IP address-specific:

- Port Range
- Protocols
- Affinity
- Load weight
- Filtering mode

By using a load weight of zero for specific virtual IP addresses, you can also define a virtual cluster that limits applications, Web sites, or virtual IP addresses to a specific subset of hosts within your Network Load Balancing (NLB) cluster. See the diagram below for an example of this use of virtual clusters.

| IP Address | Load Weights | | | |
|---|---|---|---|---|
| xxx.xxx.xxx.1 (Web site A) | 25 | 25 | 25 | 25 |
| xxx.xxx.xxx.2 (Web site B) | 50 | 50 | 0 | 0 |
| xxx.xxx.xxx.3 (Web site C) | 0 | 0 | 50 | 50 |

This diagram depicts a four host Network Load Balancing cluster. Through the use of virtual clusters defined by IP address-specific load weights, Network Load Balancing directs network traffic as follows:

- Users accessing Web Site A (IP address *nnn.nnn.nnn*.1) are directed to any of the four hosts
- Users accessing Web site B (IP address *nnn.nnn.nnn*.2), which is a virtual cluster, are directed to hosts 1 and 2
- Users accessing Web site C (IP address *nnn.nnn.nnn*.3), which is a virtual cluster, are directed to hosts 3 and 4

This is accomplished by setting the load weights as follows:

- Load weight = 0 on hosts 3 and 4 for IP address xxx.xxx.xxx.2
- Load weight = 0 on hosts 1 and 2 for IP address xxx.xxx.xxx.3.

Be aware that to use virtual clusters, all hosts in the cluster must be running one of the Windows Server 2003 family of products.

For more information on creating port rules, see Create a new port rule.

# Upgrading Network Load Balancing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrading Network Load Balancing**
Individual computers participating in a Network Load Balancing cluster can be dynamically upgraded to a newer version of Network Load Balancing without interrupting service on the cluster as a whole.

To upgrade a cluster host, simply upgrade the computer to the current version of Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition. All settings are retained. It is therefore not necessary to reconfigure Network Load Balancing parameters after you upgrade. In addition, the host automatically rejoins the cluster when the upgrade is complete.

Network Load Balancing clusters can function successfully in a mixed environment of hosts running either Network Load Balancing for the Windows server 2003 family of products or Windows 2000, Windows NT Load Balancing Service (WLBS) for Windows NT 4.0, or Convoy Cluster Software for Windows NT 4.0. After upgrading to Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition, you should run your cluster in a mixed environment for a period of time to ensure your cluster continues to operate as expected on your upgraded hosts. However, you will not be able to use the new Network Load Balancing features, such as virtual clusters, until all of your hosts are upgraded.

**Note**

- Windows NT Load Balancing Service (WLBS) is the former name of Network Load Balancing in Windows NT 4.0. Convoy Cluster Software is the former name of WLBS.

# Adjusting multicast parameters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Adjusting multicast parameters**

Network Load Balancing uses one of two methods to enable the cluster adapters on all cluster hosts to simultaneously receive network traffic for the cluster's IP addresses:

- When multicast support is enabled in the **Network Load Balancing Properties** dialog box, Network Load Balancing adds a multicast media access control (MAC) address to the cluster adapters on all cluster hosts. At the same time, the cluster adapters retain their original MAC addresses.

- When multicast support is disabled in the **Network Load Balancing Properties** dialog box (causing the host to revert to unicast mode), Network Load Balancing instructs the driver belonging to the cluster adapter to change the adapter's MAC address to the cluster MAC address. This is the same address used on all cluster hosts. (Note that some network adapters do not support changing their MAC addresses.) When this occurs, the cluster adapters are no longer addressable by their original MAC addresses.

**Advantages of using multicast support**

Multicast support has several advantages, such as removing the inherent limitations of a single network adapter, as explained in Single network adapter limitations. Network Load Balancing handles the resolution of the cluster's IP address to its associated multicast cluster MAC address used in ARP on your router. Note that in rare cases the use of a multicast MAC address might not be supported by the ARP implementation on a given router. If this problem arises, the cluster will not be accessible from outside the local subnet. To correct this problem, you must create a static ARP entry within the router. To determine how to create a static ARP entry, see the documentation for your router. For more information, see Using a router in Network Load Balancing system requirements.

**Avoiding switch port flooding**

Some network adapter drivers experience increased CPU load percentages (by 5 percent or more depending on network traffic) when handling multicast MAC addresses instead of unicast addresses. If your cluster hosts have unusually high CPU load percentages when using Network Load Balancing multicast support, disable this feature to see if it is the source of the problem. If switch flooding occurs, that is, your non-cluster hosts receive traffic destined only for the cluster hosts, then you can enable Internet Group Management Protocol (IGMP) support. For more information on avoiding switch port flooding, see Limit switch port flooding. For more information on enabling IGMP support, see Enable Internet Group Management Protocol (IGMP) support.

### Notes

- Multicast support is not enabled by default. To enable it, see Enable multicast support.

- When Network Load Balancing is enabled for use with a network adapter in multicast mode, a manually configured MAC address that may have been optionally assigned to the adapter will be removed after Network Load Balancing is later disabled. When the adapter is subsequently reinitialized (typically when the computer is restarted), the network adapter will revert to its factory-assigned MAC address. To avoid this problem, be sure to reassign the adapter's manually configured MAC address after disabling Network Load Balancing. For more information, see Remove a host from a Network Load Balancing cluster.

# Handling LAN failures

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Handling LAN failures**

If a Network Load Balancing cluster is split into multiple subnets that cannot communicate with each other, each part will reconverge as an individual cluster ready to handle all of the traffic for the cluster IP address. (This problem is distinct from a networking failure in which a single host goes offline. In that case, the host just leaves the cluster.)

If multiple subnets with clusters remain active (continue to handle incoming requests), a conflict arises when the networking failure is corrected and the cluster rejoins. In this case, some outstanding connections might have to be closed in order to establish a consistent state for the rejoined cluster. This situation occurs infrequently. It is far more probable that only one subnet will have access to the Internet, in which case no conflict arises because the other subnets do not provide service during the network outage.

# Error detection and handling

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Error detection and handling**

Network Load Balancing error-handling mechanisms are designed to minimize the possibility of disrupting the cluster's service to client requests, while allowing the cluster's parameters and member hosts to be dynamically changed. For example, you can add hosts to the cluster, remove them for maintenance, add port rules, and modify rule Network Load Balancing parameters, all without interrupting service.

The Network Load Balancing driver checks its configuration parameters entered in the **Network Load Balancing Properties** dialog box for consistency and validity. Network Load Balancing will not start cluster operations if a problem, such as an invalid IP address, is detected. All detected errors are reported in the Windows event log. For more information, see Event logging.

When a local host joins the cluster, it exchanges its primary parameter values, such as its host priority and port rules, with the other hosts in the cluster. If an inconsistency is detected among the hosts, Network Load Balancing recovers from the error according to the type of inconsistency detected, as follows:

| Inconsistency | Network Load Balancing recovery method |
|---|---|
| Duplicate host priorities | The host joining the cluster handles no traffic until convergence is complete. The cluster does not converge to a consistent state until duplicate hosts are no longer detected. |
| Different number of port rules | The host joining the cluster handles no traffic until convergence is complete. The cluster does not converge to a consistent state until all hosts have the same number of rules. |
| Inconsistent port rule | The host joining the cluster handles no traffic until convergence is complete. The cluster does not converge to a consistent state until the rule is consistent across all hosts in the cluster. |

If inconsistencies are discovered when a host attempts to join the cluster, the host should be taken out of the cluster using the **nlb.exe stop** command. Locate and correct the problem using the **Network Load Balancing Properties** dialog box on each host prior to returning the host to the cluster using the **nlb.exe start** command.

You can add port rules or update parameters by taking each host out of the cluster in turn, updating its parameters, and then returning it to the cluster. During this process, other cluster hosts detects inconsistencies in the rules and handles them as described previously. This permits the cluster to maintain service for client requests while the changes are made. For example, if a rule is added, it does not take effect until all hosts have been updated and have rejoined the cluster. If a rule is modified, the rule is not used until it is made consistent on all hosts.

**Note**

- WLBS stands for Windows NT Load Balancing Service, the former name of Network Load Balancing in Windows NT 4.0. For reasons of backward compatibility, WLBS continues to be used in certain instances.

# Event logging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Event logging**

Network Load Balancing uses Windows event logging to record information about important events. You can view the event log using Event Viewer.

Network Load Balancing classifies logged events into the following categories:

| Event category | Description |
|---|---|
| Information events | Records normal state transitions, such as driver startup, the completion of convergence, and the completion of cluster-control actions. These events are recorded for informational purposes only. |
| Warning events | Records abnormal occurrences that do not impede cluster operations. These events can indicate a configuration problem, such as an invalid dedicated IP address or other parameter. They can also indicate a temporary condition, such as limited driver resources. Cluster operations are not disrupted when warning events occur, and are not considered errors. |
| Error events | Records major problems or errors that might require immediate attention, such as significant cluster configuration parameter problems, detected inconsistencies, or unexpected execution errors. Error events usually disrupt cluster operations and might require individual hosts to be stopped and reconfigured. Note that errors can occur under normal operations when you update the cluster by adding or modifying port rules. For more information, see Error detection and handling. |

Event log records provide crucial information when you are analyzing and solving problems. Use the **nlb.exe display** command to display the most recent event log records produced by Network Load Balancing. This information should be copied into the text of any e-mail message sent to Microsoft requesting technical support. For more information, see Nlb.

**Network Load Balancing Manager logging**

Network Load Balancing Manager does not use Windows event logging and therefore you can not use Event Viewer to review messages from Network Load Balancing Manager. You instead must explicitly enable Network Load Balancing Manager logging and define a specific log file. Enable Network Load Balancing Manager logging by clicking **Log Settings** in the Network Load Balancing Manager **Options** menu. Check the **Enable logging** box and specify a name and location for the log file.

You should always manage a Network Load Balancing cluster from a trusted and secure computer, particularly when logging is enabled. The Network Load Balancing Manager log file contains potentially sensitive information about the Network Load Balancing cluster and hosts, so it must be properly secured. By default, the log file inherits the security settings of the directory in which it is created, so you might have to change the explicit permissions on the file to restrict read and write access to those individuals who don't need full control of the file. Be aware that the individual using Network Load Balancing Manager does require full control of the log file. For more information, see Access Control How To....

### Notes

- WLBS stands for Windows NT Load Balancing Service, the former name of Network Load Balancing in Windows NT 4.0. For reasons of backward compatibility, WLBS continues to be used in certain instances.

- For information on how to interpret messages, refer to the Microsoft Windows Resource Kits Web site.

# Network Load Balancing and stateful connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Load Balancing and stateful connections**

Application servers maintain two kinds of stateful connections:

- Interclient state: A state whose updates must be synchronized with transactions performed for other clients, such as merchandise inventory at an e-commerce site.
- Intraclient state: A state that must be maintained for a given client throughout a session (that can span multiple connections), such as a shopping cart process at an e-commerce site.

Network Load Balancing should not be used to scale applications that directly update interclient state, such as Microsoft SQL Server, because these applications generally were not designed to permit multiple instances to simultaneously access a shared database and synchronize updates. Instead, Network Load Balancing should be used to scale stateless front-end services, such as Microsoft Internet Information Services, that might access a shared back-end database server.

However, Network Load Balancing can be used to scale applications that manage intraclient state within a session that spans multiple connections. When client affinity is enabled, Network Load Balancing directs all TCP connections to the same cluster host. This allows session state to be maintained in host memory. Client/server applications that embed state within cookies or push it to a back-end database do not need client affinity to be maintained.

# Managing Network Load Balancing from the command line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing Network Load Balancing from the command line**

After you have installed and configured Network Load Balancing, you can control its operations and modify parameter settings using the Network Load Balancing control application, Wlbs.exe, that is installed in the *systemroot*\System32 folder. To simplify and centralize system administration, you can run Nlb.exe either on the cluster hosts or on any remote computer that can access the cluster over a local or wide area network. Certain actions, such as modifying parameters, can be performed only on the cluster hosts. Because it is a shell-based application, this application can be incorporated into administrative scripts.

The command line for Nlb.exe has the following syntax:

**Nlb** *command* [*cluster*[**:***host*] [*remote options*] ]

For more information on the Network Load Balancing control application, see Nlb. For information about using Network Load Balancing Manager from the command line, see Nlbmgr. For information about other command-line utilities, see Command-line reference A-Z. For more information about manageability, see Management Strategies and Tools.

**Controlling remote access**

You can help protect the cluster from unauthorized access by remote computers by using a strong remote control password. The password is assigned in the **Network Load Balancing Properties** dialog box for each cluster host to be protected. When password protection is enabled, remote invocations of Nlb.exe must include the **/PASSW** option followed by the password. If no password value is entered on the command line, the shell displays a prompt for a password.

**Caution**

- The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. It is highly recommended that you do not enable remote control and instead use Network Load Balancing Manager or other remote management tools such as Windows Management Instrumentation (WMI).

If you choose to enable remote control, it is vital that you restrict access by specifying a strong remote control password. It is also imperative that you use a firewall to protect the Network Load Balancing UDP control ports (the ports that receive remote control commands) in order to shield them from outside intrusion. By default, these are ports 1717 and 2504 at the cluster IP address. Use remote control only from a secure, trusted computer within your firewall. For more information on the remote control parameter, see Remote control in Network Load Balancing parameters. For more information about strong passwords, see Strong passwords.

**Note**

- WLBS stands for Windows NT Load Balancing Service, the former name of Network Load Balancing in Windows NT 4.0. For reasons of backward compatibility, WLBS continues to be used in certain instances.

# Network Load Balancing Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

The following links point to information that might help you better understand Network Load Balancing within the overall context of Windows Clustering.

- For information on the solutions that make up Windows Clustering, refer to Windows Clustering.
- For information on Server clusters, refer to Server clusters overview and the Microsoft Windows Resource Kits Web site.
- For information on server clusters and how they work with Network Load Balancing clusters, refer to Updated technical information.
- For a detailed description of how a business has used Network Load Balancing clusters and server clusters to improve performance and availability of their Web site and other services, refer to the scenario at the Microsoft Web site.

Maximizing the uptime of server systems requires careful attention to planning, design, and operations. For more information about monitoring recommendations for high-availability systems, see the "System Performance and Troubleshooting Guide" at the Microsoft Windows Resource Kits Web site. For more information about maximizing the availability of a Network Load Balancing cluster, see the "Server Management Guide" at the Microsoft Windows Resource Kits Web site and "High availability with clustering and NLB" at the Microsoft Windows Resource Kits Web site.

Microsoft maintains up-to-date product documentation at the Microsoft Web site . This site has information that is more current than the Help documentation on your product CD.

Microsoft Product Support Services provides a searchable database of technical support information for Microsoft products. You can search here for general information about Network Load Balancing or for information related to other Microsoft products. You can get to the Microsoft Product Support Services Web site by clicking the appropriate link in Support resources.

For information about unattended setup, refer to Planning for unattended Setup.

# Network Load Balancing Troubleshooting

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2012

**Troubleshooting**
What problem are you having?

- After installing Network Load Balancing and restarting a cluster host, a message appears: "The system has detected an IP address conflict with another system on the network..."
- There is no response when using ping to access the cluster's IP address from an outside network.
- There is no response when using ping to access a host's dedicated IP addresses from another cluster host.
- When attempting to use Network Load Balancing Manager to connect to a host in your cluster, you receive the error "Host unreachable".
- When using Telnet or attempting to browse a computer outside the cluster from a cluster host, there is no response.
- When invoking the Network Load Balancing remote control commands from a computer outside the cluster, there is no response from one or more cluster hosts.
- When using the dedicated IP address of a host to specify it as a target for a remote control command, there is no reply. However, specifying the host by its priority (ID) works.
- Connectivity to the cluster is denied to some, but not all users.
- You cannot view or change the Network Load Balancing properties using net config and Windows Management Instrumentation (WMI).
- An unusual number of TCP connections to the cluster's IP address are being reset by either the server or the client.
- Virtual Private Network (VPN) calls fail when you make a change that causes convergence (such as adding a host, removing a host, or draining a host).
- After the cluster hosts start, they begin converging but never complete convergence.
- The cluster moves in and out of a converged state.
- After the cluster hosts start, Network Load Balancing reports that convergence has finished, but more than one host is a default host.
- Network Load Balancing is not load balancing applications, and the default host handles all network traffic.
- Traffic alternates unexpectedly between the cluster hosts breaking TCP connections.
- Network traffic does not appear to load balance evenly among the cluster hosts.
- When you are using Network Load Balancing with Microsoft Internet Security and Acceleration (ISA) Server, one cluster host might log blocked packets that are directed to the dedicated Internet Protocol (IP) address of another host.
- You are unable to create a Network Load Balancing cluster in a 64-bit environment.

**After installing Network Load Balancing and restarting a cluster host, a message appears: "The system has detected an IP address conflict with another system on the network..."**

**Possible Cause**

The same IP address exists somewhere else on the network.

**Solution**

Choose a new IP address, or remove the duplicate address.

**Possible Cause**

You have configured different cluster operation modes (Unicast and Multicast) on the hosts causing two different MAC addresses to map to the same IP address.

**Solution**

Ensure that all hosts are configured with the same cluster operation mode. For more information see Enable Network Load Balancing.

**Possible Cause**

You configured the cluster's IP address before Network Load Balancing was bound to the network adapter.

**Solution**

Remove the cluster's IP address from TCP/IP properties, enable Network Load Balancing on the proper adapter as described in Enable Network Load Balancing and then configure the cluster's IP address.

**Possible Cause**

You added the cluster's IP address to a network adapter that has not been enabled for Network Load Balancing.

**Solution**

Remove the cluster's IP address from incorrect adapter's TCP/IP properties, enable Network Load Balancing on the proper adapter as described in Enable Network Load Balancing and then configure the cluster's IP address.

**Possible Cause**

You added the cluster's IP address in the TCP/IP dialog box, but you did not add the IP address correctly using the Network Load Balancing dialog box.

**Solution**

If you do not use Network Load Balancing Manager to configure your cluster, you must manually configure TCP/IP with the cluster's IP address. For more information, see Set up TCP/IP for Network Load Balancing.

**There is no response when using ping to access the cluster's IP address from an outside network.**

Verify that you can use **ping** to access the dedicated IP addresses for the cluster hosts from a computer outside the router. If this test fails and you are using multiple network adapters, the problem is unrelated to Network Load Balancing. If you are using a single network adapter for both the dedicated and cluster IP addresses, consider the following causes:

**Possible Cause**

You did not add the cluster's IP address correctly in the TCP/IP properties.

**Solution**

If you do not use Network Load Balancing Manager to configure your cluster, you must manually configure TCP/IP with the cluster's IP address. For more information, see Set up TCP/IP for Network Load Balancing

**Possible Cause**

If you are using multicast support, you might find that your router has difficulty resolving the primary IP address into a multicast media access control (MAC) address using the ARP protocol.

**Solution**

To check this, verify that you can use **ping** to access the cluster from a client on the cluster's subnet and to access the cluster

hosts' dedicated IP addresses from a computer outside the router. If these tests work properly, the router is probably at fault. You should be able to add a static ARP entry to the router to circumvent the problem. You can also turn off Network Load Balancing multicast support and use a unicast network address without a hub.

**Possible Cause**

When using Network Load Balancing in either multicast or unicast mode, routers need to be able to accept proxy ARP responses (IP-to-network address mappings that are received with a different network source address in the Ethernet frame).

**Solution**

Make sure that your router has proxy ARP support turned on. You can also set a static ARP entry to keep proxy ARP support disabled in the router.

**Possible Cause**

Internet control message protocol (ICMP) to the cluster is blocked by a router or firewall.

**Solution**

Allow ICMP traffic through the firewall or router. Be aware that this may expose your system to additional security risk.

**There is no response when using ping to access a host's dedicated IP addresses from another cluster host.**
**Possible Cause**

You did not add the host's dedicated IP addresses correctly in TCP/IP properties.

**Solution**

You must manually configure TCP/IP with the host's dedicated IP address. For more information, see Set up TCP/IP for Network Load Balancing

**Possible Cause**

When using Network Load Balancing in either multicast or unicast mode, routers need to be able to accept proxy ARP responses (IP-to-network address mappings that are received with a different network source address in the Ethernet frame).

**Solution**

Make sure that your router has proxy ARP support turned on. You can also set a static ARP entry to keep proxy ARP support disabled in the router.

**Possible Cause**

Internet control message protocol (ICMP) to the cluster is blocked by a router or firewall.

**Solution**

Allow ICMP traffic through the firewall or router. Be aware that this may expose your system to additional security risk.

**When attempting to use Network Load Balancing Manager to connect to a host in your cluster, you receive the error "Host unreachable".**
**Cause:** Internet control message protocol (ICMP) to the host is either blocked by a router or firewall, or disabled on the host's network adapter.

**Solution:** Enable ICMP on the host's network adapter or allow ICMP traffic through the firewall or router. Be aware that this may expose your system to additional security risk. You can also use Network Load Balancing Manager's **/noping** option. For more information, see Nlbmgr.

**When using Telnet or attempting to browse a computer outside the cluster from a cluster host, there is no response.**
**Cause:** Verify that you can use **ping** to access the computer outside the cluster. If this test is successful you might not have listed the host's dedicated IP address first in the TCP/IP properties.

**Solution:** When you must manually configure TCP/IP with the host's dedicated IP addresses and the cluster's IP address, the dedicated IP addresses must be listed first. For more information, see Set up TCP/IP for Network Load Balancing.

If ping fails to access the computer outside of the cluster refer to the problems labeled "There is no response when using **ping** to access the cluster's IP address from an outside network" and "There is no response when using **ping** to access a host's dedicated IP addresses from another cluster host" described earlier in this troubleshooting information.

**When invoking the Network Load Balancing remote control commands from a computer outside the cluster, there is no response from one or more cluster hosts.**

**Possible Cause**

Remote control commands are not being sent to the cluster's IP address. Commands must be sent to the cluster's primary IP address that was assigned in the **Network Load Balancing Properties** dialog box.

**Solution**

Be sure that you send remote commands to the correct IP address.

**Possible Cause**

The remote control traffic is being encrypted by Internet Protocol security (IPSec). Network Load Balancing remote control commands will not work correctly if they are sent from a computer that has IPSec configured such that the remote control traffic is encrypted by IPSec.

**Solution**

Disable IPSec.

For more information, see Internet Protocol Security (IPSec).

**Possible Cause**

Remote control is not enabled.

**Solution**

Enable remote control in the **Network Load Balancing Properties** dialog box.

For more information, see Configure cluster parameters.

**Caution**

- The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service and information disclosure. It is highly recommended that you do not enable remote control and instead use Network Load Balancing Manager or other remote management tools such as Windows Management Instrumentation (WMI).

If you choose to enable remote control, it is vital that you restrict access by specifying a strong remote control password. It is also imperative that you use a firewall to protect the Network Load Balancing UDP control ports (the ports receiving remote control commands) in order to shield them from outside intrusion. By default, these are ports 1717 and 2504 at the cluster's IP address. Use remote control only from a secure, trusted computer within your firewall. For more information on the remote control parameter, see Remote control in Network Load Balancing parameters. For more information about strong passwords, see Strong passwords.

**Possible Cause**

Network Load Balancing UDP control ports are protected incorrectly by a firewall. By default, remote control commands are sent to UDP ports 1717 and 2504 at the cluster IP address.

**Solution**

Be sure that these ports have not been blocked incorrectly by a router or firewall. You can also change the port number by modifying the corresponding Network Load Balancing parameter.

**Possible Cause**

You used an incorrect password when attempting to use remote control.

**Solution**

Use the remote control password that you configured when you enabled the Network Load Balancing cluster.

**When using the dedicated IP address of a host to specify it as a target for a remote control command, there is no reply. However, specifying the host by its priority (ID) works.**
**Cause:** None of the hosts have a dedicated IP addresses.

**Solution:** Assign a dedicated IP address to each host. For more information, see Configure host parameters.

**Connectivity to the cluster is denied to some, but not all users.**
**Possible Cause**

An application being load balanced in not responding.

**Solution**

This is an application specific problem not related to Network Load Balancing. Refer to your application's documentation for correction. You may need to stop and restart the application.

**Possible Cause**

If your cluster is configured for unicast mode, a switch might have learned the Network Load Balancing network adapter's MAC address.

**Solution**

Clear the switch's port to MAC address mapping.

**Possible Cause**

The cluster's IP address was not added to TCP/IP on one or more of the hosts.

**Solution**

If you do not use Network Load Balancing Manager to configure your cluster, you must manually configure TCP/IP with the cluster's IP address. For more information, see Set up TCP/IP for Network Load Balancing.

**Possible Cause**

A host is leaving the cluster because of a drainstop or stop command, but convergence did not complete correctly.

**Solution**

Wait for convergence to complete. If convergence does not complete, see the problem titled "After the cluster hosts start, they begin converging but never complete convergence" later in this troubleshooting guide.

**You cannot view or change the Network Load Balancing properties using net config and Windows Management Instrumentation (WMI).**
**Cause:** In order to view or change **Network Load Balancing properties**, you must be a member of the Administrators group.

**Solution:** Log on as a user who is in the local Administrators group of the computer that is running Network Load Balancing.

**An unusual number of TCP connections to the cluster's IP address are being reset by either the server or the client.**
**Possible Cause**

HTTP keep-alives are enabled on the Network Load Balancing hosts and keep-alive enabled clients are connecting to the cluster.

**Solution**

Disable HTTP keep-alives. For more information on HTTP keep-alives and Internet Information Services (IIS), refer to the IIS documentation set. To view the IIS documentation set from your desktop, install IIS then click the Start button, click Run, and type the following command in the Open text box: **%windir%\help\iisrv.chm**.

**Possible Cause**

Low system resources on the server are causing TCP itself to reject the connections.

**Solution**

Free up system resources by for example, adding additional system memory or closing unnecessary applications.

**Possible Cause**

The cluster has diverged into two separately converged clusters, causing more than one node to claim ownership of every connection.

**Solution**

Remove the two clusters then recreate a single cluster.

**Virtual Private Network (VPN) calls fail when you make a change that causes convergence (such as adding a host, removing a host, or draining a host).**
**Cause:** When using Network Load Balancing to load balance VPN traffic such as PPTP/GRE and IPSEC/L2TP, you must configure the port rules that govern the ports handling the VPN traffic (TCP port 1723 for PPTP and UDP port 500 for IPSEC) to use either Single or Class C affinity.

**Solution:** Configure the port rules governing ports 500 and 1723 to use either Single or Class C affinity. For more information see Network Load Balancing parameters.

**After the cluster hosts start, they begin converging but never complete convergence.**
**Possible Cause**

Either a different number of port rules or incompatible port rules on different cluster hosts were entered. This will inhibit convergence.

**Solution**

Open the **Network Load Balancing Properties** dialog box on each cluster host and verify that all hosts have identical port rules.

**Possible Cause**

You have a bad network adapter or cable.

**Solution**

Use the ping command to test connectivity. Ping the host's fully qualified domain name. You can also learn more about the problem by pinging your domain controller by IP address, and by pinging other network servers by name and IP address.

**Possible Cause**

You have mismatched duplex settings on a switch or hub.

**Solution**

Confirm that duplex settings in each of your switches and hubs is configured appropriately.

**Possible Cause**

The dedicated IP address that you used for one of the hosts already exists somewhere else on the network.

**Solution**

Choose a new IP address, or remove the duplicate address.

**Possible Cause**

You defined one or more port rules that are applicable to only specific IP addresses, but your cluster contains hosts running Windows 2000.

**Solution**

If you use IP address specific port rules, your cluster must be running a product in the Windows Server 2003 family on all hosts.

**Possible Cause**

You have configured different cluster operation modes (Unicast and Multicast) on the hosts.

**Solution**

Ensure that all hosts are configured with the same cluster operation mode. For more information see Enable Network Load Balancing.

**The cluster moves in and out of a converged state.**
**Cause:** Heartbeats are being missed due to intermittent network connectivity caused by a bad network adapter or cable, or other network problems

**Solution:** Use the ping command to test connectivity. Ping the host's fully qualified domain name. You can also learn more about the problem by pinging your domain controller by IP address, and by pinging other network servers by name and IP address.

**After the cluster hosts start, Network Load Balancing reports that convergence has finished, but more than one host is a default host.**
**Possible Cause**

The cluster hosts have become members of different subnets, so that all hosts are not accessible on the same network.

**Solution**

Be sure that all cluster hosts can communicate with each other.

**Possible Cause**

A layer three switch is being used.

**Solution**

Put a layer two switch between the hosts and the layer three switch.

**Possible Cause**

A break in a redundant switch caused the cluster to separate into two separate clusters, creating two separate default hosts.

**Solution**

Remove the two clusters then recreate a single cluster.

**Possible Cause**

Your switch is configured to reject broadcast packets.

**Solution**

Configure your switch to accept broadcast packets (be aware that this might introduce certain security risks), or configure your Network Load Balancing cluster to use multicast mode.

**Possible Cause**

One host in unable to send or receive heartbeats.

**Solution**

Use the ping command to test connectivity to each of the hosts. Ping the hosts' fully qualified domain name.

**Possible Cause**

A host is plugged into the wrong port on the switch.

**Solution**

Use the correct port on the switch.

**Network Load Balancing is not load balancing applications, and the default host handles all network traffic.**
**Possible Cause**

A port rule is missing. By default, Network Load Balancing directs all incoming network traffic not governed by port rules to the default host. This ensures that the application you do not want load balanced behaves properly.

**Solution**

To load balance an application across the cluster, create a port rule on every cluster host for the TCP/IP port(s) serviced by the application.

**Possible Cause**

You added a second host to a single host cluster, but the second host is not configured correctly. The cluster never converges and the original host continues to handle all of the traffic.

**Solution**

Carefully review and if necessary correct each of the settings on the second host, for example cluster IP address, dedicated IP address and port rules.

**Possible Cause**

If your cluster is configured for unicast mode, a switch might have learned the Network Load Balancing network adapter's MAC address.

**Solution**

Clear the switch's port to MAC address mapping.

**Possible Cause**

A proxy server is sending all connections using a single IP address to your cluster in single affinity mode.

**Solution**

Configure your proxy server to use multiple IP addresses.

**Traffic alternates unexpectedly between the cluster hosts breaking TCP connections.**
**Cause:** Unicast network addresses are causing problems with the switching hub. If you are using a switching hub to interconnect the cluster hosts, you must use Network Load Balancing multicast support; otherwise, the switch is likely to behave erratically when the same unicast network is used on multiple switch ports.

**Solution:** Check that you have selected multicast support in the **Network Load Balancing Properties** dialog box. If you do not want to use multicast support, you can interconnect the cluster hosts with a hub or coaxial cable instead of a switch.

**Network traffic does not appear to load balance evenly among the cluster hosts.**
**Cause:** The network traffic is coming from a limited number of IP addresses, possibly due to the use of a proxy server.

**Solution:** Configure your proxy server to use multiple IP addresses.

**Notes**

- These topics describe several common problems that you might encounter when installing and initially using Network Load Balancing. Each topic describes the likely reasons for each problem and one or more suggested remedies.

- These topics assume that your system and applications meet the minimum requirements for Network Load Balancing. For more information, see Checklist: Enabling and configuring Network Load Balancingand Determining which applications to use with Network Load Balancing.

- Many of the problems described here can be avoided, diagnosed and corrected by using Network Load Balancing Manager. For more information, see Network Load Balancing Manager.

- For additional troubleshooting support, go the Microsoft Product Support Services Web site by clicking on the appropriate link at Support resources and performing a search on "Network Load Balancing", "Nlb", or "Windows Server 2003."

- You should test your network and all network adapters for proper operation before installing Network Load Balancing. Be sure to follow all installation steps and check that the cluster parameters and port rules are identically set for all

cluster hosts. If a problem occurs, always check the Windows event log for a message from the Network Load Balancing driver. For more information, see Cluster parameters, Host parameters, and Port rules in Network Load Balancing parameters.

**When you are using Network Load Balancing with Microsoft Internet Security and Acceleration (ISA) Server, one cluster host might log blocked packets that are directed to the dedicated Internet Protocol (IP) address of another host.**
**Cause:** One of the cluster hosts is configured with a host priority identifier equal to 1.

**Solution:** Do not configure any cluster host with a host priority identifier of 1. Instead, use numbers that are greater than 1. For more information, see Configure host parameters.

**You are unable to create a Network Load Balancing cluster in a 64-bit environment.**
**Cause:** You might not be running the appropriate Network Load Balancing version for the environment you are using. Network Load Balancing cannot form a cluster when the 32-bit version of Network Load Balancing is used on a 64-bit computer. This issue might have gone undetected because 32-bit Network Load Balancing components (nlb.exe, wlbs.exe, and nlbmgr.exe) appear to run correctly in the 64-bit environment.

**Solution:** If you plan to use a 64-bit environment, you must use the 64-bit Network Load Balancing version.

# Server Clusters

Updated: April 10, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server clusters**
A server cluster is a group of independent computer systems, known as nodes, running Microsoft® Windows Server™ 2003, Enterprise Edition or Microsoft® Windows Server™ 2003, Datacenter Edition, and working together as a single system to ensure that critical applications and resources remain available to clients. The nodes in a cluster remain in constant communication through the exchange of periodic messages, called heartbeats. If one of the nodes becomes unavailable as a result of failure or maintenance, another node immediately begins providing service (a process known as failover).

Server clusters can combine up to eight nodes. In addition, a cluster cannot be made up of nodes running both Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition since the different operating systems may be running incompatible versions of the Cluster service. In server clusters with more than two nodes, all nodes must run Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, but not both. However, a server cluster can be operated with some nodes running the Microsoft® Windows® 2000 operating system and others running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition.

Server clusters can be set up as one of three different cluster model configurations:

- **Single node server clusters** can be configured with, or without, external cluster storage devices. For single node clusters without an external cluster storage device, the local disk is configured as the cluster storage device.
- **Single quorum device server clusters** have two or more nodes and are configured so that every node is attached to one or more cluster storage devices. The cluster configuration data is stored on a single cluster storage device.
- **Majority node set server clusters** have two or more nodes but the nodes may or may not be attached to one or more cluster storage devices. The cluster configuration data is stored on multiple disks across the cluster and the Cluster service makes sure that this data is kept consistent across the different disks.

It is recommended that you understand the advantages and limitations of the different cluster models before you configure your server cluster. For example, a majority node set cluster can tolerate fewer simultaneous node failures than an equivalent single quorum device cluster.

For more information about the three cluster models, see Choosing a Cluster Model.

For cluster storage, you can use parallel SCSI, Fibre Channel, Serial Attach SCSI (SAS), or iSCSI. For details about which types of storage can be used with a specific Windows Server 2003 operating system, see Server clusters overview.

Server clusters enable users and administrators to access and manage the nodes as a single system rather than as separate computers.

- Before creating a server cluster, see Checklists: Creating Server Clusters.
- Before installing resources for a server cluster, see Checklists: Installing Server Cluster Resources.
- To find features that have been changed in Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition, see New ways to do familiar Server Cluster tasks.
- For guidelines on securing server clusters, see Best practices for securing server clusters.
- For tips about using server clusters, see Best practices for configuring and operating server clusters.
- For help with specific tasks, see Server Cluster How To....
- For general background information, see Server Cluster Concepts.
- For problem-solving instructions, see Server Cluster Troubleshooting.

**Note**

- This feature is not included on computers running the Microsoft® Windows Server® 2003, Web Edition, operating system. For more information, see Overview of Windows Server 2003, Web Edition.

# Checklists: Creating Server Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklists: Creating server clusters**

- Checklist: Planning and creating a server cluster
- Checklist: Creating a new group
- Checklist: Creating a new resource
- Checklist: Creating a server cluster virtual server
- Checklist: Creating a server cluster file server
- Checklist: Creating a server cluster print server
- Checklist: Creating a clustered IIS Web or FTP service
- Checklist: Creating a server cluster application server
- Checklist: Validating your clustering system

# Checklist: Planning and creating a server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Planning and creating a server cluster**

**Caution**

- If you are using a shared storage device, when you power on and start the operating system, it is of vital importance that only one node has access to the cluster disk. Otherwise the cluster disks can become corrupted. To prevent the corruption of the cluster disks, shut down all but one cluster node, or use other techniques (for example, Logical Unit Number or LUN masking, selective presentation, or zoning) to protect the cluster disks, before creating the cluster. Once the Cluster service is running properly on one node, the other nodes can be added and configured simultaneously.

Follow these steps to plan for and create a server cluster. You can use the tutorial for Cluster Installation at the Microsoft Web site to help you create a server cluster. If you are upgrading your server cluster, review the cluster upgrade documentation.

**Planning issues to consider before you create your server cluster**

| Step | Reference |
|---|---|
| Review basic cluster concepts. You will need to understand nodes, failover and failback, groups, and resources before planning your server cluster. | Server Cluster Concepts<br><br>Server clusters overview |
| Review security best practices for server clusters. | Best practices for securing server clusters |
| Review limitations of server clusters. | Limitations of server clusters |
| Choose your cluster model. | Choosing a Cluster Model |
| Choose applications that can run on your server cluster. | Choosing applications to run on a server cluster |
| Organize your cluster applications and resources into groups based on resource dependencies, failover policies, and administrative convenience. | Planning your groups |
| After you choose a cluster model and determine how to group your applications and resources, you are ready to determine the hardware capacity required for each server in the cluster. | Determining server-capacity requirements |
| Plan your network hardware. | Planning your networking hardware<br><br>Best practices for configuring and operating server clusters |
| Plan your system disks.<br><br>It is recommended that the system disks on all your cluster nodes use the same drive letter. | |

| | |
|---|---|
| Plan your cluster disks.<br><br>To guard against the failure of your cluster disks, it is highly recommended that you implement a hardware RAID solution.<br><br>If your cluster disk hardware includes a SCSI bus, it is important to note that the SCSI host adapters must each have a unique SCSI ID (usually the numbers 6 and 7). In addition, the SCSI bus must be properly terminated.<br><br>By default, the New Server Cluster Wizard will automatically select the smallest disk that is larger than 500 MB as the quorum resource. If no disk larger than or equal to 500 MB is available, the New Server Cluster Wizard will select the largest disk that is at least 50 MB as the quorum resource but will generate a warning. For optimal performance of the NTFS file system, make sure that the disk containing the quorum resource is at least 500 megabytes (MB) in size. It is strongly recommended that you install the quorum resource on a separate disk, by itself, so that other applications cannot affect it. Also, ensure that the quorum disk has sufficient free space so that the Cluster service can start and continue to write to the quorum log. | Hardware redundant array of independent disks (RAID)<br><br>The documentation for your storage hardware. |

**Actions to take when creating a server cluster**

| Step | Reference |
|---|---|
| Choose your cluster hardware.<br><br>Microsoft supports only complete cluster systems chosen from the Windows Catalog; it is recommended that you do not mix and match hardware components when building your cluster. Check to ensure that your hardware, including your cluster disks, is compatible with Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. | Support resources<br><br>Best practices for configuring and operating server clusters |
| Verify the availability of domain services and add your servers to the domain. | Choosing a domain model |
| Install and configure your cluster disks.<br><br>Turn on your cluster nodes, but do not allow the operating system to start on any of the nodes. Connect your shared storage buses, completing the initial installation steps in the BIOS or EFI firmware configuration screens for your particular storage device by following the directions in the hardware documentation.<br><br>Allow the operating system to start on one node and configure the cluster disks as basic disks. Format the disks using the NTFS file system. Assign drive letters to or create mounted drives for the cluster disks on the shared bus. If you assign drive letters, the disks must have the same drive letter on all nodes in the cluster.<br><br>**Caution**<br><br>• Cluster disks on a shared bus must be partitioned as Master Boot Record (MBR) and not as GUID Partition Table (GPT) disks. | The documentation for your storage hardware.<br><br>General storage configuration tips for server clusters<br><br>Connect the shared storage buses and assign drive letters |
| Configure network hardware. | Configuring cluster network hardware |
| Configure IP address settings for your network. | Configuring cluster network hardware<br><br>Private network addressing options |

| | |
|---|---|
| Gather the information required for configuring the first node in your cluster.<br><br>You will need the following:<br><br>1. A static IP address for the cluster.<br>2. Computer accounts for the cluster nodes.<br>3. A user account for the Cluster service.<br>4. A name for the cluster, that is, the name administrators will use for connections to the cluster. (The actual applications running on the cluster will typically have different network names.)<br><br>**Caution**<br><br>• Computer accounts for the nodes must be in the same domain. It is strongly recommended that the Cluster service account be in the same domain as well.<br>• It is strongly recommended that you do not use the same account for the Cluster service and applications in the cluster (for example, Microsoft SQL Server). If you do use the same account, you may not be able to later change the Cluster service password without disrupting your cluster applications.<br>• The cluster name must be different from the domain name, from all computer names or virtual server names in the domain, and from other cluster names in the domain. | Domain accounts and the Cluster service<br><br>The Cluster service and TCP/IP |
| Create a cluster on the first node.<br><br>Use Cluster Administrator to create a cluster on the first node.<br><br>**Note**<br><br>• You cannot use the Configure Your Server or Manage Your Server tools to create a cluster or administer cluster nodes.<br><br>You can use the tutorial for Cluster Installation to complete the New Server Cluster Wizard. | Create a cluster<br><br>Microsoft Web site |
| Verify that you can see the cluster disks.<br><br>Use Disk Management to verify that you can see the cluster disks.<br><br>Use Cluster Administrator to verify that the disks are all online. | Disk Management<br><br>Bring a group online |
| Allow the remaining nodes to boot to the operating system then add them to the cluster.<br><br>Use Cluster Administrator to add one or more nodes to the cluster.<br><br>You can use the tutorial for Cluster Installation to complete the New Server Cluster Wizard. | Add additional nodes to the cluster<br><br>Microsoft Web site |
| Validate the cluster disks.<br><br>Use Disk Management to verify that all nodes see the same number of cluster disks.<br><br>Use Cluster Administrator to failover the cluster disks to each node in the cluster and verify that they come back online. | Disk Management<br><br>Test whether group resources can fail over |

| | |
|---|---|
| Configure the cluster network role and type.<br><br>By default, the New Server Cluster Wizard will set up all cluster networks as mixed (public-and-private) networks. Optionally, you can change this so that the networks are set up as private networks (that is, for node-to-node communication only) or public networks (that is, for client access only). | Change how the cluster uses a network |
| Configure the cluster network properties.<br><br>Place the private network at the top of the Network Priority list for internal node-to-node communication in the cluster. | Change network priority for communication between nodes |
| Create your resource groups and resources. | Checklist: Creating a new group<br><br>Checklist: Creating a new resource |
| Validate your clustering system. | Checklist: Validating your clustering system |

# Checklist: Creating a new group

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Creating a new group**

| Step | Reference |
|---|---|
| Review resource groups. | Server Cluster groups |
| Determine the name you will assign to the group. This name must be different from any other group name in the cluster. | Not applicable |
| (Optional) Determine the text description for the group. | Not applicable |
| (Optional) Determine the preferred owner for the group. | Not applicable |
| Use the New Group Wizard to create the group. | Create a new group in a cluster |
| Determine the group's failover/failback policy. | Failover and failback<br><br>Determining failover and move policies for groups<br><br>Set group failover policy<br><br>Set group failback policy |

# Checklist: Creating a new resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Creating a new resource**

| Step | Reference |
|---|---|
| Review the concepts behind cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Determine the name of your resource. This name must be different from any other resource name in the cluster. | Not applicable |
| Determine the type of your resource. | Resource types |
| Determine the group to which your resource will belong. | Server Cluster groups |
| Determine if the resource will run in a separate resource monitor. | Resource Monitors |
| List the possible owners of the resource. | Failover and failback |
| Determine the resource dependencies. | Resource dependencies |
| Determine the restart policy for the resource. | Specify the restart policy for a resource<br><br>Failover and failback |
| List properties specific to your resource. | Checklists: Installing Server Cluster Resources |
| Use the New Resource Wizard to create the resource. | Create a new resource |

# Checklist: Creating a server cluster virtual server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Creating a server cluster virtual server**

| Step | Reference |
| --- | --- |
| Review the concepts behind virtual servers. | Virtual servers |
| Use the Cluster Application Configuration Wizard to create your virtual server. | Start the Cluster Application Wizard |
| Configure resource dependencies in your virtual server. | Setting resource properties |

# Checklist: Creating a server cluster file server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Creating a server cluster file server**

| Step | Reference |
|---|---|
| Review server cluster components. | Server Cluster Components |
| Review cluster resources. | Server Cluster Resources |
| Determine what type of file share is appropriate for your situation.<br><br>**Note**<br><br>• If you plan to maintain home folders for a large number of users on a server cluster, you do not have to create a file share resource for every home folder (which may slow down your server cluster's performance). Instead you can create a single file share for the root home folder and use the Cluster service to share the subfolders to the individual users. | File Share resource type<br><br>Using a server cluster with large numbers of file shares |
| Plan your resource groups. | Planning your groups |
| Create a new server cluster. | Checklist: Planning and creating a server cluster |
| Create a virtual server for your file server and a file share resource. | Checklist: Creating a new group<br><br>Checklist: Creating a server cluster virtual server<br><br>Checklist: Creating a new resource<br><br>Share subfolders on a File Share resource<br><br>Create a cluster-managed encrypted file share |

# Checklist: Creating a server cluster print server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Creating a server cluster print server**

| Step | Reference |
|---|---|
| Review server cluster components. | Server Cluster Components |
| Review cluster resources. | Server Cluster Resources |
| Review documentation for the Print Spooler resource type. | Print Spooler resource type |
| Plan your resource groups. | Planning your groups |
| If a server cluster does not already exist, create a new server cluster. | Checklist: Planning and creating a server cluster |
| Create a group, a virtual server for your print server, and a printer spooler resource. | Checklist: Creating a new group<br>Checklist: Creating a server cluster virtual server<br>Checklist: Creating a new resource |

# Checklist: Creating a clustered IIS Web or FTP service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Creating a clustered IIS Web or FTP service**

**Important**

- It is recommended that you review the information on Network Load Balancing clusters before using a server cluster to create a high-availability Web server. Depending on your needs, using a Network Load Balancing cluster to load balance the incoming client HTTP traffic might be a better solution. For more information on Network Load Balancing clusters, see Network Load Balancing Clusters.

  For the most current information on server clusters and how they work with Network Load Balancing, see Updated technical information.

| Step | Reference |
|---|---|
| Review server cluster components. | Server Cluster Components |
| Review cluster resources. | Server Cluster Resources |
| Review Internet Information Services (IIS) concepts. | IIS documentation |
| Install the Microsoft Distributed Transaction Coordinator (DTC) resource. | Distributed Transaction Coordinator<br><br>Checklist: Installing a Distributed Transaction Coordinator resource |
| Install Internet Information Services (IIS). | IIS documentation |
| Decide which internet service you will provide: FTP or Web.<br><br>If you are creating an FTP server, install the FTP service and default FTP site.<br><br>**Note**<br><br>• A Web site is installed by default when you first install IIS. | IIS documentation |
| Plan your resource groups. | Planning your groups |
| Create a new cluster. | Create a cluster |
| Add nodes to the cluster. | Add additional nodes to the cluster |
| Create a group and a virtual server for your clustered IIS service. | Checklist: Creating a new group<br><br>Checklist: Creating a server cluster virtual server |

| | |
|---|---|
| Create a Generic Script Resource for the IIS service in the virtual server resource group you created above.<br><br>Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition include 2 example Visual Basic scripts that you can use for this purpose, **clusweb.vbs** and **clusftp.vbs**. By default, these are located in the %systemroot%\system32\inetsrv directory.<br><br>**Important**<br><br>• It is recommended that the Generic Script resource configured for IIS be dependent on both a Network Name resource (so that remote clients can access it) and a Physical Disk (or other storage class device) resource. The Network Name will, in turn, be dependent on the IP Address (that will correspond to the virtual root).<br><br>• If you use a Generic Script resource to host multiple Web sites, it is recommended that you run the same version of IIS on all nodes in the cluster.<br><br>**Note**<br><br>• You can run the clusweb.vbs and clusftp.vbs scripts remotely from a non-Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition computer by pointing to the %systemroot%\system32\inetsrv Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition directory where they are located. | Checklist: Installing a Generic Script resource<br><br>Setting resource properties Modify resource dependencies |
| Configure IIS bindings.<br><br>To configure an FTP site to handle requests sent to a virtual server, ensure that the FTP site is configured to listen to the IP address of the virtual server. You can do this by assigning an IP address to an FTP site.<br><br>To configure a Web site to handle requests sent to a virtual server, ensure that the Web site is configured to listen to the IP address and/or name of the virtual server. The name of the virtual server can be used as the Host Header value for the Web site. You can do this by assigning an IP address and/or Host Header values to a Web site. | IIS documentation |
| Synchronize IIS on all nodes by using the **IIScnfg.vbs /copy** command to copy the IIS configuration to other nodes. | IIS documentation |

# Checklist: Creating a server cluster application server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Creating a server cluster application server**

| Step | Reference |
| --- | --- |
| Review server cluster components. | Server Cluster Components |
| Review cluster resources. | Server Cluster Resources |
| Review the requirements for your application. | Your application documentation<br><br>Checklist: Installing a Generic Application resource |
| Plan your resource groups. | Planning your groups |
| Create a group, a virtual server for your application, and a generic application resource. | Checklist: Creating a new group<br><br>Checklist: Creating a server cluster virtual server<br><br>Checklist: Creating a new resource |

# Checklist: Validating your clustering system

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Validating your clustering system**

| Step | Reference |
|---|---|
| One by one, take each resource group offline then bring it back online.<br><br>**Note**<br><br>• The default Cluster Group (containing the quorum resource) will not go offline. | Take a group offline<br><br>Bring a group online |
| Test that resources can fail over by moving resource groups from one node to another. | Test whether group resources can fail over |
| Test the failover policies for the resource groups. | Test group failover policy |
| Test that the cluster can recover from node failures. | Test node failure |
| Test that the cluster can recover from private network failures. | Test private network failures |
| Review your system logs for any server cluster errors recorded by the Cluster service.<br><br>In Event Viewer, server cluster errors logged by the Cluster service show up under the Source column as "ClusSvc". | Event Viewer |

# Checklists: Installing Server Cluster Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklists: Installing server cluster resources**

- Checklist: Installing a DHCP Service resource
- Checklist: Installing a Distributed File System (DFS) root resource
- Checklist: Installing a Distributed Transaction Coordinator resource
- Checklist: Installing a File Share resource
- Checklist: Installing a Generic Application resource
- Checklist: Installing a Generic Script resource
- Checklist: Installing a Generic Service resource
- Checklist: Installing an IP Address resource
- Checklist: Installing a Local Quorum resource
- Checklist: Installing a Majority Node Set resource
- Checklist: Installing a Message Queuing resource
- Checklist: Installing a Network Name resource
- Checklist: Installing a Physical Disk resource
- Checklist: Installing a Print Spooler resource
- Checklist: Installing a Volume Shadow Copy Service Task resource
- Checklist: Installing a WINS Service resource

# Checklist: Installing a DHCP Service resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a DHCP Service resource**

| Step | Reference |
|---|---|
| Review the concepts behind cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Review the concepts behind Dynamic Host Configuration Protocol (DHCP). | DHCP |
| Plan common resource settings. | Checklist: Creating a new resource |
| Configure location of DHCP database and backup of database files. | DHCP Service and WINS Service resource types |
| If you already use DHCP, and you want to retain your existing DHCP database files, move the files to the new DHCP database before bringing the new DHCP server online. | Backing up the DHCP database |
| Make certain that you install the DHCP Service on all nodes. | Install a DHCP server |
| Use the New Resource Wizard to create the resource.<br>**Important**<br>• When you create a DHCP Service resource on a node, the Cluster service sets the startup type for the DHCP service on that node to **Manual**. The Cluster service also stops the DHCP service on all the other nodes, but, on those nodes not hosting the DHCP Service resource, the Cluster service leaves the DHCP service startup type set to **Automatic**. This DHCP service startup type will be set to Manual on any of the other nodes only when the DHCP Service resource fails over. In addition, if you subsequently evict a node from the cluster, the DHCP service will not be restarted on that evicted node. | Create a new resource<br>Configure how a service is started |

# Checklist: Installing a Distributed File System (DFS) root resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a Distributed File System (DFS) root resource**

| Step | Reference |
|---|---|
| Review the concepts behind cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Plan common resource settings. | Checklist: Creating a new resource |
| Review Distributed File System (DFS) information. | Distributed File System (DFS) |
| Using the DFS Microsoft Management Console (MMC) snap-in, make sure that a DFS root does not already exist. | Show a DFS root |
| Use the New Resource Wizard to create the resource. | Create a new resource |

# Checklist: Installing a Distributed Transaction Coordinator resource

Updated: January 20, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a Distributed Transaction Coordinator resource**

| Step | Reference |
|---|---|
| Review the concepts behind cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Plan common resource settings. | Checklist: Creating a new resource |
| Create or select the group you want to install the Distributed Transaction Coordinator (DTC) resource into.<br><br>By default, the DTC resource will install into the first group it locates that has an IP, Name, and Physical Disk resource, unless you identify a specific group. | Checklist: Creating a new group<br><br>Distributed Transaction Coordinator |
| Use the New Resource Wizard to create the resource.<br><br>Make the Distributed Transaction Coordinator resource dependent on the Physical Disk resource. | Create a new resource |

| **Important** |
|---|
| In Windows Server 2003 Service Pack 1 (SP1) and later service packs, DTC provides the administrator with additional settings that control the level of authentication required between computers involved in transactions. However, there are limitations in the way you can use these settings in a clustered environment. You cannot use the **Mutual Authentication Required** transaction mode with computers that are in a clustered environment, or any computers that are negotiating transactions with such computers. In that context, you can use the **Incoming Caller Authentication Required** transaction mode instead. For more information, see Distributed Transaction Coordinator (http://go.microsoft.com/fwlink/?LinkId=209176) and New functionality in the Distributed Transaction Coordinator service in Windows Server 2003 Service Pack1 and in Windows XP Service Pack 2 (http://go.microsoft.com/fwlink/?LinkId=209177). |

# Checklist: Installing a File Share resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a File Share resource**

| Step | Reference |
|---|---|
| Review the concepts behind cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies.<br><br>**Important**<br><br>• It is recommended that the File Share resource be dependent on a Physical Disk and a Network Name resource. | Server Cluster groups |
| Review the behavior of the file share resource type. | File Share resource type |
| Plan common resource settings. | Checklist: Creating a new resource |
| Determine whether you will use the advanced properties of the File Share resource type. | File Share resource type |
| Use the New Resource Wizard to create the resource. | Create a new resource |
| Configure file share permissions using Cluster Administrator. | Using Cluster Administrator<br><br>Start Cluster Administrator in Microsoft Management Console |

# Checklist: Installing a Generic Application resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a Generic Application resource**

| Step | Reference |
|---|---|
| Review the concepts behind cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Plan common resource settings. | Checklist: Creating a new resource |
| Install your application on all nodes.<br>**Note**<br>• Before attempting to cluster your application, contact the application vendor for specific installation instructions or recommendations on configuring it optimally on your server cluster. | Generic Application resource type |
| Note the command line for your application. | The documentation for your application. |
| Determine the directory in which your application needs to run. | The documentation for your application. |
| Determine whether your application can display windows on the node on which it runs. | The documentation for your application. |

| | |
|---|---|
| Determine which application registry keys need to be replicated.<br><br>**Information on registry key replication**<br><br>Server clusters provides the ability for Generic Service and Generic Application resource types to specify registry keys below HKEY_LOCAL_MACHINE that need be replicated to all nodes in the cluster.<br><br>Some services or applications might update registry information while they are running by use of Win32 registry functions. The Cluster service provides registry checkpointing for noncluster-aware applications that may use these functions. Registry checkpointing for these resources occurs under the following conditions:<br><br>• When you specify a new registry key for the resource, the specified key is checkpointed.<br>• When the resource goes online, the registry keys are updated with the previously checkpointed information.<br>• When the resource is brought offline, all the checkpoints associated with this resource are saved.<br>• When the resource is online and changes are made to the registry key which is registered with the cluster server for replication, the Cluster service makes sure the updates are written to a checkpoint maintained on the quorum device.<br><br>If you manually update these registry keys while the application or service is offline, the changes may not be replicated or may be lost. To prevent this from happening, make any manual changes while the service or application resource is online.<br><br>Cluster aware applications need to make use of cluster registry functions as provided in the cluster API set when working with registry keys under HKEY_LOCAL_MACHINE\Cluster. Refer to the Windows Clustering documentation in the Platform Software Development Kit (SDK) for more information on this topic. | The documentation for your application. |
| Determine whether a dependent network name needs to be substituted for the computer name.<br><br>Applications can make application program interface (API) calls to determine the name of the computer on which they are running. Making the generic application dependent on a network name resource causes the **Use Network Name** check box in **Cluster Administrator** to be selected. In such a case, the network name is returned instead of the computer name when the application makes the API call. This enables applications that are not cluster aware to continue to appear to be running on the same computer even after they move to a different cluster node. | The documentation for your application.<br><br>For more information on API calls for server clusters, see the Microsoft Platform Software Development Kit (SDK). |
| Determine whether any application-specific registry keys need to be replicated on all cluster nodes.<br><br>As described previously, this pertains to applications that are not cluster-aware. An application can store data in the registry. If the application is moved but the registry data is not moved with it, the application's state is lost. If the cluster administrator specifies the root of the registry key, it enables the Cluster service to "watch" that key. The Cluster service captures the data in the key and any changes that occur. When the generic application resource is moved, the Cluster service moves the registry data to the new resource host and then brings the generic application resource online. | The documentation for your application. |
| Use the New Resource Wizard to create the resource. | Create a new resource |

# Checklist: Installing a Generic Script resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a Generic Script resource**

| Step | Reference |
| --- | --- |
| Review server cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Plan common resource settings. | Checklist: Creating a new resource |
| Note the name of the generic script along with the path to the script file. | For more information on developing generic scripts, see the Microsoft Platform Software Development Kit (SDK). |
| Use the New Resource Wizard to create the resource. | Create a new resource |

# Checklist: Installing a Generic Service resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing a Generic Service resource**

| Step | Reference |
|---|---|
| Review server cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Plan common resource settings. | Checklist: Creating a new resource |
| Note the exact service name as it appears in the registry under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services**. | The documentation for your service. |
| Note the startup parameters of your service. | The documentation for your service. |
| Ensure that the service is installed on all nodes. | Not applicable |
| Determine which service registry keys need to be replicated on all nodes.<br><br>**Information on registry key replication**<br><br>Server clusters provides the ability for Generic Service and Generic Application resource types to specify registry keys below HKEY_LOCAL_MACHINE that need to be replicated to all nodes in the cluster.<br><br>Some services or applications may update registry information while they are running by use of Win32 registry functions. The Cluster service provides registry checkpointing for noncluster-aware applications that may use these functions. Registry checkpointing for these resources occurs under the following conditions:<br><br>• When you specify a new registry key for the resource, the specified key is checkpointed.<br>• When the resource goes online, the registry keys are updated with the previously checkpointed information.<br>• When the resource is brought offline, all the checkpoints associated with this resource are saved.<br>• When the resource is online, and changes are made to the registry key that is registered with the cluster server for replication, the Cluster service ensures that the updates are written to a checkpoint maintained on the quorum device.<br><br>If you manually update these registry keys while the application or service is offline, the changes may not be replicated or may be lost. To prevent this from happening, make any manual changes while the service or application resource is online.<br><br>Cluster-aware applications need to make use of cluster registry functions as provided in the cluster application program interface (API) set when working with Cluster registry keys under HKEY_LOCAL_MACHINE. Refer to the Windows Clustering documentation in the Platform Software Development Kit (SDK) for more information on this topic. | The documentation for your service.<br><br>Checklist: Installing a Generic Application resource |

| | |
|---|---|
| Determine whether a dependent network name needs to be substituted for the computer name.<br><br>Applications can make application program interface (API) calls to determine the name of the computer on which they are running. Making the generic application dependent on a network name resource causes the **Use Network Name** check box in **Cluster Administrator** to be selected. In such a case, the network name is returned instead of the computer name when the application makes the API call. Thus, applications that are not cluster aware continue to appear to be running on the same computer even after they move to a different cluster node. | The documentation for your application. |
| Determine whether any application-specific registry keys need to be replicated on all cluster nodes.<br><br>This pertains to applications that are not cluster aware. An application may store data in the registry. If the application is moved, but the registry data is not moved with it, the application's state is lost. If the cluster administrator specifies the root of the registry key, it enables the Cluster service to "watch" that key. The Cluster service captures the data in the key and any changes that occur. When the generic application resource is moved, the Cluster service moves the registry data to the new resource host and then brings the generic application resource online. | The documentation for your application. |
| Use the New Resource Wizard to create the resource. | Create a new resource |

# Checklist: Installing an IP Address resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installing an IP Address resource**

| Step | Reference |
|---|---|
| Review the concepts behind cluster resources. | Server Cluster Resources |
| Review resource groups and resource dependencies. | Server Cluster groups |
| Review TCP/IP concepts. | TCP/IP Concepts |
| Plan common resource settings. | Checklist: Creating a new resource |
| Obtain an Internet Protocol (IP) address and subnet mask from your network administrator.<br><br>This address must be a static IP address not already in use on the network. Make sure that the subnet mask is the same subnet mask as the one for the associated cluster network. | IP Addressing and Routing |
| Determine whether or not NetBIOS needs to be enabled for this IP address.<br><br>If NetBIOS for the IP address is enabled, it allows a dependent network name to be published using NetBIOS. If it is not enabled, the dependent network name will only be published using DNS. | Disable WINS/NetBT name resolution<br><br>DNS |
| Determine the network on which to create this resource.<br><br>**Important**<br><br>• It is recommended that you create IP Address resources on a network accessible by clients, that is, a public or mixed network. | Server cluster networks |

# New ways to do familiar Server Cluster tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar tasks**

The following table lists common tasks for configuring server clusters in Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. The user interface for performing these tasks is different from the way it was in Windows 2000.

| If you want to | In Windows 2000 use | In Windows Server 2003 family use |
|---|---|---|
| Create a new cluster. | **Add or Remove Programs** to install the Cluster service then use Cluster Administrator to add the first node to the cluster. | Cluster Administrator and select the **Create new cluster** option. For more information, see Checklist: Planning and creating a server cluster and Create a cluster. |
| Add nodes to a cluster. | **Add or Remove Programs** to install the Cluster service on each server to be added to the cluster then use Cluster Administrator locally to add each node, one by one, to the cluster. | Cluster Administrator and select the **Add nodes to cluster** option to add one or more nodes all at once. You can also add nodes locally or remotely. For more information, see Add additional nodes to the cluster. |
| Restore the cluster quorum for all nodes in the cluster. | Cluster Administrator to stop the Cluster service on all nodes. Then use Backup to restore the System State data, and finally the Clusrest.exe tool to copy the restored data to the quorum disk. | Backup to restore the System State data and select the advanced restore **When restoring the Cluster Quorum, mark the restored data as Authoritative** option. For more information, see Restore the cluster database on a local node. |
| Uninstall the Cluster service. | **Add or Remove Programs** to uninstall the Cluster service on each node. | Cluster Administrator to evict the last node in the cluster. |
| Create a Web or FTP server. | Cluster Administrator to create an IIS instance resource. Then configure the IIS bindings and use the **IISSYNC** tool to replicate the IIS configuration to all nodes. | Cluster Administrator to create a Generic Script resource for running the IIS service. Then configure the IIS bindings and use the IIS Backup/Restore feature to replicate the IIS configuration to all nodes. For more information, see Checklist: Creating a clustered IIS Web or FTP service. |
| Change network roles, names, and priorities. | The New Server Cluster Wizard and change these network properties during setup. | Cluster Administrator after setup to change the properties of the cluster networks. For more information, see Change how the cluster uses a network, Change the name or description of a network, and Change network priority for communication between nodes. |
| Delete a resource. | Cluster Administrator to first take the resource offline before deleting it. | Cluster Administrator to delete it. For more information, see Delete a resource. |
| Change the password for the Cluster service account. | Cluster Administrator to first stop the Cluster service on all nodes. Then use Active Directory Users and Computers to change the password for the account before restarting the Cluster service and bringing the nodes back online. | Cluster.exe commands to dynamically change the password on the domain controller and the cluster nodes without bringing down the entire cluster. For more information, see Change the Cluster service account password. |

# Server Cluster Best Practices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices**

- Best practices for configuring and operating server clusters
- Best practices for securing server clusters

# Best practices for configuring and operating server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices for configuring and operating server clusters**
The following guidelines will help you effectively use a server cluster:

**Secure your server cluster.**
To prevent your server cluster from being adversely affected by denial of service attacks, data tampering, and other malicious attacks, it is highly recommended that you plan for and implement the security measures detailed in Best practices for securing server clusters.

**Check that your server cluster hardware is listed in the Windows Catalog.**
For Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition, Microsoft supports only complete server cluster systems chosen from the Windows Catalog. To see if your system or hardware components, including your cluster disks, are compatible, see Support resources. For a geographically dispersed cluster, both the hardware and software configuration must be certified and listed in the Windows Catalog.

The network interface controllers (NICs) used in certified cluster configurations must be selected from the Windows Catalog.

It is recommended that your cluster configuration consist of identical storage hardware on all cluster nodes to simplify configuration and eliminate potential compatibility problems.

**Partition and format disks before adding the first node to your cluster.**
Partition and format all disks on the cluster storage device before adding the first node to your cluster. You must format the disk that will be the quorum resource. All partitions on the cluster storage device must be formatted with NTFS (they can be either compressed or uncompressed), and all partitions on one disk are managed as one resource and move as a unit between nodes.

**Important**

- Cluster disks on the cluster storage device must be partitioned as master boot record (MBR) and not as GUID partition table (GPT) disks.

**Correctly set up your server cluster's networks.**
Follow the guidelines below to reduce network problems in your server cluster:

- Use identical network adapters in all cluster nodes, that is, make sure each adapter is the same make, model, and firmware version.

- Use at least two interconnects. Although a server cluster can function with only one interconnect, at least two interconnects are necessary to eliminate a single point of failure and are required for the verification of original equipment manufacturer (OEM) clusters.

- Reserve one network exclusively for internal node-to-node communication (the private network). Do not use teaming network adapters on the private networks.

- Set the order of the network adapter binding as follows:

  1. External public network

  2. Internal private network (Heartbeat)

  3. [Remote Access Connections]

  For more information, see Modify the protocol bindings order.

- Manually set the speed and duplex mode for multiple speed adapters to the same values and settings. If the adapters are connected to a switch, ensure that the port settings of the switch match those of the adapters. For more information, see Change network adapter settings.

- Use static IP addresses for each network adapter on each node.

- For private networks, define the TCP/IP properties for static IP addresses following the guidelines at Private network addressing options. That is, specify a class A, B, or C private address.

- Do not configure a default gateway or DNS or WINS server on the private network adapters. Also, do not configure private network adapters to use name resolution servers on the public network; otherwise, a name resolution server on the public network might map a name to an IP address on the private network. If a client then received that IP address from the name resolution server, it may fail to reach the address because no route from the client to the private network address exists.

- Configure WINS and/or DNS servers on the public network adapters. If Network Name resources are used on the public networks, set up the DNS servers to support dynamic updates; otherwise, the Network Name resources may not fail over correctly. For more information, see Configure TCP/IP settings.

- Configure a default gateway on the public network adapters. If there are multiple public networks in the cluster, configure a default gateway on only one of these. For more information, see Configure TCP/IP settings.

- Clearly identify each network by changing the default name. For example, you could change the name of the private network connection from the default *Local Area Connection* to *Private Cluster Network*.

- Change the role of the private network from the default setting of **All communications (mixed network)** to **Internal cluster communications only (private network)** and verify that each public network is set to **All communications (mixed network)**. For more information, see Change how the cluster uses a network.

- Place the private network at the top of the Network Priority list for internal node-to-node communication in the cluster. For more information, see Change network priority for communication between nodes.

**Do not install applications into the default Cluster Group.**

**Do not delete or rename the default Cluster Group or remove any resources from that resource group.**
The default Cluster Group contains the settings for the cluster and some typical resources that provide generic information and failover policies. This group is essential for connectivity to the cluster. It is therefore very important to keep application resources out of the default Cluster Group and so prevent clients from connecting to the Cluster Group's IP address and network name resources. If a resource for an application is added to this group and the resource fails, it may cause the cluster group to fail also, therefore reducing the overall availability of the entire cluster. It is highly recommended that you create separate resource groups for application resources.

For more information, see Planning your groups and Checklist: Planning and creating a server cluster.

**Back up your server cluster.**
To be able to effectively restore your server cluster in the event of application data or quorum loss, or individual node or complete cluster failure, follow these steps when preparing backups:

1. Perform an Automated System Recovery (ASR) backup on each node in the cluster.

2. Back up the cluster disks from each node.

3. Back up each individual application (for example, Microsoft Exchange Server or Microsoft SQL Server) running on the nodes.

### Note

- By default, Backup Operators do not have the user rights necessary to create an Automated System Recovery (ASR)

backup on a cluster node. However, Backup Operators can perform this procedure if that group is added to the security descriptor for the Cluster service. You can do that using Cluster Administrator or cluster.exe. For more information, see Give a user permissions to administer a cluster and Cluster.

For more information, see Backing up and restoring server clusters. For more information on backing up applications in a cluster, see the documentation for that application.

**Maintain a backup of the RAID controller.**
In a single quorum device server cluster, the RAID controller is a single point of failure. Always maintain a backup of the RAID controller configuration in case the RAID controller is replaced.

**Do not use APM/ACPI Power saving features.**
APM/ACPI Power saving features must not be enabled on server cluster members. A cluster member that turns off disk drives or enters "system standby" or "hibernate" mode can initiate a failure in the cluster. If multiple cluster nodes have power saving enabled, this can result in the entire cluster becoming unavailable.

Cluster members must use any power scheme that sets the **Turn off hard disks** option to **Never**, for example, the **Always On** power scheme. For more information on choosing a power scheme (located under **Power Options** in Control Panel), see Choose a power scheme.

For cluster nodes without Terminal Services installed, see Configure the Always On power scheme without Terminal Services installed.

For cluster nodes with Terminal Services installed, see Configure the Always On power scheme with Terminal Services installed.

**Note**

- Installing Terminal Services on a system reduces the power management options available to the user. The **System standby** and **System hibernates** options are not available.

**Give the Cluster service account full rights to administer computer objects if Kerberos authentication is enabled for virtual servers.**
If you enable Kerberos authentication for a virtual server's Network Name resource, the Cluster service account does not need full access rights to the computer object associated with that Network Name resource. The Cluster service can use the default access rights given to members of the authenticated users group, but certain operations (for example, renaming the computer object) will be restricted. It is recommended that you work with your domain administrator to set up appropriate administration rights and permissions for the Cluster service account.

For more information, see information about Kerberos authentication in Virtual servers.

**Do not install scripts used by Generic Script resources on cluster disks.**
It is recommended that you install script files used by Generic Script resources on local disks, not on cluster disks. Incorrectly written script files can cause the cluster to stop responding. Installing the script files on a local disk makes it easier to recover from this scenario. For guidelines on writing scripts for the Generic Script resource, see the *Microsoft Platform Software Development Kit* (SDK). For information on troubleshooting Generic Script resource issues, see article Q811685, "A Server Cluster with a Generic Script Resource Stops Responding" in the Microsoft Knowledge Base.

# Best practices for securing server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Best practices for securing server clusters**
Use the following guidelines to help keep your server cluster from being adversely affected by denial of service attacks, data tampering, and other malicious attacks:

**Apply the latest software updates.**
Apply the latest software updates, including security updates and service packs. Windows Server 2003 Service Pack 1 (SP1) contains a large number of improvements to security. We highly recommend that the version of Windows Server 2003 that you run is no earlier than Windows Server 2003 with SP1.

**Obtain the latest information about security.**
Review the Microsoft Web site from time to time for information about security. For example, review one or more of the following:

- Information about Server Security on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkID=59992).
- Knowledge Base article 891597, "How to apply more restrictive security settings on a Windows Server 2003-based cluster server" on the Microsoft Support Web site (http://go.microsoft.com/fwlink/?LinkID=59993).

**Restrict physical access to the server cluster and related infrastructure components to trusted personnel.**
Only allow authorized personnel to have physical access to the server cluster nodes and related infrastructure components (for example, the network and storage components). For more information about standard best practices for securing servers, see Best practices for security.

**Secure your cluster networks.**
**For public or mixed networks**: Ensure that all servers (for example, infrastructure servers such as DNS or WINS servers) that are attached to the cluster subnet (or any other subnet) are secure and trusted. Also, use a firewall to protect your cluster from unauthorized client access.

**For private networks**: Physically disjoint the private network(s) from other networks. Specifically, do not use a router, switch, or bridge to join a private cluster network to any other network. Do not include other network infrastructure or application servers on the private network subnet.

If heartbeat messages that are carried by private or mixed networks are disrupted (for example, by unauthorized users flooding the cluster networks), the cluster's reaction to these false failures may affect not only groups with IP address resources, but also the health of the cluster nodes. Repeated failover of critical cluster resources (for example, resources associated with Microsoft Exchange Server) may cause clients to lose access to the cluster.

**If you use Windows Firewall, use the Security Configuration Wizard to configure it.**
The Security Configuration Wizard simplifies the process of configuring Windows Firewall for cluster nodes. For more information, see Using Windows Firewall with a server cluster.

**Administer cluster nodes remotely only from trusted, secure computers.**
If the remote computers are compromised, untrustworthy or malicious code can be started unknowingly by the cluster administration tools and adversely affect the cluster itself.

**Make the Cluster service account a member of the local Administrators group on all nodes, but do not make it a member of the domain administrator group.**
By giving the minimal possible administration rights and permissions to the Cluster service account, you avoid potential security issues if that account is compromised. For more information about the administration rights and permissions required by the Cluster service account, see Change the account under which the Cluster service runs.

**Take steps to protect the Cluster service account, and do not use the Cluster service account to administer the cluster.**
The Cluster service account has elevated administration rights and permissions. Limit the use of the account, restrict the number of people who know the account name and password, and from time to time, change the password.

For more information about using another user account to administer a cluster, see Give a user permissions to administer a cluster.

For detailed information about the rights and permissions required for the Cluster service account, see Change the account under which the Cluster service runs.

For information about changing the password of the Cluster service account, which you can do without any downtime, see Change the Cluster service account password.

**Use different accounts for the Cluster service and applications in the cluster.**
This will limit exposure to the application and not the cluster account if an application account is compromised. In addition, if you use cluster.exe to change the password for the Cluster service account and one or more applications also use that account, your cluster applications may not function correctly. For more information, see Change the Cluster service account password.

**Use different Cluster service accounts for multiple clusters.**
This will limit exposure to one cluster only if a Cluster service account is compromised.

**Remove the Cluster service account after evicting all the nodes in your cluster.**
The cluster administration tools will not automatically delete the Cluster service account when all nodes have been evicted from the cluster. The Cluster service account has a high level of administration rights and permissions, and that can present potential security issues if it is compromised; it is highly recommended that you remove this account from the local Administrators group if you no longer have use for it. However, because the administrative rights and permissions for the Cluster service account are granted locally on each cluster node and not domain wide, the impact of a compromised account is limited to just the cluster nodes. For more information about deleting user accounts, see Delete a local user account.

**For clusters in an Active Directory domain, enable Kerberos authentication for Network Name resources.**
Kerberos authentication is much more secure than the alternative, NTLM authentication. Note that when you enable Kerberos authentication, you must add certain rights and permissions to the account that the Cluster service creates for the Network Name resource, and possibly to the Cluster service account itself. For more information, see Knowledge Base article 307532, "How to troubleshoot the Cluster service account when it modifies computer objects," on the Microsoft Support Web site (http://go.microsoft.com/fwlink/?LinkId=59994).

**Audit security-related events in the cluster.**
To ensure that only trusted personnel have user rights and permissions to administer the cluster and to track additions of unauthorized user accounts, audit changes to the local Administrators group. Note that, by default, when you create a server cluster or add nodes, the Cluster service account is added to the local Administrators group on each node. For more information about auditing security events, see Auditing Security Events.

**Limit and audit access to shared data (for example, files and folders on cluster disks).**
If you want to audit access to shared data, enable auditing on all cluster nodes. For more information, see Securing shared data in a cluster.

**Limit client access to cluster resources.**
Use Windows Server 2003 family security features to control client access to cluster resources as described in Limiting client access to cluster resources. Note that when you create user and group accounts through which you control access to cluster resources, you must use domain-level accounts, not local accounts, so that appropriate access is available regardless of which node currently owns a clustered resource.

**Limit access to the quorum disk and ensure that the quorum disk always has sufficient free space.**
To help reduce the risk of unauthorized reads and writes to the quorum disk, it is highly recommended that you give access to the quorum disk only to the Cluster service account and members of the local Administrators group. For the Cluster service to start and continue to write to the quorum log, the quorum disk must have sufficient free space. It is recommended that the quorum disk be at least 500 megabytes (MB) in size. For more information, see Checklist: Planning and creating a server cluster and Disk resource security.

**Ensure that all applications running in the cluster are from a trusted source and that access to the cluster disks is restricted only to applications that are managed as a cluster resource.**
For more information, see Disk resource security.

**Secure script files called by Generic Script resources.**
Use NTFS file-level security for execute permissions on script files and permissions for APIs called in those scripts. For more information, see Limiting client access to cluster resources.

**Ensure that applications called by Generic Application resources are from a trusted source and that files, registry checkpoints, and other resources needed for those applications are in a secure location.**
Applications launched as a Generic Application resource will run under the context of the Cluster service account, with its elevated administration rights and permissions. Therefore, ensure that such applications are from a trusted source. In addition, we recommend that in Cluster Administrator, when configuring the parameters for a Generic Application resource, you do not

select **Allow application to interact with desktop** unless it is necessary. For more information, see Limiting client access to cluster resources.

**Secure the cluster configuration log files created when remotely administering a cluster.**
After using the New Server Cluster Wizard and the Add Nodes Wizard from a remote computer, the cluster configuration log file generated by those wizards is saved to the remote computer (at %systemroot%\system32\LogFiles\Cluster\ClCfgSrv.log). This log file contains important information about the cluster. Restrict access to that file to cluster administrators and the Cluster service account. For more information, see Set, view, change, or remove permissions on files and folders.

| **Note** |
| --- |
| If you do not have administrative rights and permissions on the node on which you are using the New Server Cluster Wizard or Add Nodes Wizard, the log file will be written to the local %Temp% directory. |

**Do not copy files to the local cluster directories in a majority node set cluster.**
When using the majority node set model, each node maintains a copy of the quorum database in the cluster directories located at %systemroot%\Cluster\MNS.%ResourceGUID%$\%ResourceGUID%$\MSCS. If you put files in the directories below the \Cluster directory, and then delete the Majority Node Set resource, those files will be deleted by the Cluster service.

**Do not change the default security settings on the HKEY_LOCAL_MACHINE system registry subtree.**
By default, only members of the Administrators group in the Builtin folder and the local system account have Full Control of the HKEY_LOCAL_MACHINE system registry subtree. If this registry subtree is compromised, some resources (for example, the Generic Script resource) may fail to start. For more information about securing the system registry, see Maintain Registry Security.

For more information about security in a server cluster, see Managing Security in a Cluster.

# Server Cluster How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

- Create a Cluster and Manage Nodes
- Create and Administer File and Print Server Clusters
- Manage Accounts and Domains in a Cluster
- Manage the Cluster Configuration and Diagnostic Logs
- Perform Advanced Administrative Tasks
- Manage Server Cluster Groups
- Manage Resources
- Use Cluster Administrator
- Manage Networks
- Manage Cluster Hardware
- Back Up and Restore Server Clusters
- Test Cluster Failures and Failover Policies

# Create a Cluster and Manage Nodes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Create a cluster and manage nodes**

- Create a cluster
- Add additional nodes to the cluster
- Evict a node from the cluster
- Repair a node without evicting it from the cluster
- Pause a node
- Resume a node
- Stop the Cluster service
- Start the Cluster service
- Set the Cluster service to only start manually

# Create a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a cluster**

1. Open Cluster Administrator.
2. In the **Open Connection to Cluster** dialog box that appears, in **Action**, select **Create new cluster**, then click **OK**.
3. The New Server Cluster Wizard appears. Click **Next** to continue.

   **Important**

   - During the cluster creation process (using the **Quorum** button on the **Proposed Cluster Configuration** page) you will be able to select a quorum resource type (that is, a Local Quorum resource, Physical Disk or other storage class device resource, or Majority Node Set resource). For information on how these quorum resource types relate to the different cluster models, see "Choosing a cluster model" in Related Topics.

4. Upon completion of the New Server Cluster Wizard, click **Finish**.

**Caution**

- If you are using a shared storage device, when you power on and start the operating system, it is of vital importance that only one node has access to the cluster disk. Otherwise the cluster disks can become corrupted. To prevent the corruption of the cluster disks, shut down all but one cluster node, or use other techniques (for example, Logical Unit Number or LUN masking, selective presentation, or zoning) to protect the cluster disks, before creating the cluster. Once the Cluster service is running properly on one node, the other nodes can be added and configured simultaneously.
- When creating a server cluster, all nodes in the cluster must have the same system default locale. That is, the language and country or region selected during the installation of the operating system on each node must be the same. For more information on changing the system default locale, see "To change number, currency, time, and date settings" in Related Topics.

**Important**

- When you create a cluster, Physical Disk resources will be automatically created for cluster disks that use drive letters. However, if your cluster disks use mount points, Physical Disk resources will not be automatically created for those disks; you must manually create disk resources for cluster disks that use mount points. For more information on how to do this, see "Checklist: Installing a Physical Disk resource" in Related Topics.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- You can also open the New Server Cluster Wizard from the **File** menu, by clicking **New**, then clicking **Cluster**.
- You can safely cancel and restart the installation process at any time.

- A majority node set server cluster is best used in controlled, targeted scenarios, as part of a cluster solution offered by your Original Equipment Manufacturer (OEM), Independent Software Vendor (ISV), or Independent Hardware Vendor (IHV). The single quorum device server cluster, the standard cluster model available in Windows NT and Windows 2000, will still cover the vast majority of your cluster deployment needs.

- Of the default resource types, only the Physical Disk, Local Quorum, or Majority Node Set resource can be a quorum resource. However, third party vendors can supply other storage class resource types that are quorum capable.

  If you want to change the disk used for the quorum resource after creating the cluster, see "Use a different disk for the quorum resource" in Related Topics.

- To create and configure a cluster after an unattended setup, run a script to invoke the **cluster /create:** command and supply all the necessary configuration information on the command line. For information about unattended setup, see "Planning for unattended setup" in Related Topics. For more information on the cluster command line syntax, see "Cluster" in Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add additional nodes to the cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add additional nodes to the cluster**

1. Open Cluster Administrator.
2. In the **Open Connection to Cluster** dialog box that appears, in **Action**, select **Add nodes to cluster**. Then in **Cluster or server name**, either type the name of an existing cluster, select a name from the drop-down list box, or click **Browse** to search for an available cluster.
3. Click **OK** to continue.
4. The Add Nodes Wizard appears. Click **Next** to continue.
5. Upon completion of the Add Nodes Wizard, click **Finish**.

### Caution

- If you are using a shared storage device, when you power on and start the operating system, it is of vital importance that only one node has access to the cluster disk. Otherwise the cluster disks can become corrupted. To prevent the corruption of the cluster disks, shut down all but one cluster node, or use other techniques (for example, Logical Unit Number or LUN masking, selective presentation, or zoning) to protect the cluster disks, before creating the cluster. Once the Cluster service is running properly on one node, the other nodes can be added and configured simultaneously.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- You can also add a node to an existing cluster from the **File** menu, by first clicking **Open Connection** to connect to an existing cluster. Then, you can open the Add Nodes Wizard from the **File** menu, by clicking **New**, then **Node**.
- You can safely cancel and restart the installation process.
- If the computer you are logged onto is already a node on an existing cluster, Cluster Administrator will connect to that cluster by default.
- After you have added new nodes to a server cluster, use Cluster Administrator to fail over the cluster disks and verify that they come back online. For information on how to do this, see "To test whether group resources can fail over" in Related Topics.
- To add nodes to an existing cluster after an unattended setup, run a script to invoke the **cluster /add:** command and supply all the necessary configuration information on the command line. For information about unattended setup, see "Planning for unattended setup" in Related Topics. For more information on the cluster command line syntax, see "Cluster" in Related Topics.
- Allow the process of adding or evicting nodes to complete before changing the quorum in any way. For example, if you are adding a node, wait until that process is complete before changing from a single quorum device cluster to a majority node set cluster.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Evict a node from the cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To evict a node from the cluster**

1. Close all applications on the node that is to be removed.
2. Open Cluster Administrator.
3. Review the failover policies of the resource groups on the node to be evicted.

   For information on how to do this, see "Determining failover and move policies for groups" in Related Topics.
4. If necessary, move all groups on the node to be evicted to another node or nodes in the cluster.

   For information on how to do this, see "To move a group to another node" in Related Topics.
5. Select the node to be evicted.
6. Stop the Cluster service if the node being evicted is not the last node in the cluster. That is, on the **File** menu, click **Stop Cluster Service**.

   For information on how to do this, see "To stop the Cluster service" in Related Topics.

   If the node being evicted is the last node in the cluster, proceed to the next step.
7. On the **File** menu in Cluster Administrator, click **Evict Node**.

**Caution**

- Prior to evicting a node, check with application vendors to determine whether your applications require unclustering.
- Application-specific data may be lost if you do not close your applications before you perform this procedure.

**Important**

- Evicting the last node from the server cluster will not automatically delete the Cluster service account. It is highly recommended that you remove this account from the local Administrators group if you no longer have use for it. However, because the administration rights and permissions for the Cluster service account are granted locally on each cluster node and not domain wide, the impact of a compromised account is limited to just the cluster nodes. For more information, see Best practices for securing server clusters.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- In some cases you may be unable to stop the Cluster service on a node or evict the last node from the cluster, for example, if you are administering a mixed-version server cluster from a Windows 2000 node and try to evict a Windows

Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition node. In these cases, you can manually remove the configuration of the Cluster service on that node by typing **cluster node***node name***/force**[**cleanup**] at the command line. For more information on the **cluster node** command-line options, see Related Topics.

- When you evict a node from the cluster, that node is configured as a stand-alone node (that is, not a cluster node). The clustering software remains installed on the node. You can re-add the evicted node to this cluster or create a new cluster on that node at any time.

- Typically, you remove a node from a cluster when testing, redeploying, or replacing a node.

- Allow the process of adding or evicting nodes to complete before changing the quorum in any way. For example, if you are evicting a node, wait until that process is complete before changing from a single quorum device cluster to a majority node set cluster.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Repair a node without evicting it from the cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To repair a node without evicting it from the cluster**

1. Open Cluster Administrator.
2. In the console tree, click the node requiring repair.
3. On the **File** menu, click **Stop Cluster Service**.
4. If the node must be rebooted after being repaired, set the Cluster service to start manually.

   For more information, see "To set the Cluster service to only start manually" in Related Topics.
5. Perform repair operations on the node.
6. On the **File** menu, click **Start Cluster Service** to restart the Cluster service on that node.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Pause a node

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To pause a node**

1. Open Cluster Administrator.
2. In the console tree, click the node.
3. On the **File** menu, click **Pause Node**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- When you pause a node, existing groups and resources stay online, but additional groups and resources cannot be brought online on the node. Pausing a node is used for maintenance and testing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Repair a node without evicting it from the cluster
Resume a node

# Resume a node

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To resume a node**

1. Open Cluster Administrator.
2. In the console tree, click the node.
3. On the **File** menu, click **Resume Node**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Pause a node
Repair a node without evicting it from the cluster

# Stop the Cluster service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To stop the Cluster service**

1. Open Cluster Administrator.
2. In the console tree, click the node.
3. On the **File** menu, click **Stop Cluster Service**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. In addition, your account must be added to the security descriptor for the Cluster service. To do this, you can use Cluster Administrator or cluster.exe. For more information, see "To give a user permissions to administer a cluster" and "Cluster" in Related Topics. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- When you stop the Cluster service on a node, you prevent clients from accessing cluster resources through that node. In this event, all groups move to another node (if the failover policies allow it).

  This set of circumstances may also affect the availability of the cluster. For example, if the node to which the groups failed over fails, and your cluster consists of only two nodes, there will be no other node available to which the groups can then fail over.
- This procedure, stopping the Cluster service, can also be performed in Computer Management, which may be necessary if Cluster Administrator fails. You can also start the Cluster service in Computer Management.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start the Cluster service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start the Cluster service**

1. Open Cluster Administrator.
2. In the console tree, click the node.
3. On the **File** menu, click **Start Cluster Service**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. In addition, your account must be added to the security descriptor for the Cluster service. To do this, you can use Cluster Administrator or cluster.exe. For more information, see "To give a user permissions to administer a cluster" and "Cluster" in Related Topics. As a security best practice, consider using Run as to perform this procedure. For more information, see Default local groups, Default groups, and Using Run as.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- You can also start the Cluster service from Computer Management. For more information, see "To set the Cluster service to only start manually" in Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the Cluster service to only start manually

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the Cluster service to only start manually**

1. Open Computer Management.
2. In the console tree, click **Services**.

   **Where?**

   - Computer Management/Services and Applications/Services

3. In the details pane, click **Cluster Service**.
4. On the **Action** menu, click **Properties**.
5. In **Startup type**, select **Manual**, and then click **OK**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.
- To start the Cluster service even if there are problems with the quorum resource, you can use **fixquorum** as a start parameter. That is, in **Start parameters**, type **/fixquorum**, and then click **Start**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create and Administer File and Print Server Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Create and administer file and print server clusters**

- Create a cluster-managed printer
- Create a cluster-managed file share
- Create a cluster-managed encrypted file share
- Share subfolders on a File Share resource
- Set client-side caching for a File Share resource
- Enable Shadow Copies for Shared Folders in a cluster

# Create a cluster-managed printer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a cluster-managed printer**

1. Open Cluster Administrator.

2. Create a virtual server, that is, a resource group containing a Network Name resource (where the Network Name resource is the name of a virtual server), an IP address resource, and a Physical Disk resource, if these do not already exist.

   For more information on creating a new resource group and resources, see "To create a new group" and "To create a new resource" in Related Topics.

   For more information, see "Virtual servers" in Related Topics.

3. Create a Print Spooler resource in that virtual server and make it dependent on the Network Name and Physical Disk resources.

   **Important**

   - These two resources are required dependencies for the Print Spooler resource.

   For more information, see "Setting resource dependencies" and "To modify resource dependencies" in Related Topics.

4. Bring the virtual server containing the Print Spooler resource online.

   For more information, see "To bring a group online" in Related Topics.

5. Install printer drivers for your printer on the virtual server.

   **To install printer drivers on the virtual server:**

   a. Click **Start** and then click **Run**.

   b. In the **Run** dialog box, type *MyVirtualServer* where *MyVirtualServer* is the name of the virtual server that the print spooler resource depends on.

      The virtual server opens.

   c. Open **Printers and Faxes**, right-click and select **Server Properties**, then click the **Drivers** tab.

   d. Install the printer drivers.

   **Important**

   The port monitor must be installed on all nodes in the cluster before installing printer drivers on the virtual server. For the Windows Server 2003 family, the port monitor for the Standard TCP/IP Port is installed by default with the operating system. For two other types of ports, you must first install the appropriate port monitor on each node before installing the printer drivers, printer port, and printer queue on the virtual server.

   a. LPR Ports: The LPR port monitor files are shipped on the Windows Server 2003 family media. For more information on installing the LPR port monitor and adding it to the list of **Available port types** for a node, see "To

add a port" in Related Topics.

b. Custom IHV Ports: Printer drivers from Independent Hardware Vendors (IHVs) may include a custom IHV port monitor that must first be installed on each node. To install the IHV port monitor on each node, install the driver package on each virtual server in the cluster. Contact your IHV to verify that the third party port monitor is compatible with the Cluster service before installing on the cluster nodes.

For more information, see "To add printer drivers for other versions of Windows" in Related Topics.

6. Install a printer port for your printer on the virtual server.

   **To install a printer port on the virtual server:**

   a. Click **Start** and then click **Run**.

   b. In the **Run** dialog box, type *MyVirtualServer* where *MyVirtualServer* is the name of the virtual server that the print spooler resource depends on.

      The virtual server opens.

   c. Open Printers and Faxes, right-click and select **Server Properties**, then click the **Ports** tab.

   d. Add a port.

   For more information, see "To add a port" in Related Topics.

7. Add a print queue to the virtual server.

   **To install a print queue on the virtual server:**

   a. Open the remote printers folder of the virtual server.

   b. Use the **Add Printer** Wizard to add a new print queue.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

- You can use the **Add Printer** Wizard to combine steps 5 through 7 above into a single step by adding the printer drivers, printer port, and print queue successively. However, before using the **Add Printer** Wizard in this way, make sure that the appropriate port monitor is already installed on all nodes in the cluster.

- Not all printer ports may be used in a server cluster. LPR and Standard TCP/IP Port, both provided with the Windows Server 2003 family, may be used in a server cluster. Check your printer documentation to verify that your printer can use one of these two ports.

- To share out the printer, you must share out the print queue from the virtual server itself and not from the individual nodes.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a cluster-managed file share

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a cluster-managed file share**

1. Using Windows Explorer, create a folder on the cluster disk.

   **Caution**

   - Do not create a share for this folder.

2. Verify that the Cluster service account has Full Control rights to this folder for the NTFS file system.

   For more information on setting folder permissions, see "To set, view, change, or remove file and folder permissions" in Related Topics.

3. Open Cluster Administrator.

4. Create a Physical Disk resource for the drive on which the folder is located, a Network Name resource, and an IP Address resource, if these do not already exist, and place them in the same resource group.

5. Create a File Share resource in the same resource group as the resources above.

   By default, Cluster Administrator will create a **Normal** File Share resource.

6. Optionally, click **Advanced** to change the File Share resource type from **Normal** to **DFS root** or **Share subdirectories**.

   For more information on these three File Share resource types, see "File Share resource type" in Related Topics.

   **Important**

   - If the file share is configured as a DFS root, it must be dependent on a Network Name resource.

7. Although it is not required, it is recommended that you set up the File Share resource so that it has a dependency on the Physical Disk resource as well as the Network Name resource.

   For more information on creating a new resource and setting up a dependency, see "To create a new resource" in Related Topics.

8. In the details pane, click the File Share resource that you created, then on the **File** menu, click **Properties**.

9. On the **Parameters** tab in **Path**, type the path to the folder whose subfolders you want to share.

10. To configure file share permissions, click **Permissions**.

    For more information about setting permissions, including NTFS permissions, see "To set permissions on a shared resource" in Related Topics.

11. On the **File** menu, click **Bring online**.

**Caution**

- Always use the Cluster Administration tools and not Windows Explorer to manage these file shares. Changes made using Windows Explorer will be lost when these file shares fail over to other nodes in the cluster.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create a cluster-managed encrypted file share

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a cluster-managed encrypted file share**

1. Open Cluster Administrator.
2. Create a cluster-managed file share.

   For more information, see "To create a cluster-managed file share" in Related Topics.
3. In the console tree, double-click **Groups**, and then click the group that contains the File Share resource that you created in step 2.
4. In the details pane, click the Network Name resource in that you will use to connect to this file share.
5. On the **File** menu, click **Take Offline**.
6. On the **File** menu, click **Properties**.
7. On the **Parameters** tab, select **Enable Kerberos Authentication**, and then click **OK**.
8. In the details pane, click the Network Name resource for the file share.
9. On the **File** menu, click **Bring Online**.
10. On the domain controller, configure all accounts used by the cluster nodes to be trusted for delegation. You must also configure the computer account used by the Network Name resource on which you enabled Kerberos to be trusted for delegation.

    For more information, see "To allow a user to be trusted for delegation" in Related Topics.

    **Important**

    - The group containing the file share resource is a virtual server because it contains a Network Name and an IP Address resource. All accounts used to connect to this virtual server must also be trusted for delegation.
11. On the domain controller, enable roaming profiles for all users or service accounts that store data in the folder managed by the File Share resource.

    For more information, see "To create a roaming user profile" in Related Topics.

    **Important**

    - Enabling roaming profiles ensures that the encryption keys for a folder are still valid even when the File Share resource managing that folder fails over.
12. Enable encryption on the folder managed by the File Share resource.

    For more information, see "To encrypt a file or folder" in Related Topics.

**Note**

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Share subfolders on a File Share resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To share subfolders on a File Share resource**

1. Open Cluster Administrator.

2. Create a File Share resource.

   For more information on creating a new resource, see Related Topics.

3. In the console tree, double-click **Groups**, and then click the group that contains the File Share resource that you created in step 2.

4. In the details pane, click the File Share resource that you created. On the **File** menu, click **Properties**.

5. On the **Parameters** tab in **Path**, type the path to the folder whose subfolders you want to share.

6. To configure file share permissions, click **Permissions**.

   For more information about setting permissions, including NTFS permissions, see "To set permissions on a shared resource" in Related Topics.

7. Click **Advanced**, and then click **Share subdirectories** to enable the combo file share option that allows File Share resources to share subfolders. If you want to prevent users from seeing the subdirectory shares when they browse the network, click **Hide subdirectories shares**, and then click **OK**.

   For more information about file and printer sharing, see "File and Printer Sharing for Microsoft networks" in Related Topics.

8. On the **File** menu, click **Bring online**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

- The combo file share option permits a File Share resource to share subfolders. Subfolders of a combo file share are shared using the folder name. You cannot specify a name for a subfolder share. The only way to change a subfolder file share name is to change the subfolder name (for example, using Windows Explorer). Changing the name of a shared subfolder breaks the file share temporarily. The subfolder file share will be unavailable for the time specified by the **File Share resource Is Alive** poll interval. The subfolder will be shared again the next time the **File Share resource Is Alive** poll is called.

- If you select the **Hide subdirectories shares** option you do not have to type $ as the last character when specifying the file share name. The File Share resource will automatically hide the subdirectories when you select the **Hide subdirectories shares** option.

- For more information, see article Q256926, "Implementing Home Folders on a Server" in the Microsoft Knowledge Base.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

# Set client-side caching for a File Share resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set client-side caching for a File Share resource**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the appropriate File Share resource.
4. On the **File** menu, click **Properties**.
5. Click the **Parameters** tab, then click the **Caching** button.
6. Select the **Allow caching of files in this shared folder** check box to enable client-side caching for this File Share resource.
7. In **Setting**, select the appropriate client-side caching setting as shown in the table below.

| Caching setting in Cluster Administrator | Command line option in cluster.exe (cluster resource) | Description |
|---|---|---|
| **Allow caching of files in this shared folder** is not enabled | **CSCCache** is set to 48 | Client-side caching is disabled for all files on the file share. |
| **Automatic caching of programs and documents** | **CSCCache** is set to 32 | Client-side caching is disabled for those files that are only opened, but not modified. |
| **Automatic caching of documents** | **CSCCache** is set to 16 | Changes in all files opened on the client will be reconciled between the client and the server cluster. |
| **Manual caching of documents** | **CSCCache** is set to 0 | Changes in only those files specifically identified on the file share will be reconciled between the client and the server cluster. |

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- Client-side caching allows network users to access files on clustered file shares, even when the client computer is disconnected from the network, by caching these offline files on the client computer. You can also set the client-side caching for a File Share resource at the command line by using the corresponding **cluster resource** command option as shown in the table above. For more information, see "Cluster resource" in Related Topics.
- For more information on setting up your computer to use offline files, see "Sharing a drive or folder overview" in Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable Shadow Copies for Shared Folders in a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Shadow Copies of Shared Folders in a cluster**

1. On the cluster node where you want to enable Shadow Copies of Shared Folders, create a cluster-managed file share.

2. Set up the File Share resource so that it has a dependency on the Physical Disk resource that manages the shadow copies and designated storage volumes, as well as the Network Name resource for the file share.

   For more information, see "To create a cluster-managed file share" in Related Topics below.

   **Important**

   - If the shadow copy volume and the designated storage volume are on separate disks, the Physical Disk resources that manage those volumes must both be in the same resource group.

3. Open Computer Management.

4. In the console tree, right-click **Shared Folders**, select **All Tasks**, and click **Configure Shadow Copies**.

   **Where?**

   - Computer Management/System Tools/Shared Folders

5. Click the volume where you want to enable Shadow Copies of Shared Folders, and then click **Enable**.

   **Important**

   - The Computer Management tool automatically generates a scheduled task to create the shadow copies on the storage volume and a Volume Shadow Copy Service Task resource to manage that scheduled task. It also creates a dependency on the Physical Disk resource that manages the storage volume containing the shadow copies. For more information on the default settings for the Volume Shadow Copy Service Task resource created when you enable Shadow Copies of Shared Folders, see "Using Shadow Copies of Shared Folders in a server cluster" in Related Topics below.

**Important**

- If the shadow copy volume and the designated storage volume are on separate disks, enabling Shadow Copies of Shared Folders will automatically make the Physical Disk resource that manages the shadow copy volume dependent on the Physical Disk resource that manages the storage volume.

- When you enable shadow copies, the shadow copy volumes (and all other resources directly or indirectly dependent on the disk) go offline for a brief period while the resource dependencies are created. The shadow copy volumes are not accessible to applications and users while they are offline.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

- You cannot enable Shadow Copies of Shared Folders for the quorum resource, although you can enable Shadow Copies of Shared Folders for a File Share resource.

- You can also access Shadow Copies of Shared Folders by right-clicking a fixed NTFS volume in **My Computer** or in the Disk Management snap-in details pane (in **Computer Management**). Click **Properties**, and then click the **Shadow Copies** tab.

- You can use the Disk Management snap-in to manage Shadow Copies of Shared Folders on remote servers as well. In the **Computer Management** console tree, right-click **Disk Management**, point to **All Tasks**, and then click **Configure Shadow Copies**.

- By enabling Shadow Copies of Shared Folders, you also create a default schedule and settings for subsequent shadow copies. To make changes to these defaults, click **Settings**.

- You can only enable Shadow Copies of Shared Folders on a per-volume basis; that is, you cannot select specific shared folders and files on a volume to be copied or not copied.

- The scheduled task that is automatically created when you enable shadow copies on a cluster node will only appear in the Scheduled Tasks folder when the associated Volume Shadow Copy Service Task resource is online. If you want to change the schedule, use Computer Management; do not use the Scheduled Tasks folder.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Accounts and Domains in a Cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage accounts and domains in a cluster**

- Change the account under which the Cluster service runs
- Change the Cluster service account password
- Give a user permissions to administer a cluster
- Move a server cluster to another domain

# Change the account under which the Cluster service runs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the account under which the Cluster service runs**

1. Stop the Cluster service on all nodes:

   - Make sure the account has membership in the local Administrators group on all nodes.
   - Open Local Security Policy and Grant the following rights to the account, or to the local Administrators group, on all nodes:

   **Where?** Security Settings/Local Policies/User Rights Assignments

   - **Act as part of the operating system**
   - **Back up files and directories**
   - **Restore files and directories**
   - **Adjust memory quotas for a process**
   - **Log on as a service**
   - **Increase scheduling priority**

   By default, the Cluster service account inherits the following user rights as a result of being a member of the local Administrators group:

   - **Manage auditing and security log**
   - **Debug programs**
   - **Impersonate a client after authentication**

   If your organization has removed these user rights from the default set of privileges assigned to the local Administrators group, you need to specifically assign these user rights to the Cluster service account.

   - Open Computer Management.
   - In Computer Management, double-click **Services and Applications**, and then click **Services**.
   - In the details pane, click **Cluster Service**.
   - On the **Action** menu, click **Stop**.

2. Repeat step 1 on all other nodes.

3. In the details pane of one node, double-click **Cluster service**.

4. On the **Log On** tab, type the account name in **This account**, type the password in **Password**, and then confirm the password and click **OK**.

5. On the **Action** menu, click **Start**.

6. Repeat steps 2, 3, 4, and 5 on all other nodes.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

- To open Local Security Policy, click **Start**, point to **Settings**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Local Security Policy**. Select **Show Advanced User Rights** to view all the available security settings.

- The Cluster service on all nodes must be stopped and restarted during this procedure. The Cluster service must use the same account and password at all times on all nodes within the cluster.

- You must use Active Directory Users and Computers to view account properties if the account is in a Windows 2000 or Windows Server 2003 family domain. You must use User Manager for the Domain to view account properties if the account is in a Windows NT 4.0 domain. User Manager for the Domain can be installed using the client-based Network Administration tools by running Setup.exe from the Windows NT Server 4.0 media in the Clients\Srvtools\Winnt\ directory or by running Usrmgr.exe from the Clients\Srvtools\Winnt\I386 or Clients\Srvtools\Winnt\Alpha directory.

- For more information on granting account rights, see Related Topics.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Updated technical information

# Change the Cluster service account password

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the Cluster service account password**

1. Log on to a computer in the domain. The account you use to log in must belong to the local administrative group on all the cluster nodes.

   **Important**

   - To be able to change the Cluster service account password, you must have appropriate security administrative rights and permissions to be able to traverse directories in the cluster domain even if you do not have user rights on the traversed directory (Bypass traverse checking). By default, this user right is enabled for all users, but some administrators may disable it for everyone.

     For more information, see "Bypass traverse checking" in Related Topics.

   - For multiple clusters that use the same Cluster service account, it is highly recommended that you change the password for all the clusters at the same time.

   - You can only use this procedure to change the Cluster service account if applications (for example, Microsoft SQL Server 2000) do not use the same account as the Cluster service account. If you use this procedure on a server cluster where the Cluster service and one or more applications use the same account, your cluster applications may not function correctly. To resolve this problem, change the application account password (see your application's documentation for details).

2. Open Command Prompt

3. Type the following command, using the table below as a guide:

   **cluster/cluster:***cluster_name1*[,*cluster_name2*, ...] **/changepass**[**word**][**:***new_password*[,*old_password*]] [**/skipdc**] [**/force**] [**/***options*]

   For more information on the other optional password change cluster.exe commands, see "Cluster" in Related Topics.

| Argument | Description |
|---|---|
| **/cluster:***cluster_name1*[,*cluster_name2*, ...] | Identifies the cluster(s) for the account password change. If multiple clusters are specified in one operation, they must all use the same Cluster service account. If some nodes are unavailable, the account password is not changed on any of the nodes nor on the domain controller. |
| **/changepass**[**word**] [**:***new_password*[,*old_password*]] | Changes the Cluster service account password on the domain controller and all the cluster nodes from *old_password* to *new_password*. If not supplied as part of the command, you will be prompted to provide the *new_password* and/or the *old_password*. You can specify a blank password by supplying two double quotes ("""). |
| **/skipdc** | Changes the Cluster service account password only on the cluster nodes. You can use this command if you previously issued a **cluster /changepass** command for multiple clusters and the Cluster service account password was not updated on all the clusters, for whatever reason. If you use this argument, you do not have to supply the *old_password* parameter. |

| | |
|---|---|
| **/force** | Forces the execution of the password change command on the available nodes in the cluster even if some of the cluster nodes are not available.<br><br>**Important**<br><br>• Any node that is down when the password is changed will be unable to later join the cluster until the Cluster service account password for that node is updated manually using Computer Management. |

For the first example, to change the password for clusters CLUS1 and CLUS2 from B2PartTwo! to WordTestPassPartOne! on the domain controller and on all cluster nodes, type:

**cluster /cluster:CLUS1,CLUS2 /changepass:WordTestPassPartOne!, B2PartTwo!**

For the second example, if 2 of the nodes in cluster CLUS1 were down, you could force this password change on the domain controller and on all available cluster nodes in CLUS1 by typing:

**cluster /cluster:CLUS1 /changepass:WordTestPassPartOne!, B2PartTwo! /force**

## Notes

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- To view the complete syntax for this command, at a command prompt, type:

  **cluster /changepass /?**

- If you do not use the **/force** command in a cluster where some of the nodes are unavailable, the Cluster service password for any available cluster nodes or the domain controller will not be updated.

- You cannot use this method to change the Cluster service account password if some nodes in the cluster are running Windows NT or Windows 2000, while others are running Windows Server 2003 family operating systems.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Give a user permissions to administer a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To give a user permissions to administer a cluster**

1. Open Cluster Administrator.
2. Select the cluster.
3. On the **File** menu, click **Properties**.
4. On the **Security** tab, give users permissions to administer the cluster.

### Important

- It is recommended that you allow only trusted personnel to administer a cluster.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- To administer a cluster using Cluster Administrator, you must use an account that is a member of the local Administrators group on each node. The account should be a domain account and can be a member of other groups, such as global groups.
- You can use an account that is a domain user account or a member of a global group to remotely or locally administer a cluster if you use cluster.exe or cluster scripting tools. For more information, see Cluster and the Microsoft Platform Software Development Kit (SDK).
- The local Administrator account and local system account always have access to the cluster.
- When you perform this procedure, the server on which you run Cluster Administrator must run one of the following versions of the operating system and service pack:
    - Windows Server 2003
    - Windows Server 2003 with Service Pack 1
    - A product in the Windows 2000 Server family with Service Pack 2 or later

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Domain accounts and the Cluster service

Change the account under which the Cluster service runs

# Move a server cluster to another domain

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To move a server cluster to another domain**

1. Create a user account for the Cluster service in the new domain.

   For more information, see "To create a new user account" in Related Topics.

2. Open Local Security Policy.

   **Where?**

   - Security Settings/Local Policies/User Rights Assignments

3. Grant that account the following rights:

   - **Act as part of the operating system**
   - **Back up files and directories**
   - **Restore files and directories**
   - **Adjust memory quotas for a process**
   - **Log on as a service**
   - **Increase scheduling priority**

   By default, the Cluster service account inherits the following user rights as a result of being a member of the local Administrators group:

   - **Manage auditing and security log**
   - **Debug programs**
   - **Impersonate a client after authentication**

   If your organization has removed these user rights from the default set of privileges assigned to the local Administrators group, you need to specifically assign these user rights to the Cluster service account.

   **Important**

   - The new Cluster service account must have administrative rights and permissions on all nodes in the cluster.

4. Stop the Cluster service on all nodes.

   For more information, see "To stop the Cluster service" in Related Topics.

5. Power down all nodes except one.

6. Move the node to another domain.

   For more information, see "To join a domain" in Related Topics.

7. Set the Cluster service to start manually.

   For more information, see "To set the Cluster service to only start manually" in Related Topics.

8. Restart the node.

9. On the node, change the service account used by the Cluster service to log on to the domain using the user account you just created.

   **How?**

   a. Open Computer Management.

   b. In the console tree, click **Services**.

      **Where?** Computer Management/Services and Applications/Services

   c. In the details pane, click **Cluster Service**.

   d. On the **Action** menu, click **Properties**.

   e. On the **Log On** tab, select **This account**, and then supply the new account and password.

10. Start the Cluster service.

    For more information, see "To start the Cluster service" in Related Topics.

11. Verify that cluster node is operating correctly.

    **How?**

    a. Bring all resources online.

       For more information, see "To bring a resource online" in Related Topics.

    b. Ping the IP address of the cluster, the individual nodes, and any resource containing an IP address (for example, a virtual server) from all clients. That is, on each client, type the following at the command prompt:

       **ping** xxx.xxx.xxx.xxx

       where xxx.xxx.xxx.xxx is the IP address.

    **Important**

    - At this point, you can still cancel the move by moving this node back into the old domain and starting those nodes that have not yet been moved.

12. Power up another node and repeat steps 5-10 to migrate the other nodes, one by one, to the new domain.

### Caution

- Use this procedure only if your cluster is extremely simple; otherwise recreate your existing cluster in the new domain.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage the Cluster Configuration and Diagnostic Logs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage the cluster configuration and diagnostic logs**

- View the cluster configuration log
- View the cluster diagnostic log
- Change the size of the cluster diagnostic log

# View the cluster configuration log

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the cluster configuration log**

1. Open Command Prompt
2. Locate the ClCfgSrv.log file.

   By default, the log file for the New Server Cluster Wizard and the Add Nodes Wizard can be found at %systemroot%\system32\LogFiles\Cluster\ClCfgSrv.log.
3. Use any text editor to view the log file.

### Important

- After using the New Server Cluster Wizard and the Add Nodes Wizard from a remote computer, the cluster configuration log file generated by those wizards is saved to the remote computer. This log file may contain company-sensitive data such as a complete description of the cluster configuration, including IP addresses. This information could be used by malicious users to attack the cluster; it is recommended that you restrict access to that file to cluster administrators and the Cluster service account. For more information, see Best practices for securing server clusters.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.
- If you do not have administrative rights on the node on which you are using the New Server Cluster Wizard or Add Nodes Wizard, the log file will be written to the local %Temp% directory.
- This log file contains all of the errors, warnings, and informational messages that have been generated by the New Server Cluster Wizard or the Add Nodes Wizard when creating a new cluster or when the cluster membership changes (for example, if a new node is added to the cluster).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

Checklist: Planning and creating a server cluster

# View the cluster diagnostic log

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the cluster diagnostic log**

1. Open Command Prompt
2. Locate the cluster.log file.

   By default, the log file for the Cluster service can be found at %systemroot%\Cluster\cluster.log.
3. Use any text editor to view the log file.

   For more information about interpreting the entries in the cluster log, see "Interpreting the Cluster Log" at the Microsoft Windows Resource Kits Web site.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Change the size of the cluster diagnostic log
Managing the Cluster Service from the Command Line

# Change the size of the cluster diagnostic log

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the size of the cluster diagnostic log**

1. Open Control Panel.
2. Double-click **System**.
3. On the **Advanced** tab, click **Environment Variables**.
4. Under **System variables**, click **New**.
5. In the **New System Variable** dialog box, in **Variable name**, type **ClusterlogSize**, and in **Variable value**, type the size in megabytes that you want the cluster log to be.
6. Click **OK** until you exit the **System Properties** page.
7. Stop and restart the Cluster service. For more information on starting and stopping the Cluster service, see Related Topics.

## Notes

- To open a Control Panel item, click **Start**, click **Control Panel**, and then double-click the appropriate icon.
- The default diagnostic cluster log size is 8 megabytes (MB), but can be changed in the manner described previously.
- When the cluster log file is full, the Cluster service overwrites the first half of the log with the second half. Therefore, if the cluster log size is *n*MB, then only (*n*/2)MB of that log is guaranteed to be valid.
- You must set ClusterlogSize as a System variable, not a user variable.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Perform Advanced Administrative Tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Perform advanced administrative tasks**

- Use a different disk for the quorum resource
- Recover from a corrupted quorum log or quorum disk
- Migrate a multinode cluster to a single-node configuration
- Force quorum in a majority node set server cluster
- Enable Kerberos authentication for virtual servers

# Use a different disk for the quorum resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To use a different disk for the quorum resource**

1. Choose the disk that you will use for the quorum resource. If the disk has two or more NTFS partitions, ensure that all partitions on the disk are assigned drive letters.
2. Open Cluster Administrator.
3. If one does not already exist, create a Physical Disk or other storage-class resource for the new disk.

   For more information, see "Checklist: Installing a Physical Disk resource" in Related Topics.
4. In the console tree, click the Resources folder.
5. In the details pane, click the resource that you will use for the quorum resource.
6. On the **File** menu, click **Take Offline.**
7. In the console tree, click the cluster name.
8. On the **File** menu, click **Properties**.
9. On the **Quorum** tab, click **Quorum resource**, and then select a new disk or storage-class resource you want to use as the quorum resource for the cluster.
10. In **Partition**, if the disk has more than one partition, click the partition where you want the cluster specific data kept.
11. In **Root path**, type the path to the folder on the partition; for example:

    \MSCS\
12. In the console tree, click the Resources folder.
13. In the details pane, click the new quorum resource.
14. On the **File** menu, click **Bring Online**.

**Important**

- If Cluster Administrator does not open, it may be because the Cluster service is not started. To start the Cluster service, see "To set the Cluster service to only start manually" in Related Topics.
- If the quorum resource becomes corrupted, you cannot move it until it is repaired. For more information, see "Node-to-node connectivity problems" in Related Topics.
- If the Cluster service is stopped on any other node, or the node is shut down, that node will not be able to form a cluster. Only nodes that are online when this change is made can form the cluster. However, nodes that are offline can still join the cluster and will be able to form a cluster after they have joined the cluster at least once.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

- Of the default resource types, only the Physical Disk, Local Quorum, or Majority Node Set resource can be a quorum resource. However, third party vendors can supply other storage class resource types that are quorum capable.

- When you are making changes to the quorum, do not add or evict nodes at the same time.

- If you designate a resource as the quorum resource without first taking that resource offline, restart a node afterwards. This will ensure that normal checkpointing is initiated for the quorum resource. Checkpointing is the saving of an extra copy of cluster configuration data and is normally done at four-hour intervals.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Recover from a corrupted quorum log or quorum disk

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To recover from a corrupted quorum log or quorum disk**

1. If the Cluster service is running, open Computer Management.
2. In the console tree, double-click **Services and Applications**, and then click **Services**.
3. In the details pane, click **Cluster Service**.
4. On the **Action** menu, click **Stop**.
5. Repeat steps 1, 2, 3, and 4 for all nodes.
6. If you have a backup of the quorum log, restore the log by following the instructions in "Backing up and restoring server clusters" in Related Topics.
7. If you do not have a backup, select any given node. Make sure that **Cluster Service** is highlighted in the details pane, and then on the **Action** menu, click **Properties**.

   Under **Service status**, in **Start parameters**, specify **/fixquorum**, and then click **Start**.
8. Switch from the problematic quorum disk to another quorum resource.

   For more information, see "To use a different disk for the quorum resource" in Related Topics.
9. In Cluster Administrator, bring the new quorum resource disk online.

   For information about how to do this, see "To bring a resource online" in Related Topics.
10. Click **Start**, click **Run**, and type a command with the following syntax:

    **cluster** [*ClusterName*] **res** *QuorumDiskResourceName* **/maint:on**
11. Run Chkdsk, using the switches **/f** and **/r**, on the quorum resource disk to determine whether the disk is corrupted.

    For more information on running Chkdsk, see "Chkdsk" in Related Topics.
12. Click **Start**, click **Run**, and type a command with the following syntax:

    **cluster** [*ClusterName*] **res** *QuorumDiskResourceName* **/maint:off**
13. If no corruption is detected by Chkdsk, it is likely that the log was corrupted. Proceed to step 15.

    If corruption is detected on the disk, check the system log in Event Viewer for possible hardware errors.

    Resolve any hardware errors before continuing.
14. Stop the Cluster service after Chkdsk is complete, following the instructions in steps 1-4.
15. Make sure that **Cluster Service** is highlighted in the details pane. On the **Action** menu, click **Properties**.

    Under **Service status**, in **Start parameters**, specify **/resetquorumlog**, and then click **Start**.

This restores the quorum log from the node's local database.

**Important**

- The Cluster service must be started by clicking **Start** on the service control panel. You cannot click **OK** or **Apply** to commit these changes as this does not preserve the **/resetquorumlog** parameter.

16. Restart the Cluster service on all other nodes.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.

- The quorum disk must be formatted with the NTFS file system.

- If none of the nodes are running, or one node fails while you are changing the quorum resource, only the running nodes are able to form the cluster, and the offline node is only able to join the cluster. After the offline node has joined the cluster, all nodes are again able to form or join the cluster. This design prevents the offline node from forming the cluster using the old quorum resource.

- Optionally, after step 13 above, you can use the ClusterRecovery tool, available in the *Microsoft Windows Server 2003 Resource Kit*, to restore the registry checkpoint files.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Migrate a multinode cluster to a single-node configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To migrate a multinode cluster to a single-node configuration**

1. If your multinode cluster has been upgraded from Windows 2000 or Windows NT 4.0, open Command Prompt, and type the following to create the Local Quorum resource type:

   **cluster restype "local quorum" /create /dll:clusres.dll /type:"local quorum"**

   If your multinode cluster is not an upgraded cluster, skip this step.

2. Open Cluster Administrator.

3. Create a Local Quorum resource on the node you want to configure as the single-node cluster.

   For more information on creating a new resource, see "To create a new resource" in Related Topics.

   For more information on the Local Quorum resource type, see "Local Quorum resource type" in Related Topics.

4. Remove all nodes from the cluster except the node you want to configure as the single-node cluster.

   For more information on removing a node, see "To evict a node from the cluster" in Related Topics.

5. Verify that the single node now owns all resource groups by clicking on **Groups** in the console tree and reviewing the **Owner** column in the details pane.

6. Change the quorum resource to use the Local Quorum resource.

   In the console tree, click the cluster name. On the **File** menu, click **Properties**. On the **Quorum** tab, click **Quorum resource**, and then select **Local Quorum**.

7. Select the appropriate partition.

8. Select the appropriate directory (root path). By default, the cluster database for a single-node cluster is stored at %systemroot%\Cluster\MSCS.

**Important**

- If the quorum resource becomes corrupted, you cannot move it until it is repaired. For more information, see "Node-to-node connectivity problems" in Related Topics.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

- Of the default resource types, only the Physical Disk, Local Quorum, or Majority Node Set resource can be a quorum resource. However, third party vendors can supply other storage class resource types that are quorum capable.

- Cluster disks on a shared bus must be partitioned as master boot record (MBR) and not as GUID partition table (GPT) disks.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Force quorum in a majority node set server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To force quorum in a majority node set server cluster

1. Open Cluster Administrator.

2. Stop the Cluster service on all remaining nodes.

   For more information on stopping the Cluster service, see "To stop the Cluster service" in Related Topics.

3. Open Registry Editor.

4. Create a String value called ForceQuorum under the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ClusSvc\Parameters subkey

5. Set the value of ForceQuorum to a comma-separated list of the names of the nodes that are to be part of the quorum set.

   For example, if the cluster that has lost quorum contains nodes "Node5", "Node6" and "Node7", then set up the ForceQuorum registry key as "Node5,Node6,Node7".

   **Caution**

   - If you do not list all the nodes stopped in step 2 in the ForceQuorum key, then you must either power off the nodes not listed or physically disconnect them from the network before performing the next step.

6. Start the Cluster service on the remaining nodes.

   For more information on starting the Cluster service, see "To start the Cluster service" in Related Topics.

### Important

- When you force quorum in a majority node set cluster, an error message from the Service Control Manager may appear, indicating that the Cluster service failed to start. You can safely ignore this message at this time; the Cluster service will continue startup after the end of the startup timeout period for Service Control Manager.

- Do not change your cluster configuration while the cluster is operating in this interim state. For example, do not add or remove nodes, or install or modify applications running in the cluster. Changing the cluster configuration in this interim operating state may result in application data inconsistencies.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your

account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable Kerberos authentication for virtual servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Kerberos authentication for virtual servers**

1. Open Cluster Administrator.
2. In the console tree, click the Groups folder.
3. Select the appropriate virtual server.
4. In the details pane, click the Network Name resource for that virtual server.
5. On the **File** menu, click **Take Offline**.
6. On the **File** menu, click **Properties**.
7. On the **Parameters** tab, select **Enable Kerberos Authentication**, and then click **OK**.
8. In the details pane, click the Network Name resource for that virtual server.
9. On the **File** menu, click **Bring Online**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- Do not rename a Network Name resource and change the Kerberos authentication setting at the same time. Instead, allow time for changes to replicate after performing each action. Otherwise, clients might not be able to connect to the virtual server that uses the Network Name resource.
- If you enable Kerberos authentication for a virtual server's Network Name resource, make sure that the Cluster service account has appropriate rights to the computer object associated with that Network Name resource. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Server Cluster Groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage groups**

- Create a new group in a cluster
- Delete a group in a cluster
- Bring a group online
- Take a group offline
- Change the properties of a group
- Set group failover policy
- Set group failback policy
- Specify preferred owners of a group
- Move a group to another node
- Rename a group

# Create a new group in a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a new group**

1. Open Cluster Administrator.
2. On the **File** menu, point to **New**, and then click **Group**.
3. In the New Group Wizard, in **Name**, type a name for the new group.
4. In **Description**, type any comments you want, and then click **Next**.
5. Under **Available nodes**, click the nodes you want to be the preferred owners for the group, and then click **Add**.

   You can also leave **Preferred owners** empty. This means that it does not matter to which node the group fails back after failover takes place. For more information, see "Failover and failback" in Related Topics.
6. To change the priority of an owner, select the owner, click **Move Up** or **Move Down**, and then click **Finish**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The name that you give the group is for administrative purposes only. It is not the same as a network name, which is the name that clients can use to connect to the group. However, make sure this name is different from any other group name in the cluster.
- Cluster Administrator lists the group description and the group name in the details pane.
- All resources within the new group fail over together. To have the group fail back to a certain node, specify that node as the preferred owner and enable failback. You can balance groups among all nodes to maximize the performance of the cluster. However, you can choose not to have a preferred owner if the location of the group does not greatly affect performance.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete a group in a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a group**

1. Open Cluster Administrator.
2. In the console tree, click the Groups folder.
3. In the details pane, click the group you want to remove.
4. Delete or move all resources in the group.

   For more information on deleting or moving resources, see Related Topics.
5. On the **File** menu, click **Delete**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

# Take a group offline

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To take a group offline**

1. Open Cluster Administrator.
2. In the console tree, double-click the Groups folder.
3. In the details pane, click the group you want.
4. On the **File** menu, click **Take Offline**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- Resources in a group go offline in the order of their dependencies.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the properties of a group

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the properties of a group**

1. Open Cluster Administrator.
2. In the console tree, click the Groups folder.
3. In the details pane, click the group you want.
4. On the **File** menu, click **Properties**.
5. Click each tab and set the various properties for the group.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The settings on the tabs give general information about the group and define how it performs during failover and failback.
- Every new cluster includes at least one default group: Cluster Group. This group contains the settings for the default cluster and some typical resources that provide generic information and failover policies. Do not delete or rename the Cluster Group or move the resources in it.

  It is important to keep the Cluster Group separate. If another resource is added to this group and the resource fails, it may cause the Cluster Group to fail also, making it impossible to access the cluster using the cluster name.

  If the quorum resource is located in the Cluster Group and that resource group is moved, state change operations for other resource groups will be blocked until the Cluster Group move is completed.

  The availability of the quorum resource takes priority over failover policies set for other resources in the Cluster Group.
- You can use the default groups as templates for creating your own groups. For example, you might add an IP Address resource, Network Name resource, and a Generic Script IIS FTP service resource to Disk Group 1, and then rename the group FTP Group.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set group failover policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set group failover policy**

1. Open Cluster Administrator.
2. In the console tree, click the Groups folder.
3. In the details pane, click the appropriate group.
4. On the **File** menu, click **Properties**.
5. On the **Failover** tab, type values for **Threshold** and **Period**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The failover policy for a group is the maximum number of times (**Threshold**) that the group is allowed to fail over in the specified number of hours (**Period**) before it is left in a failed state. If a group fails over more often than this, the Cluster service leaves it offline. For example, if a group failover threshold is set to 5 and its failover period to 3, the Cluster service will fail over the group at most five times within a three-hour period. The sixth time a resource in the group fails, the Cluster service fails all other resources in the group and leaves the entire group offline instead of failing over the group.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Server Cluster groups

# Set group failback policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set group failback policy**

1. Open Cluster Administrator.
2. In the console tree, click the Groups folder.
3. In the details pane, click the appropriate group.
4. On the **File** menu, click **Properties**.
5. On the **Failback** tab, click **Prevent failback** or **Allow failback**.

   If you click **Allow failback**, then either click **Immediately**, or click **Failback between** and set the time interval.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- To set the time interval for **Failback between**, enter numbers between 0 and 23 for the beginning and end of the interval. If the first number is greater than the second, the interval ends on the following day. The numbers correspond to the local time of the cluster group, as read on a 24-hour clock.

  It is important to set the failback time because you may not want failback to occur during hours of peak usage.
- If no preferred owners are specified for the group, then failback does not occur.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Specify preferred owners of a group

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify preferred owners of a group**

1. Open Cluster Administrator.
2. In the console tree, click the Groups folder.
3. In the details pane, click the appropriate group.
4. On the **File** menu, click **Properties**.
5. On the **General** tab, next to **Preferred owners**, click **Modify**.
6. In the **Modify Preferred Owners** dialog box, enter any changes you want to make:
   - To add one or more preferred owners, under **Available nodes**, not **Preferred owners**, click the nodes you want to add, and then click the right arrow.
   - To remove a preferred owner, under **Preferred owners**, click the nodes you want to remove, and then click the left arrow.
   - To change the priority of a preferred owner, click the node, and then click the up or down arrow.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- If more than one node is listed under **Preferred owners**, failover priority is determined by the order of the list. It also controls failback behavior. If failback is enabled, the group will fail back to the highest-priority node that is available. For more information, see "Determining failover policies for groups" in Related Topics.
- If no preferred owners are specified, failback does not occur.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Move a group to another node

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To move a group to another node**

1. Open Cluster Administrator.
2. In the console tree, double-click the Groups folder.
3. In the console tree, click the group you want to move.
4. On the **File** menu, click **Move Group**.
5. In clusters with more than two nodes, select **Best Possible** or select the node to which you want to move the group.

   For more information on the logic used for the **Best Possible** option, see "Determining failover and move policies for groups" in Related Topics.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- After the transfer, the new node owns all resources in the group. Verify that the **Owner** column in the details pane reflects this change.
- A list of the nodes in the cluster appears only in clusters containing three or more nodes.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Rename a group

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To rename a group

1. Open Cluster Administrator.
2. In the console tree, expand the Groups folder.
3. In the details pane, click the group you want to rename.
4. On the **File** menu, click **Rename**.
5. In the details pane, type a new name for the group.

   This name is for administrative purposes only.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The group name must be different from any other group name in the cluster.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage resources**

- Create a new resource
- Delete a resource
- Bring a resource online
- Take a resource offline
- Run a disk maintenance tool such as Chkdsk on a Physical Disk resource
- View or set resource properties
- View or set resource type properties
- Specify the restart policy for a resource
- Modify resource dependencies
- Specify which nodes can own a resource
- Move a resource to another group
- Rename a resource
- Initiate a resource failure

# Create a new resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create a new resource**

1. Open Cluster Administrator.
2. In the console tree, double-click the Groups folder.
3. In the details pane, click the group to which you want the resource to belong.
4. On the **File** menu, point to **New**, and then click **Resource**.
5. In the New Resource Wizard, type the appropriate information in **Name** and **Description**, click the appropriate information in **Resource type** and **Group**, and then click **Next**.
6. Add or remove possible owners of the resource, and then click **Next**.
7. To add dependencies, under **Available resources**, click a resource, and then click **Add**.

   Or, to remove dependencies, under **Resource dependencies**, click a resource, and then click **Remove**.
8. Repeat step 7 for any other resource dependencies, and then click **Next**.
9. Set resource properties in the *resource***Parameters** dialog box, where *resource* is the name of the resource type.

   Different resource types contain different configuration information in their respective dialog boxes.

   For more information on setting resource properties, see Related Topics.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- Before adding a resource to your cluster, you must verify that the following are true:
  - The type of resource is either one of the basic types provided with the Windows Server 2003 family or a custom resource type provided by the resource vendor.
  - A group already exists within the cluster to which your resource will belong.
  - All dependent resources have been created.
- A resource that fails frequently can affect its associated Resource Monitor and other resources interacting with that Resource Manager. For this reason, a separate Resource Monitor is recommended for any resource that has failed repeatedly in the past.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete a resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete a resource**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the resource you want to remove.
4. On the **File** menu, click **Delete**.

   **Caution**

   - When you delete a resource, Cluster Administrator also deletes all the resources that have a dependency on the deleted resource.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The Cluster service requires that a resource be offline before deleting it. If the resource is online, Cluster Administrator will automatically take the resource offline before deleting it.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Bring a resource online

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To bring a resource online**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the resource you want.
4. On the **File** menu, click **Bring Online**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- Bringing a resource online causes all resources on which the resource depends to be brought online.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Take a resource offline

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To take a resource offline**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the resource you want.
4. On the **File** menu, click **Take Offline**.

   **Caution**

   - Taking a resource offline causes all resources that depend on that resource to be taken offline.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

# Run a disk maintenance tool such as Chkdsk on a Physical Disk resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To run a disk maintenance tool such as Chkdsk on a Physical Disk resource**

1. Determine whether an application is dependent on the Physical Disk resource and whether that application will fail (or will not respond smoothly) if it cannot access or write to the disk. If so, pause or stop the application, or notify users that the application will become unavailable.

2. Open a command prompt.

3. Turn on maintenance mode by typing a command with the following syntax:

   **cluster** [*ClusterName*] **res** *DiskResourceName* **/maint:on**

4. Confirm that maintenance mode is on by typing a command with the following syntax:

   **cluster** [*ClusterName*] **res** *DiskResourceName* **/maint**

5. Run your disk maintenance tool, for example, Chkdsk.

6. When the maintenance tool has finished running, type a command with the following syntax:

   **cluster** [*ClusterName*] **res** *DiskResourceName* **/maint:off**

7. Confirm that maintenance mode is off by typing a command with the following syntax:

   **cluster** [*ClusterName*] **res** *DiskResourceName* **/maint**

8. Check the state of any application that is dependent on the Physical Disk resource. If necessary, restart the applications and inform users that the applications are available.

**Notes**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

- You can use maintenance mode only on a Physical Disk resource, and only when that resource is online.

- Maintenance mode is designed to allow maintenance tools to run on a Physical Disk resource without being interrupted by failover. While maintenance mode is on, the resource appears to be online, but your maintenance tool might make the disk unavailable to applications (for example, when you run Chkdsk with the **/f** option to fix disk errors, the disk becomes unavailable). While maintenance mode is on, failures from Looks Alive and Is Alive polling are ignored and therefore the running of the maintenance tool on the resource does not trigger a failover.

- Maintenance mode will remain on until you turn it off or until one of the following occurs:

  - The resource goes offline or fails.

  - The node on which the resource is running restarts or loses communication with other nodes (which causes failover of all resources on that node).

- As soon as any maintenance tools (for example, Chkdsk) have finished running, turn the maintenance mode off.
- An event is logged when maintenance mode is turned on or off.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**Formatting legend**

| Format | Meaning |
| --- | --- |
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

# Specify the restart policy for a resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify the restart policy for a resource**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the resource you want.
4. On the **File** menu, click **Properties**.
5. On the **Advanced** tab, make the changes you want.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The settings on the **Advanced** tab specify the restart policy for a resource.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Specify which nodes can own a resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify which nodes can own a resource**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the appropriate resource.
4. On the **File** menu, click **Properties**.
5. On the **General** tab, next to **Possible owners**, click **Modify**.
6. Specify which nodes you want to be possible owners.
   - To add a possible owner, under **Available nodes**, click a node, and then click the right arrow.
   - To remove a possible owner, under **Possible owners**, click a node, and then click the left arrow.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- A possible owner is a node that is capable of running a resource.
- If you want to make a group capable of failing over, it must have more than one possible owner.
- If a resource has no possible owners, it will not come online. This can be useful if you want to keep a resource offline but you do not want to delete it and lose its configuration settings.
- If the resource DLL for a particular resource type is not available on some nodes, these nodes are automatically removed from the possible owners list for all the resources of this type.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Move a resource to another group

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To move a resource to another group**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the resource you want to move.

   **Caution**

   - When you move a resource to another group, all resources that depend on it or on which it depends are also moved.

4. On the **File** menu, point to **Change Group**, and then click the name of the group to which you want to transfer ownership. Alternatively, you can select the resource you want to move, then drag and drop it to another group.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Rename a resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To rename a resource**

1. Open Cluster Administrator.
2. In the console tree, click the Resources folder.
3. In the details pane, click the resource you want to rename.
4. On the **File** menu, click **Rename**.
5. Type a new name for the resource.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- Changing the name of a resource does not affect the failover policy for that resource or for the other resources in the group to which it belongs. Also, changing the resource name does not affect the dependencies that other resources might have on the resource.
- The resource name is only used for administrative purposes.
- The resource name must be unique within the same cluster; other clusters may use the same resource name.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Take a resource offline

# Initiate a resource failure

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To initiate a resource failure**

1. Open Cluster Administrator.
2. In the console tree, click the Groups folder, and then click the group that contains the resource to fail.
3. In the details pane, click the resource you want.
4. On the **File** menu, click **Initiate Failure**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- When a resource fails, it automatically restarts if a restart policy is defined for it.
- If a resource fails repeatedly, the entire group to which the resource belongs can fail over, depending on the failover policy defined for the group.
- This command is useful for testing the restart and failover policies of the resource and group.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Use Cluster Administrator

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Use Cluster Administrator**

- Connect to a cluster with Cluster Administrator
- Change the maximum quorum-log size
- Rename a cluster
- Start the Cluster Application Wizard
- Start Cluster Administrator in Microsoft Management Console

# Connect to a cluster with Cluster Administrator

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect to a cluster with Cluster Administrator**

1. Open Cluster Administrator.
2. If you are already connected to an existing cluster, on the **File** menu, click **Open Connection**.

   If you are not connected to a cluster, the **Open Connection to Cluster** dialog box will appear.
3. In **Action**, select **Open connection to cluster**. Then in **Cluster or server name**, type the network name or IP address of an existing cluster, or select a name from the drop-down list box, or click **Browse** to search for an available cluster.

### Caution

- If you use Cluster Administrator or cluster.exe to manage a server cluster, the locale settings for the user account must match the system default locale on the computer used to manage the cluster. For more information on changing the system default locale, see "To change number, currency, time, and date settings" in Related Topics.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- When you start Cluster Administrator, connections left open when you closed the previous session are restored. If no connections were left open, Cluster Administrator prompts you to type a cluster name, a node, or an IP address before it displays any information. If you do not want to open old connections, you can start Cluster Administrator from the command line with the **cluadmin /noreconnect** command. For more information on administering a cluster from the command line, see "Managing a server cluster from the command line" in Related Topics.
- You can simultaneously connect to multiple clusters, but be aware that multiple connections can affect the performance of Cluster Administrator.

  To prevent this problem, you can start a new instance of Cluster Administrator for each cluster you want to administer.
- Use the network name or IP address of either the cluster or one of its nodes to open a connection to a cluster. If Cluster Administrator cannot find the cluster by its name, type the name of an active node in the cluster. You can also connect to the cluster by opening Cluster Administrator on a cluster node and entering a PERIOD (.) in **Cluster or server name**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Managing a Server Cluster from the Command Line

# Change the maximum quorum-log size

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the maximum quorum-log size**

1. Open Cluster Administrator.
2. In the console tree, click the cluster.
3. On the **File** menu, click **Properties**.
4. Click the **Quorum** tab.
5. In **Reset quorum log at**, type the maximum size (in increments of 64 kilobytes) that the quorum log file can be before the cluster resets it.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The cluster records all changes to the cluster database in the quorum log file. When the quorum log attains the specified size, the cluster saves the database and resets the log file.
- By default, the maximum size of the quorum log is 4096 kilobytes. You may want to increase the size of the quorum log if the cluster checkpoint file stored on the quorum disk is larger than 4096 kilobytes.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Rename a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To rename a cluster**

1. Open Cluster Administrator.
2. In the console tree, click the cluster you want to rename.
3. On the **File** menu, click **Rename**.
4. Type the new name for the cluster next to its icon.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The cluster name cannot be the same as the computer name of a cluster node, and it cannot conflict with any other server, cluster, or domain name in use on your network.
- The new name does not take effect until the Cluster Name resource is taken offline and brought back online. The Cluster Name resource is found in the Cluster Group resource group in a newly created cluster.
- The cluster name can also be changed by displaying the properties of the Cluster Name resource, selecting the **Parameters** tab, then clicking on the **Rename** button.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start the Cluster Application Wizard

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start the Cluster Application Wizard**

1. Open Cluster Administrator.
2. On the **File** menu, click **Configure Application**.
3. Follow the instructions in the wizard and provide all the information required to run the application on a server cluster, for example, the virtual server to host the application, the resource to manage your application, resource dependencies, failover and failback policies, and so on as shown in the table below.

| Information required | What it is used for |
|---|---|
| Internet protocol (IP) address | To create a new virtual server for your application, you need an IP address. You do not need an IP address if your application runs in an existing virtual server. |
| Virtual server resource group | Your clients will access your application through a virtual server: a cluster resource group with an IP address and a network name. Using the wizard, you can create a new resource group for a virtual server, use an existing resource group, or use an existing virtual server. |
| Resource type for your application | You can create a resource to manage your application using the wizard. You need to know the resource type for the resource. |
| Application resource name | If you use the wizard to create a resource for your application, you must name the resource. |
| Application resource dependencies | If the application requires other resources to run, you can create resource dependencies using the wizard. |

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start Cluster Administrator in Microsoft Management Console

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start Cluster Administrator in Microsoft Management Console**

1. Open Computer Management.
2. In the console tree, double-click to expand **Services and Applications**.
3. Right-click **Cluster**, and then click **Manage**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.
- Cluster Administrator is not a Microsoft Management Console (MMC) snap-in.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Networks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage networks**

- Change the name or description of a network
- Enable a network for cluster use
- Disable a network for cluster use
- Change how the cluster uses a network
- Change the description of a network interface
- Change network priority for communication between nodes
- Troubleshoot client-to-virtual server connectivity

# Change the name or description of a network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the name or description of a network**

1. Open Cluster Administrator.
2. In the console tree, double-click to expand **Cluster Configuration**, and then click **Networks**.
3. In the details pane, click the network.
4. On the **File** menu, click **Properties**.
5. To change the name of the network, in **Name**, type a new name.
6. To describe the network, in **Description**, type a new description.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The description provides information about the network. It appears in the details pane of Cluster Administrator when you click the Networks folder. The network description is optional.
- When the name of a network is changed in the cluster, the name of the associated network connection is changed in the Network Connections folder on every node in the cluster.

  Also, if the name of a network connection in the Network Connections folder on any node is changed, the associated network in the cluster will also be changed, along with the network connection on all other nodes.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable a network for cluster use

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable a network for cluster use**

1. Open Cluster Administrator.
2. In the console tree, double-click to expand **Cluster Configuration**, and then click **Networks**.
3. In the details pane, click the network you want to enable.
4. On the **File** menu, click **Properties**.
5. Select the **Enable this network for cluster use** check box.
6. Specify how you want the network to be used by the cluster:
    - To use the network for communications with clients and between nodes, click **All communications (mixed network)**.
    - To use the network only for communications between nodes, click **Internal cluster communications only (private network)**.
    - To use the network only for communications with clients, click **Client access only (public network)**.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- If multiple network interfaces exist on the same subnet, only the first one can be used. Others will be ignored by the Cluster service.
- With Windows Server 2003 with Service Pack 1, if you use Windows Firewall, use the Security Configuration Wizard to configure it. For more information, see "Using Windows Firewall with a Server Cluster" in Related Links.
- If you are protecting your network with a firewall other than Windows Firewall, take note of the following list of ports needed by server clusters:
    - 135 (RPC endpoint mapper/DCOM).
    - 135 (RPC endpoint mapper over UDP).
    - 3343 (used by the Cluster Network Driver).
    - 445 (SMB).
    - 139 (NetBIOS session service).

- For cluster nodes running many services, ports 5000-5099 (or more) might need to be open for remote RPC connectivity to Cluster Administrator. When these ports are closed, event log error 1721 might occur when you connect to a cluster through Cluster Administrator (unless you just type a period in Cluster Administrator).

  This problem can occur because the Cluster service requires at least 100 ports for communication through remote procedure calls (RPC). The number of ports available to the Cluster service can become too small when other services are using some of the necessary ports. Such services include Windows DNS service, Windows Internet Name Service (WINS), the Microsoft SQL Server service, and others.

- If the nodes are separated by a firewall, ports 8011-8031 must be open for internode RPC connectivity. Otherwise, errors in the cluster log will indicate that a "Sponsor" is not available. These errors occur because there are not enough ports available for RPC communication between a node that is trying to join the cluster and a node that can "sponsor" that node.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Disable a network for cluster use

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To disable a network for cluster use**

1. Open Cluster Administrator.
2. In the console tree, double-click to expand **Cluster Configuration**, and then click **Networks**.
3. In the details pane, click the network you want to disable.
4. On the **File** menu, click **Properties**.
5. Clear the **Enable this network for cluster use** check box.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- After you disable a network for cluster use, the cluster cannot use the network for any communications between nodes or with clients.
- Before you disable a network for cluster use, verify that IP address resources are not configured to use that network. If IP address resources are configured to use the network, you will be unable to clear the **Enable this network for cluster use** check box.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change how the cluster uses a network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change how the cluster uses a network**

1. Open Cluster Administrator.
2. In the console tree, double-click to expand **Cluster Configuration**, and then click **Networks**.
3. In the details pane, click the appropriate network.
4. On the **File** menu, click **Properties**.
5. Under **Enable this network for cluster use**, specify how you want the network to be used by the cluster:
   - To use the network for communication with clients and between nodes, click **All communications (mixed network)**.
   - To use the network only for communications between nodes, click **Internal cluster communications only (private network)**.
   - To use the network only for communications with clients, click **Client access only (public network)**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- It is strongly recommended that at least two networks be configured for communication among nodes (either private or mixed). For more information, see "Best practices for configuring and operating server clusters" in Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the description of a network interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the description of a network interface**

1. Open Cluster Administrator.
2. In the console tree, double-click to expand **Cluster Configuration**, and then click **Network Interfaces**.
3. In the details pane, click the interface for the network on a node.
4. On the **File** menu, click **Properties**.
5. In **Description**, type information about the network interface on the node.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- The description can provide information about the network interface on a specific node. Your information appears in the details pane when you click the Network Interfaces folder. The description is optional. However, it is strongly recommended that the network interface description reflects its role.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change network priority for communication between nodes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change network priority for communication between nodes**

1. Open Cluster Administrator.
2. In the console tree, click the cluster.
3. On the **File** menu, click **Properties**.
4. Click the **Network Priority** tab.
5. Under **Networks used for internal cluster communications**, click a network.
6. Click **Move Up** to increase the network priority.

   - or -

   Click **Move Down** to lower the network priority.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- If multiple networks are configured as private or mixed, you can specify which one to use for internode communication. It is recommended that private networks have higher priority than mixed networks. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Troubleshoot client-to-virtual server connectivity

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To troubleshoot client-to-virtual server connectivity**

Follow the steps below to troubleshoot client-virtual server connectivity issues.

1. Make sure the IP address and dependent Network Name resources are online.

2. Use **ipconfig /all** to examine the TCP/IP configuration for all adapters. Make sure the IP address of the resource is registered to the correct adapter and that each adapter has a primary address. If the resource's IP address is not registered but the resource is online, take the resource offline and then bring it back online. If the address is still not registered with the correct adapter, consult the diagnostic cluster log.

3. If NetBIOS has been enabled for the IP address resource, verify that the network name is properly associated with its dependent IP address resource.

   Use **nbtstat** to display the node's NetBIOS name registrations. For example, type the following at the Windows Server 2003 family command prompt:

   **nbtstat -n**

   The output from this command displays the IP addresses that are registered with NetBIOS. Cluster IP address resources are listed under the heading, **\Device\NetBt_IF***x*, where *x* is a number. Under **NetBIOS Local Name Table**, you will find the NetBIOS names that are associated with the IP addresses. For each dependent network name, there are two entries: *Name***<20>** and *Name***<00>**, where *Name* is the virtual network name.

   The following is an example of this output:

   **\Device\NetBt_If2:**

   **Node ipAddress: [172.31.248.167] Scope Id: []**

   **NetBIOS Local Name Table**

   | Name | Type | Status |
   |---|---|---|
   | CLWCLUS | <20> Unique | Registered |
   | CLWCLUS | <00> Unique | Registered |

   If the NetBIOS names are unregistered, or if there are registration conflicts, use **nbtstat -rr** to release the old NetBIOS names and renew their registrations. For example, type the following at the Windows Server 2003 family command prompt:

   **nbtstat -rr**

4. Verify that DNS is available and functioning correctly.

   Use the **netdiag** command line tool (available in the *Microsoft Windows Server 2003 Resource Kit*) to evaluate the registration of DNS. For example, type the following at the Windows Server 2003 family command prompt:

   **netdiag /test:DNS /d:***xxx.xxx.xxx.xxx***/debug**

   where *xxx.xxx.xxx.xxx* is the IP address of the virtual server.

   If the output suggests that connectivity to the DNS server is suspect or DNS registration for the virtual name may have

failed, check to see that the network connections on the virtual server are configured with the correct IP addresses of the DNS servers to be used for name resolution.

5. Try to ping the group's IP address from all clients and cluster nodes.

   For example, on each client, and all cluster nodes, type the following at the Windows Server 2003 family command prompt:

   **ping** *xxx.xxx.xxx.xxx*

   where *xxx.xxx.xxx.xxx* is the IP address of the virtual server.

   This tests for physical connectivity between the clients and cluster node, and between the cluster nodes.

6. Try to ping the virtual server network name from each client and cluster node.

   For example, at the Windows Server 2003 family command prompt on each client and on all cluster nodes, type the following:

   **ping** *Netname*

   where *Netname* is the network name for the virtual server.

   This test uses the appropriate name-resolution mechanism (DNS or WINS). If you can ping the IP address but ping returns **unknown host** when you ping the network name, then the client is unable to resolve the network name to an IP address. Check connectivity to the name server or servers by pinging their IP addresses (**ipconfig all** will list the addresses for each network adapter). If DNS is in use on the network but the name returned is not a fully qualified domain name (FQDN), (that is, just the NetBIOS name is returned), then connectivity to the DNS server is suspect or DNS registration for the virtual name may have failed.

7. If the virtual server has a File Share resource, try to connect to the resource using **net use**.

   For example, at the Windows Server 2003 family command prompt, type the following:

   **net use** * *Virtualserver**Sharename*

   where *Virtualserver* is the network name for the virtual server and *Sharename* is the share name for the File Share resource.

   If you are unable to connect to the resource, you may not have the appropriate permissions set for the resource. For more information, see "Set permissions on a shared resource" in Related Topics.

8. If clients are unable reconnect to the virtual server after a failover or move, verify that the router/switch between the client and the cluster is able to correctly handle the ARP cache flush protocol. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage Cluster Hardware

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Manage cluster hardware**

- Install local storage buses and devices
- Connect the shared storage buses and assign drive letters
- Add drives on the shared storage bus
- Add a network adapter
- Install an additional shared storage bus
- Replace the redundant array of independent disks (RAID) controller
- Configure the Always On power scheme without Terminal Services installed
- Configure the Always On power scheme with Terminal Services installed

# Install local storage buses and devices

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install local storage buses and devices**

1. Move all groups off the node on which you want to add the hardware.

   For more information, see "To move a group to another node" in Related Topics.

2. Shut down Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition on the node to which you want to add the hardware, and then turn off the computer.

3. Install and configure the card and devices for the new local storage bus, and then install the appropriate drivers.

4. Turn on the computer and restart Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition on the node to which you added the hardware.

5. If you installed a new drive, partition and format it, assigning new drive letters or mounted drives as appropriate.

6. If you want to use Encrypted File System (EFS) on this local device, enable encryption on the device (using either the drive letter or mount point). Then, create roaming profiles for all users or service accounts that store data on that device.

   For more information, see "To encrypt a file or folder" and "To create a roaming user profile" in Related Topics.

7. In Cluster Administrator, verify that the node has rejoined the cluster.

8. Move the groups referenced in step 1 to the node with the new hardware, as appropriate for your cluster configuration.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Connect the shared storage buses and assign drive letters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To connect the shared storage buses and assign drive letters**

1. Install Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition on all nodes.

   **Caution**

   - All nodes in a cluster must be running the same version of the operating system, that is, either Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. You cannot run both Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition on nodes in the same cluster.

2. Prepare the controllers for the shared storage bus, following the instructions in your storage bus owner's manual.

3. Install the controllers for the shared storage bus, but do not connect them to the shared storage bus.

4. Connect the shared storage devices to the shared buses, and then connect the shared storage buses to all nodes.

5. Start the operating system on the first node on which you intend to create the cluster.

6. Format the disks on the cluster storage device as NTFS.

   For more information, see "To format a basic volume" in Related Topics.

   **Caution**

   - Each disk on the cluster storage device must be a basic disk, not a dynamic disk.

7. Partition the disks on the cluster storage device.

   For more information, see "To create a partition or logical drive" in Related Topics.

8. Do one of the following:

   - Assign drive letters to the disks on the cluster storage device.

   - Assign mount points to the disks on the cluster storage device.

     For more information, see "To assign, change, or remove a drive letter" and "To create a mounted drive" in Related Topics.

   **Caution**

   - Make sure that you create unique mounted drives so that they do not conflict with existing local drives on any node in the cluster.

   - Do not create mounted drives between disks on the cluster storage device (cluster disks) and local disks.

   - Do not create a mounted drive from a clustered disk to the cluster disk that contains the quorum resource (the

quorum disk). You can, however, create a mounted drive from the quorum disk to a clustered disk.

- Mounted drives from one cluster disk to another must be in the same cluster resource group, and must be dependent on the root disk.

9. Label all partitions to match their drive letters or mount points assigned in the step above.

10. Use Cluster Administrator to add the first node to the cluster.

    For more information, see "To add the first node to the cluster" in Related Topics.

    **Caution**

    - Completely create the cluster on one node before you join additional nodes to the cluster.

    **Important**

    - When you create a cluster, Physical Disk resources will be automatically created for cluster disks that use drive letters. However, if your cluster disks use mount points, Physical Disk resources will not be automatically created for those disks; you must manually create disk resources for cluster disks that use mount points. For more information on how to do this, see "Checklist: Installing a Physical Disk resource" in Related Topics.

11. Join one or more additional nodes to the cluster.

    For more information, see "To add additional nodes to the cluster" in Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

# Add drives on the shared storage bus

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add drives on the shared storage bus**

1. Turn off all nodes.

   **Important**

   - Unless your shared drive supports hot swapping, you must shut down and turn off all cluster nodes to add drives. If your shared drive supports hot swapping, turn off all but one node.

2. Add or replace drives on the shared storage bus, following the manufacturer's recommendations on configuring a new drive.

3. Turn on the first node, if it is not already on.

4. On the first node, use Computer Management to:

   - Write a signature to the new disk.
   - Make sure the disk is a basic disk and not a dynamic disk.
   - Format the drive as NTFS.
   - Partition the drive.

     For more information, see "To create a partition or logical drive" in Related Topics.

   - Assign drive letters or mount points to the partitions on the disk that do not conflict with any other local or clustered drive letters or mount points already in use.

     For more information, see "To assign, change, or remove a drive letter" and "To create a mounted drive" in Related Topics.

   - Label each partition to match its corresponding drive letter or mount point.

5. Create a Physical Disk or other storage-class type resource for the new disk.

   For information on how to do this, see "Checklist: Installing a Physical Disk resource", and "To create a new resource" in Related Topics.

6. Bring the new resource online.

   For information on how to do this, see "To bring a resource online" in Related Topics.

7. Restart all remaining nodes.

8. Make sure the new drive is functioning correctly by placing the Physical Disk resource in a separate group and successively failing that group over to the other nodes in the cluster.

   For information on how to do this, see "To test whether group resources can fail over" in Related Topics.

**Notes**

- To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.
- On a 2-node SCSI bus, the SCSI host adapters must each have a unique SCSI ID (usually the numbers 6 and 7). In addition, the SCSI bus must be properly terminated.
- On a Fibre Channel bus, devices can be added at any time.
- Cluster disks on a shared bus must be partitioned as Master Boot Record (MBR) and not as GUID partition table (GPT) disks.
- For a quorum resource, you cannot enable Shadow Copies of Shared Folders.
- For mounted drives, do not create mount points between clustered and local disks and do not create mount points to the Quorum disk. If you assign mount points from one shared disk to another, the disks must be in the same resource group and the mounted drive must be dependent on the root disk.
- You can enable Encrypted File System (EFS) on this cluster device and make encrypted directories accessible to clients. For more information, see "To create a cluster-managed encrypted file share" in Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add a network adapter

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add a network adapter**

1. Shut down the operating system on the node to which you want to add the hardware, and then turn off the computer.
2. Install the adapter.
3. Turn on the computer and restart the operating system on the node to which you added the hardware.
4. Load the driver for the network adapter.

### Note

- Confirm that your hardware is designed for Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition by reviewing the compatibility information in Support resources.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Install an additional shared storage bus

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install an additional shared storage bus**

1. Shut down the operating system on all nodes and turn off all computers.
2. Prepare one controller for the shared storage bus, referring to your storage bus owner's manual for instructions.

   Install the controllers for the shared storage bus, but do not connect them to the shared storage bus.

   For SCSI controllers, make sure that the SCSI controllers for the shared SCSI bus are using different SCSI IDs. SCSI controller IDs are preset to 7. Reset one SCSI controller ID to 6.
3. Connect the shared storage devices to the shared bus, and then connect the shared storage bus to all nodes.
4. Start the operating system on one node. Turn on a second node, and press F8 when the operating system Loader screen appears (not allowing the operating system to start).
5. On the first node, use Disk Management to assign drive letters to the disks available on the new shared storage bus.

   **Where?**

   - Computer Management/Storage/Disk Management
6. Make sure the Cluster service is running on this node.
7. Create new resource groups if needed and install a Physical Disk or other storage-class type resource for each new disk.

   For more information see, "Checklist: Creating a new group", "To create a new group", "Checklist: Creating a new resource", and "To create a new resource" in Related Topics.
8. Shut down the first node, but do not turn off the computer.
9. On a second node, select the operating system and press ENTER.
10. Restart the first node.

**Caution**

- Do not run the operating system on all nodes at the same time until you have completed this procedure.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Replace the redundant array of independent disks (RAID) controller

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To replace the redundant array of independent disks (RAID) controller**

- Replacing the RAID controller and updating controller configuration is hardware dependent. Refer to your hardware vendor for information on replacing your RAID controller and the effect that removal of the controller from the shared bus will have on termination.

**Note**

- Replacing the RAID controller may affect the quorum disk. It is therefore advisable to back up the individual nodes and the cluster disks before replacing the RAID controller. If the quorum disk is affected, it can then be restored from the backup.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure the Always On power scheme without Terminal Services installed

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the Always On power scheme without Terminal Services installed**

1. Open Control Panel.
2. Double-click **Power Options**.
3. In the **Power Options Properties** dialog box, under **Power schemes**, verify that **Always On** is selected.
4. Under **Settings for Always On power scheme**, verify that **Turn off hard disks** is set to **Never**.
5. Verify that **System standby** is set to **Never**.
6. Verify that **System hibernates** is set to **Never**.

### Important

- APM/ACPI Power saving features must not be enabled on server cluster members. A cluster member that turns off disk drives or enters "system standby" or "hibernate" mode can initiate a failure in the cluster. If multiple cluster nodes have power saving enabled, this can result in the entire cluster becoming unavailable.

### Note

- To open a Control Panel item, click **Start**, click **Control Panel**, and then double-click the appropriate icon.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**

Power Options overview

# Configure the Always On power scheme with Terminal Services installed

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the Always On power scheme with Terminal Services installed**

1. Open Control Panel.
2. Double-click **Power Options**.
3. In the **Power Options Properties** dialog box, under **Power schemes**, verify that **Always On** is selected.
4. Under **Settings for Always On power scheme**, verify that **Turn off hard disks** is set to **Never**.

### Important

- APM/ACPI Power saving features must not be enabled on server cluster members. A cluster member that turns off disk drives can initiate a failure in the cluster. If multiple cluster nodes have power saving enabled, this can result in the entire cluster becoming unavailable.

### Notes

- To open a Control Panel item, click **Start**, click **Control Panel**, and then double-click the appropriate icon.
- Installing Terminal Services on a system reduces the power management options available to the user. The **System standby** and **System hibernates** options are not available.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Back Up and Restore Server Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Back up and restore server clusters**

- Back up cluster disk signatures and partition layouts
- Back up the cluster quorum
- Back up data on cluster nodes
- Restore the cluster database on a local node
- Restore the contents of a cluster quorum disk for all nodes in a cluster
- Restore a damaged cluster node using Automated System Recovery

# Back up cluster disk signatures and partition layouts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To back up cluster disk signatures and partition layouts**

1. Open Backup.

   The Backup or Restore Wizard starts by default, unless it is disabled.

2. Click **Advanced Mode** on the Backup or Restore Wizard.

3. On the **Tools** menu, click **ASR Wizard**.

4. Follow the instructions that appear on your screen.

### Important

- You will need a blank 1.44 MB floppy disk to save your system settings and media to contain the backup files. If your computer does not have a floppy drive, see "Troubleshooting" in Related Topics.

### Notes

- To start Backup, click **Start**, point to **All programs**, point to **Accessories**, point to **System Tools**, and then click **Backup**.

- By default, Backup Operators do not have the user rights necessary to create an Automated System Recovery (ASR) backup on a cluster node. However, Backup Operators can perform this procedure if that group is added to the security descriptor for the Cluster service. You can do that using Cluster Administrator or cluster.exe. For more information, see Give a user permissions to administer a cluster and Cluster.

- Automated System Restore not only backs up cluster disk signatures and partition layouts, it also backs up the system state and other data associated with the operating system.

- You later need to restore the signature of the quorum disk, for example, if you experience a complete system failure, and the signature of the quorum disk has changed since you last backed up, or if you experience Event ID 1034 errors when replacing a disk.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**
**Concepts**
Backing up and restoring server clusters
Backup Troubleshooting

# Back up the cluster quorum

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To back up the cluster quorum**

1. Open Cluster Administrator.
2. If you are not already connected to a cluster, connect to one.

   For more information, see "To connect to a cluster with Cluster Administrator" in Related Topics.
3. In the console tree, click the cluster node.
4. On the **File** menu, click **Properties** and verify that the Cluster service is running on the node on which you are performing the backup.
5. Open Backup.

   The Backup or Restore Wizard starts by default, unless it is disabled.
6. Click **Advanced Mode** on the Backup or Restore Wizard.
7. Click the **Backup** tab, then in **Click to select the check box for any drive, folder, or file that you want to back up** click the box next to **System State**.

   This will back up the contents of the cluster quorum along with other system state data.

   For more information, see "To back up System State data" in Related Topics.

### Important

- It is highly recommended that you use the Backup utility as described in this procedure to perform regular backups of the cluster quorum. The cluster quorum contains information that is indispensible to the operation of the server cluster, for example, the current cluster configuration, application registry checkpoints, and cluster recovery log.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.
- To start Backup, click **Start**, point to **All programs**, point to **Accessories**, point to **System Tools**, and then click **Backup**.
- During backup, the following error may be displayed: "Completed with Skipped Files." This error may be ignored. The Mscs directory from the Cluster quorum drive is still successfully backed up.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**See Also**

**Concepts**

Back up System State data

# Back up data on cluster nodes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To back up data on cluster nodes**

1. Open Backup.

   The Backup or Restore Wizard starts by default, unless it is disabled.

2. Follow the wizard instructions, selecting **All information on this computer** on the **What to Back Up** page.

   This will back up all data on the node and all the cluster disks currently owned by that node. Cluster disks not owned by that node will not be backed up.

### Important

- You will need a blank 1.44 MB floppy disk to save your system settings and media to contain the backup files. If your computer does not have a floppy drive, see "Troubleshooting the Backup Utility" in Related Topics.

- If a cluster disk owned by the node being backed up fails over to another node during the backup process, the backup set will not contain a full backup of that disk.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To start Backup, click **Start**, point to **All programs**, point to **Accessories**, point to **System Tools**, and then click **Backup**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Backing up and restoring server clusters
Backup Troubleshooting

# Restore the cluster database on a local node

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restore the cluster database on a local node**

1. Open Backup.

   The Backup or Restore Wizard starts by default, unless it is disabled.

2. Click **Advanced Mode** on the Backup or Restore Wizard.

3. Click the **Restore and Manage Media** tab, and then in **Click to select the check box for any drive, folder, or file that you want to restore**, click the box next to **System State**.

4. Click **Start Restore**.

   This will stop the Cluster service on the local node and restore the cluster configuration (the cluster registry file ClusDB located in the *systemroot*\cluster subdirectory) for that node.

   For more information on backup and restore procedures, see "Backing up and restoring data" in Related Topics.

5. Reboot the node when prompted.

   Rebooting the operating system replaces the cluster configuration file currently in use with the restored copy.

6. Verify that the Cluster service restarted on the local node.

   **Where?**

   - Computer Management/Services and Applications/Services

**Important**

- If the signature of the quorum disk has changed since you last backed up, instead of restoring the System State only, use Automated System Recovery in the Backup or Restore Wizard to restore the quorum disk signature along with the System State.

  For information on how to use Automated System Recovery, see "To recover from a system failure using Automated System Recovery" in Related Topics.

- If you do not have a backup set available, you can manually restore the cluster database on the local node by copying the *systemroot*\cluster\CLUSDB file from another node. If the copy operation fails, follow the troubleshooting steps in General administrative problems.

**Notes**

- You must be an administrator or a backup operator to restore System State data. For more information on permissions or user rights, see Related Topics.

- To start Backup, click **Start**, point to **All programs**, point to **Accessories**, point to **System Tools**, and then click **Backup**.

- You can only restore the cluster quorum disk on a local node. You cannot restore the cluster quorum disk on a remote computer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Restore the contents of a cluster quorum disk for all nodes in a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restore the contents of a cluster quorum disk for all nodes in a cluster**

1. Open Backup.

   The Backup or Restore Wizard starts by default, unless it is disabled.

2. Click **Advanced Mode** on the Backup or Restore Wizard.

3. Click the **Restore and Manage Media** tab, and then in **Click to select the check box for any drive, folder, or file that you want to restore**, click the box next to **System State**.

4. Click **Start Restore**.

5. On the **Confirm Restore** dialog box, click **Advanced**.

6. Select **Restore the Cluster Registry to the quorum disk and all other nodes**, then click **OK**.

7. This action will stop the Cluster service on the local node and restore the cluster configuration (the cluster registry file ClusDB located in the *systemroot*\cluster subdirectory) for that node.

   For more information on backup and restore procedures, see "Backing up and restoring data" in Related Topics.

8. Reboot the node when prompted.

   This will restart the Cluster service on the local node and stop the Cluster service on all other nodes in the cluster. Backup will then copy the restored quorum data from the restarted node to the cluster quorum disk and all other nodes in the cluster.

9. Start the Cluster service on the other nodes in the cluster.

   For more information on starting the Cluster service, see "Start the Cluster service" in Related Topics.

10. Verify that the Cluster service restarted on all nodes.

    **Where?**

    - Computer Management/Services and Applications/Services

**Important**

- Backup will stop the Cluster service on all other nodes of the server cluster after the node that was restored reboots. The entire server cluster will therefore be down while the restored quorum data is copied to the quorum disk and the other nodes in the cluster.

**Notes**

- You must be an administrator or a backup operator to restore System State data. For more information on permissions or user rights, see Related Topics.

- To start Backup, click **Start**, point to **All programs**, point to **Accessories**, point to **System Tools**, and then click **Backup**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Restore a damaged cluster node using Automated System Recovery

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To restore a damaged cluster node using Automated System Recovery**

1. Make sure you have the following on hand before you begin the recovery procedure:

   - Your previously created Automated System Recovery (ASR) floppy disk and ASR backup media. The ASR disk and media contain the backed up cluster disk signatures, partition layouts, and cluster quorum (as part of the system state).
   - Your previously created backup media containing the data on the cluster nodes.
   - The original operating system installation CD.
   - If you have a mass storage controller and you are aware that the manufacturer has supplied a separate driver file for it (different from driver files available on the Setup CD), obtain the file (on a floppy disk) before you begin this procedure.

2. Insert the original operating system installation CD into the CD drive of the damaged cluster node.

   **Important**

   - If you are restoring a disk signature to a damaged cluster disk, power down all other cluster nodes except the one on which you are performing the ASR restore. This cluster node must have exclusive rights to the damaged cluster disk.

3. Restart your computer. If you are prompted to press a key to start the computer from CD, press the appropriate key.
4. If you have a separate driver file as described in step 1, to use the driver as part of Setup, press F6 when prompted.
5. Press **F2** when prompted during the text-only mode section of Setup. You will be prompted to insert the ASR floppy disk you have previously created.
6. Follow the directions on the screen.
7. If you have a separate driver file as described in step 1, press F6 (a second time) when prompted after the system reboots.
8. Follow the directions on the screen.
9. Once you have completed all the restore steps, the restored node can rejoin the cluster.

**Notes**

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- This procedure is useful if your cluster node is damaged because of corrupt or missing system files or Cluster registry files, hard disk failure, or changes to disk signatures due to a disk replacement (Event ID 1034 errors).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test Cluster Failures and Failover Policies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Test cluster failures and failover policies**

- Test group failover policy
- Test whether group resources can fail over
- Test private network failures
- Test node failure

# Test group failover policy

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test group failover policy**

1. Open Cluster Administrator.
2. In the console tree, double-click the Groups folder.
3. In the details pane, click the group.
4. On the **File** menu, click **Properties**.
5. On the **Failover** tab, set the **Threshold** to 0, and then click **OK**.
6. In the Cluster Administrator console tree, click the group.
7. In the details pane, click a resource.
8. On the **File** menu, click **Properties**.
9. On the **Advanced** tab, select the **Affect the group** check box, if it is not already selected.
10. On the Advanced tab, set the **Threshold** to 0, and then click **OK**.
11. On the **File** menu, click **Initiate Failure**.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test whether group resources can fail over

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test whether group resources can fail over**

1. Open Cluster Administrator.
2. In the console tree, double-click the Groups folder.
3. In the console tree, click a group.
4. On the **File** menu, click **Move Group**.

   On a multinode cluster server, when using **Move Group**, select the node to move the group to.

   Make sure the **Owner** column in the details pane reflects a change of owner for all of the group's dependencies.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test private network failures

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test private network failures**

1. Open Cluster Administrator.

2. Verify that there are at least two networks set up for internal cluster communication and determine which network has the highest priority for internal cluster communications.

   For more information, see "To change network priority for communication between nodes" in Related Topics. When you follow that procedure, Cluster Administrator will only list those networks that support internal cluster communication.

3. If there are two or more internal networks, continue to step 4, otherwise stop here and do not continue.

4. On one node, unplug the cable for the highest priority network identified above.

5. In the console tree, click the cluster node and verify that the state of the node is still **Up** (that is, actively participating in all cluster operations).

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.

- To open Cluster Administrator, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Cluster Administrator**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Change network priority for communication between nodes

# Test node failure

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test node failure**

- Test node failure using one of the following four methods:

  - Stop the Cluster service on the node.

    This prevents clients from accessing cluster resources through that node. In this event, all resources owned by this node fail over to other nodes in the server cluster. For more information on stopping the Cluster service, see Related Topics.

  - Turn off the power on the node.

    This tests the ability of the server cluster to fail over all the resources that were owned by the powered down node.

  - On one node, unplug the network cables for all networks enabled for intracluster communications.

    This test disables all intracluster network interfaces for the node and prevents the node from exchanging heartbeats with the Cluster Network Driver on the other active nodes. In this event, the Cluster service then initiates failover of the resources owned by the node to the other nodes in the server cluster.

### Note

- Disconnecting the SCSI or fiber cable between the host bus adapter and the cluster storage device is not a supported node failure test.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Server clusters overview

Updated: April 10, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server clusters overview**

A server cluster is a group of independent computer systems, known as nodes, working together as a single system to ensure that critical applications and resources remain available to clients. These nodes must be running Microsoft® Windows Server™ 2003, Enterprise Edition or Microsoft® Windows Server™ 2003, Datacenter Edition. Clustering allows users and administrators to access and manage the nodes as a single system rather than as separate computers. For more information about nodes, see Nodes.

A server cluster can consist of up to eight nodes and may be configured in one of three ways: as a single node server cluster, as a single quorum device server cluster, or as a majority node set server cluster. For more information about these three server cluster models, see Choosing a Cluster Model.

Every node may be attached to one or more cluster storage devices. For most versions of Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, the choices for cluster storage include iSCSI, Serial Attached SCSI, parallel SCSI, and Fibre Channel. The following table provides details about the storage you can use with each version of the operating system, along with the maximum number of nodes you can have with each storage type:

| **Description of Operating System** | **Storage** | **Maximum Nodes** |
|---|---|---|
| Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition<br><br>Versions:<br>• Windows Server 2003<br>• Windows Server 2003 with Service Pack 1 (SP1)<br>• Windows Server 2003 R2<br><br>Platforms:<br>• x86 and x64 (not Itanium) | Parallel SCSI | 2 |
| Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition<br><br>Versions:<br>• Windows Server 2003<br>• Windows Server 2003 with SP1<br>• Windows Server 2003 R2<br><br>Platforms:<br>• x86, x64, and Itanium | Fibre Channel | 8 |

| | | |
|---|---|---|
| Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition<br><br>Versions:<br>• Windows Server 2003 with SP1<br>• Windows Server 2003 R2<br><br>Platforms:<br>• x86, x64, and Itanium | iSCSI<br><br>or<br><br>Serial Attached SCSI (SAS) | 8 |

The following figure shows a four-node cluster that provides high availability for four different types of applications or services:

A server cluster runs several pieces of software that fall into two categories: the software that makes the cluster run (clustering software) and the software that you use to administer the cluster (administrative software). By default, all clustering and administration software files are automatically installed on your computer when you install any operating system in the Microsoft® Windows Server 2003 family of products.

**Important**

- Only computers running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition can be cluster nodes.

**Clustering software**

The clustering software enables the nodes of a cluster to exchange specific messages that trigger the transfer of resource operations at the appropriate times. There are two main pieces of clustering software: the Resource Monitor and the Cluster service. The Resource Monitor facilitates communication between the Cluster service and application resources. The Cluster service runs on each node in the cluster and controls cluster activity, communication between cluster nodes, and failure operations. When a node or application in the cluster fails, the Cluster service responds by restarting the failed application or dispersing the work from the failed system to the remaining nodes in the cluster. For more information about this process, see Failover and failback.

**Administrative software**

Administrators use cluster management applications to configure, control, and monitor clusters. The Windows Server 2003 family provides Cluster Administrator for this purpose. Any computer running Microsoft Windows NT® version 4.0 Service Pack 3 or later, regardless of whether it is a cluster node, can install Cluster Administrator. By default, a copy of Cluster Administrator is automatically installed on your computer when you install Microsoft® Windows Server® 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition. For information about remote administration, see Installing Cluster Administrator on a remote computer.

You can also create, configure, and administer clusters using the **cluster** command. For more information, see Administering

Server Clusters. You can use or create custom administration tools developed using the Cluster automation interfaces. For more information about the Cluster automation interfaces, see the *Microsoft Platform Software Development Kit* (SDK), available separately.

Administrators organize cluster resources into functional units, called groups, and assign these groups to individual nodes. If a node fails, the Cluster service transfers the groups that were being hosted by the node to other nodes in the cluster. This transfer process is called failover. The reverse process, failback, occurs when the failed node becomes active again, and the groups that were failed over to other nodes are transferred back to the original node. For more information about resources, see Server Cluster Resources. For more information about groups, see Server Cluster groups.

# Understanding Server Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding server clusters**

Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition use clustering to provide high-availability application support. A server cluster is a group of independent computer systems, called nodes, working together as a single system. Server clusters allow users and administrators to access and manage the nodes as a single system rather than as separate computers.

The following sections describe how Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition use server clusters to provide high availability, easy manageability, and enhanced scalability:

- Cluster application types
- Server Cluster Components
- Cluster Objects
- Server Cluster Networking

# Cluster application types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster application types**

Applications that run in a server cluster fall into one of four categories:

- **Cluster-unaware applications**

  These types of applications do not interact with the server cluster at all but can still fail over. Failure detection is limited. The Cluster service protects these applications mainly against hardware failures.

- **Cluster-aware applications**

  These types of applications are characterized by superior failure detection. The Cluster service can protect these applications not only against hardware but also against software failures.

- **Cluster management applications**

  These types of applications, which include Cluster Administrator and Cluster.exe, allow administrators to manage and configure clusters. For more information, see Server Cluster Components.

- **Custom resource types**

  Resource types provide customized cluster management and instrumentation for applications, services, and devices. For more information, see Resource types.

For more information on the concepts in this topic, see:

- Cluster Administrator

- Administering Server Clusters

# Server Cluster Components

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server cluster components**

Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition use the server cluster components to create server clusters that provide high availability, easy manageability, and enhanced scalability. These components work together to manage the cluster objects.

The diagram shows how the cluster components relate to three types of applications and to each other within a single cluster node.

For definitions of these application types, see Cluster application types.

For more information on cluster objects, see Cluster Objects.

For more information on the individual server cluster components, see:

- Cluster service
- Resource Monitors
- Resource dynamic-link libraries (DLLs) in clusters running Windows Server 2003
- Cluster Administrator
- Cluster Automation Server
- Cluster database
- Network and disk drivers

# Cluster service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster service**
The Cluster service manages all cluster-specific activity. The Cluster service is installed at the same time as the operating system. One instance of the Cluster service runs on every node in a cluster. The Cluster service handles the following operations:

- Manages cluster objects and configuration
- Manages local restart policy
- Coordinates with other instances of the Cluster service in the cluster
- Handles event notification
- Facilitates communication among other software components
- Performs failover operations

For more information on cluster objects, see Cluster Objects.

# Resource Monitors

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource Monitors**

A Resource Monitor is a cluster component that acts as an intermediary between the Cluster service and a resource dynamic-link library (DLL). When the Cluster service makes a request of a resource, the Resource Monitor transfers that request to the appropriate resource DLL. When a resource DLL must report status or notify the Cluster service of an event, the Resource Monitor ensures that the information is delivered successfully. Resource Monitors are passive communication layers; they do not initiate operations.

The Resource Monitor runs in a process separate from the Cluster service for the following reasons:

- To protect the Cluster service from resource failures.
- To allow the Resource Monitor to take action if the Cluster service fails. The Resource Monitor detects Cluster service failure and responds by taking all of the resources and groups on the affected node offline.

Every cluster node runs one or more Resource Monitors. By default, the Cluster service starts only one Resource Monitor to interact with all of the resources hosted by the node. However, this default can be overridden by an administrator using either Cluster Administrator or another management application. Assign potentially problematic resource DLLs to their own Resource Monitor to prevent faulty behavior from affecting other resources and other Resource Monitors.

- For more information on the Cluster service, see Cluster service.
- For more information on Cluster Administrator, see Cluster Administrator.
- For more information on the resource DLLs, see Resource dynamic-link libraries (DLLs) in clusters running Windows Server 2003.

# Resource dynamic-link libraries (DLLs) in clusters running Windows Server 2003

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource dynamic-link libraries (DLLs)**

This topic provides a brief description of resource DLLs in server clusters running Windows Server 2003.

Resource DLLs contain instructions that manage cluster resources of one or more types. The most important role of the resource DLL is to detect application failures.

When the Cluster service issues a request to a resource, that request is passed to the Resource Monitor. The Resource Monitor, in turn, calls an entry point function in the resource DLL responsible for the resource.

Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition define several resource types and provide resource DLLs to manage them. However, a server cluster is not limited to the resource types provided with the operating system. Developers can create their own resource DLLs to replace or augment the resource DLLs provided with the operating system. Custom resource DLLs have detailed knowledge of the resources they manage and are used by resource monitors to determine the resource state (dead/alive).

# Cluster Administrator

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster Administrator**
Administrators use cluster management applications to configure, control, and monitor clusters. Cluster Administrator is one such application and exists for this purpose. On computers that are not cluster nodes, for example Windows XP Professional, you install Cluster Administrator using Windows Server 2003 Administration Tools. On computers running the Windows Server 2003, Standard Edition family of products, Cluster Administrator is installed, along with the Cluster service, when you install the operating system.

**Important**

- Only computers running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition can be cluster nodes.

For more information, see Installing Cluster Administrator on a remote computer.

You use Cluster Administrator to create the cluster, join nodes to the cluster, manage cluster objects, establish groups, initiate failover, handle maintenance, and monitor cluster activity through a convenient graphical interface. Developers providing their own resource types can write an extension that enables Cluster Administrator to manage their custom types. For more information on developing extensions, see the Microsoft Platform Software Development Kit (SDK).

For more information on using Cluster Administrator to manage your server cluster, see Using Cluster Administrator.

# Cluster Automation Server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster Automation Server**

The Cluster Automation Server exposes a set of Component Object Model (COM) objects to any scripting language that supports automation, such as Visual Basic or the Windows Script Host (WSH). By enabling object-oriented design and the use of high-level languages, the Cluster Automation Server simplifies the process of creating a cluster-management application.

For information on how to write scripts using the Cluster Automation Server, see the *Microsoft Platform Software Development Kit (SDK)*. For more information on WSH, see Windows Script Host. For more information on cluster-management applications, see Cluster application types.

# Cluster database

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster database**
The cluster registry is stored in the cluster database on each node. By default, the cluster database for a single quorum device server cluster is located at %systemroot%\Cluster\CLUSDB; for a majority node set server cluster, the cluster database is located at %systemroot%\Cluster\MNS.%ResourceGUID%$\%ResourceGUID%$\MSCS. A copy of the cluster registry is also stored in the CHKxxx.TMP file on the quorum disk. The quorum log maintains consistency between the two versions of the cluster registry. The cluster database resides in the Windows Server 2003 family registry on each cluster node. It contains information about all physical and logical elements in a cluster, including cluster objects, their properties, and configuration data.

**Important**

- Do not use the **net use** command to connect to the share containing the cluster database files (%systemroot%\Cluster\MNS.%ResourceGUID%$\%ResourceGUID%$\MSCS) in a majority node set server cluster. Otherwise, the Majority Node Set resource (the quorum resource) may be unable to connect to the share and may fail to come online.

Each node's Cluster service maintains a consistent, updated image of the cluster database through the following mechanisms:

- **Global updates**. The Cluster service replicates changes to the cluster database uniformly across all nodes.

  Changes to the cluster database are replicated across all nodes automatically every 4 hours and also when any of the following events occur:

  1. A resource is taken online.
  2. A resource is taken offline.
  3. The Resource Monitor detects a change to one of the registry keys.

- **Periodic checkpointing**. The Cluster service on the node that owns the quorum resource regularly saves a copy of the cluster database to ensure consistency.

- **Quorum resource**. The Cluster service ensures that the quorum resource's recovery log contains the most recent cluster database information. Any changes between checkpoints are logged to the quorum disk if the Cluster service fails to replicate it among all nodes. The main purpose of the quorum resource is to maintain cluster consistency.

For more information on the concepts in this topic, see:

- Nodes
- Cluster Objects
- Cluster service
- Quorum resource

# Network and disk drivers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network and disk drivers**

**Network drivers**
Each node in the cluster runs an instance of the Cluster Network Driver, Clusnet.sys. The Cluster Network Driver is responsible for:

- Providing highly available intracluster communication by monitoring and leveraging all network paths between nodes.
- Routing messages for intracluster traffic.
- Detecting communication failure. Each node's Cluster Network Driver exchanges periodic messages, called heartbeats, with the Cluster Network Driver on the other active nodes. If a node fails to respond to a heartbeat message, the Cluster Network Driver on the node that detects the failure notifies the Cluster service that the corresponding network interface has failed. If all other intracluster network interfaces for that node fail, the Cluster service will then initiate failover of the node. Note that failure of a node to respond to a heartbeat message can be caused by node failure, network interface failure, or network failure.

The Cluster Network Driver on each node uses the Internet Assigned Numbers Authority (IANA)-assigned port of 3343. For information on removing malicious processes bound to the cluster network ports, see information about the Cluster service failing to start and returning ERROR_SHARING_VIOLATION in General administrative problems.

**Disk drivers**
Each node in the cluster runs an instance of the Cluster Disk Driver, Clusdisk.sys. The Cluster Disk Driver is responsible for:

- Maintaining exclusive ownership of cluster disks. Only the node that owns the physical disk resource can access the disk. All other nodes cannot access this disk.
- Placing reservations on disks so that they cannot be accessed by another node. If a node owns a particular disk and that disk is online, then reservations placed by Clusdisk will prevent other nodes from accessing that disk. For disks that are offline, Clusdisk will prevent disk access by blocking I/O on the local system.

# Cluster Objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster objects**
Cluster objects are the physical and logical units managed by the Cluster service. For more information on Cluster service, see Cluster service. Each object is associated with:

- One or more properties, or attributes, that define the object and its behavior within the cluster.
- A set of cluster-control codes used to manipulate the object's properties.
- A set of object-management functions used to manage the object through the Cluster service.

This section covers:

- Server cluster networks
- Server cluster network interfaces
- Nodes
- Resource types
- Server Cluster groups
- Server Cluster Resources

# Server cluster networks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server cluster networks**

A network (sometimes called an interconnect) performs one of the following roles in a cluster:

- A *private network* carries internal cluster communication. The Cluster service authenticates all internal communication, but administrators who are particularly concerned about security can restrict internal communication to physically secure networks.
- A *public network* provides client systems with access to cluster application services. IP Address resources are created on networks that provide clients with access to cluster services.
- A *mixed* (public-and-private) *network* carries internal cluster communication and connects client systems to cluster application services.
- A network that is not enabled for use by the cluster (that is, neither public nor private) carries traffic unrelated to cluster operation.

Make certain that the private network is at the top of the Network Priority list for internal node-to-node communication in the cluster. For more information, see Change network priority for communication between nodes.

**Tolerating network failure**

The Cluster service uses all available private and mixed networks for internal communication. Configure multiple networks as private or mixed to protect the cluster from a single network failure.

If there is only one such network available and it fails, the cluster nodes stop communicating with each other. When two nodes are unable to communicate, they are said to be partitioned. After two nodes become partitioned, the Cluster service automatically shuts down on one node to guarantee the consistency of application data and the cluster configuration. This can lead to the unavailability of all cluster resources.

For example, if each node has only one network adapter, and the network cable on one of the nodes fails, each node (because it is unable to communicate with the other) attempts to take control of the quorum resource. There is no guarantee that the node with a functioning network connection will gain control of the quorum resource. If the node with the failed network cable gains control, the entire cluster is unavailable to network clients.

However, if each node has at least two networks and both networks are configured for internal communication (for example both are mixed networks), the Cluster service can tolerate network failures. In this scenario, the Cluster service can detect a public network adapter failure and fail over all resources that depend on that adapter (through its IP address) to a node where this network is available. This is accomplished because the private network is still functioning properly. If, on the other hand, an adapter on the private network fails, the Cluster service can use the public network for internal communication. This is accomplished because the public network is mixed, allowing both internal and client traffic.

Note that there must be a unique subnet for each network in the Cluster.

**Node-to-node communication**

The Cluster service does not use public-only networks for internal communication, even if a public network is the only available network. For example, suppose a cluster has Network A configured as private and Network B configured as public, and Network A fails. The Cluster service does not use Network B because it is public only; thus, the nodes stop communicating and the cluster breaks apart.

For more information on the concepts in this topic, see:

- Nodes
- Quorum resource
- Network state management and failure detection

- Network communication between nodes
- Manage Networks
- Server cluster network interfaces

# Server cluster network interfaces

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network interfaces**

A network interface is a card or other network adapter that connects a computer to a network. The Cluster service keeps track of all network interfaces in a server cluster. This allows you to view the state of all cluster network interfaces from a cluster management application, such as Cluster Administrator. For more information, see Network state management and failure detection.

Windows Server 2003 family operating systems automatically detect the addition and removal of network interfaces. For more information, see Plug and Play network support.

# Nodes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Nodes**

A server cluster node is a system that has a working installation of Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition and the Cluster service. By definition, a node is always a member of a server cluster. For more information on the Cluster service, see Cluster service.

Nodes have the following characteristics:

- Every node is attached to one or more cluster storage devices. Each cluster storage device attaches one or more disks. The disks store all of the cluster's configuration and resource data. Each disk can be owned by only one node at any point in time, but ownership can be transferred between nodes. The result is that each node has access to all cluster configuration data.
- Every node communicates with the other nodes in the cluster through one or more physically independent networks, known as interconnects. Network adapters, also called network interfaces, attach nodes to networks.
- Every node in the cluster can detect another system joining or leaving the cluster.
- Every node in the cluster can detect the resources that are running locally and the resources that are running on the other cluster nodes.
- All nodes in the cluster are grouped under a common name, the cluster name, which is used when accessing and managing the cluster.

The following states describe a node's participation in server cluster operation:

| State | Meaning |
|---|---|
| Down | The node is not actively participating in cluster operations. |
| Joining | The node is in the process of becoming an active participant in the cluster operations. |
| Paused | The node is actively participating in cluster operations but cannot take ownership of resource groups and cannot bring resources online. |
| Up | The node is actively participating in all cluster operations. |
| Unknown | The state cannot be determined. |

An active node can host cluster groups. For more information about groups, see Server Cluster groups.

When running Cluster Administrator for the first time on a server node, the administrator can choose whether that node forms its own cluster or joins an existing cluster. When a node is powered up, the Cluster service already installed on that node searches for other active nodes on networks enabled for internal cluster communications.

**Forming a new cluster**

If a cluster does not already exist, the node attempts to form its own cluster by gaining control of the quorum resource. If the node gains control of the quorum resource, the node forms its own cluster and uses the recovery logs in the quorum resource to update its cluster database. The Cluster service maintains a consistent, updated copy of the cluster database on all active nodes

For more information about the quorum resource, see Quorum resource. For more information on the cluster database, see Cluster database.

**Joining an existing cluster**

A node can join an existing cluster if it can communicate with another cluster node. If a cluster exists and the joining node finds

an active node, it attempts to join that node's cluster. If it succeeds, the Cluster service then validates the node's name and verifies version compatibility. If the validation process succeeds, the node joins the cluster. The node updates its copy of the cluster database from that on the other active nodes.

# Resource types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource types**

Cluster resources are categorized by type. The Windows Server 2003 family defines several types of resources and provides resource dynamic-link libraries (DLLs) to manage the types. Developers are encouraged to create new types to fit the specific needs of their cluster-aware applications and services. By creating a new resource type, developers can have more control over how the Cluster service manages their application or service.

For more information on the resource types provided with the operating system, see Standard Resource Types.

For more information on the concepts in this topic, see:

- Server Cluster Resources
- Resource dynamic-link libraries (DLLs) in clusters running Windows Server 2003

# Server Cluster groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Groups**

A group is a collection of cluster resources with the following characteristics:

- Groups define the units of failover. That is, when one resource in a group fails and it is necessary to move the resource to an alternate node, all of the resources in the group are moved to the alternate node. For more information, see Failover and failback.

- A group is always owned by one node at any point in time. Likewise, a resource is always owned by a single group. These relationships ensure that all of a group's members reside on the same node.

For more information on resources or nodes, see Server Cluster Resources or Nodes.

Groups enable resources to be combined into larger logical units. Typically, a group is made up of related or dependent resources, such as applications and their associated peripherals and data. Indeed, groups define dependency boundaries for resources: resources cannot depend on resources in other groups. Because most application-level resources have some dependency on storage, most groups are configured around storage-class resources. A simple rule of thumb is this: If a resource uses shared storage resources, the resource belongs in the same group as that storage resource.

However, groups can also be established with resources that are unrelated and nondependent to balance the load or for administrative convenience. For more information on dependent resources, see Resource dependencies. For more information on setting resource dependencies, see Modify resource dependencies.

Every group maintains a prioritized list of the nodes that can act as its host. The preferred nodes list is generated from two sources:

- The Cluster service produces a list of preferred nodes for a group from the list of possible owners that is maintained by the group's resources. For more information on Cluster service, see Cluster service.

- Administrators can add nodes to the list through a cluster-management application, such as Cluster Administrator. For more information on using Cluster Administrator to specify the preferred owners of a group, see Specify preferred owners of a group.

To fully exploit the processing power of a cluster, establish at least as many groups as there are nodes in the cluster and evenly distribute these groups across the cluster.

The following topics discuss important concepts related to groups:

- Virtual servers

- Failover and failback

# Virtual servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Virtual servers**

To access a network application or resource in a nonclustered environment, network clients must connect to a physical server (that is, a specific computer on the network identified by a unique network name and Internet protocol (IP) address). If that server fails, access to the application or resource is impossible.

Through server clusters, Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition enable the creation of virtual servers. Unlike a physical server, a virtual server is not associated with a specific computer and can be failed over like a group. If the node hosting the virtual server fails, clients can still access its resources using the same server name.

A virtual server is a group that contains:

- A Network Name resource.
- An IP Address resource.
- All other resources, including applications, to be accessed by the clients of the virtual server.
- Other virtual servers.

For more information on groups, see Server Cluster groups.

A virtual server acts like a physical server in the following ways:

- Allows access to network resources.
- Is published to network clients under a unique server name.
- Is associated with a network name and an IP address.

**Kerberos authentication for virtual servers**

Server clusters can maintain an Active Directory computer object for virtual servers in a cluster. This allows clients accessing these virtual servers to use the security features provided by Kerberos as well as NTLM. Applications that can use Active Directory, such as Message Queuing on a virtual server, can now publish information to these computer objects.

Limitations include:

- You cannot apply Group Policy to a virtual server or the applications running on the virtual server. That is, when a virtual computer object is part of an Organizational Unit that has an associated Group Policy object, that Group Policy is not applied to the virtual server object.
- The Cluster service account is limited to creating a maximum of 10 virtual server computer objects in Active Directory by default. For information on overriding this default, see **Granting additional permissions to the Cluster service account** below.
- You cannot rename a Network Name resource and change the Kerberos authentication setting at the same time. Instead, you must allow time for changes to replicate after performing each action.

By default, Kerberos authentication for virtual servers is not enabled. You can use Cluster Administrator or cluster.exe commands to enable this feature and to configure the Kerberos properties for the network name resource of the virtual server. For more information on configuring these Kerberos properties, see Enable Kerberos authentication for virtual servers and see the listing for RequireKerberos in Cluster resource.

**The Cluster service account and Active Directory access rights**

By default, the Cluster service account is a member of the Authenticated Users group, and as such, will have the user right**Add workstations to domain**. For this user right, the default quota limitation on the number of computer accounts that can be created is 10. The value of the quota can be changed by the domain administrator.

**Note**

- This quota applies to the Cluster service account and not to the individual server cluster. If the same Cluster service account is used for multiple servers clusters, then the quota applies to the total number of computer accounts in all the clusters.

The default permissions granted to the Cluster service account when the computer object is created as a result of using this **Add workstations to domain** user right do not allow the Cluster service account to rename or disable the virtual computer object. These operations are attempted when the name of the Network Name resource is changed or if Kerberos authentication is in the process of being disabled.

**Granting additional permissions to the Cluster service account**

There are a number of techniques that can be used to overcome the limitation on the number of virtual server computer objects that the Cluster service account can create. All of these techniques include granting the Cluster service account one or more permissions on objects in Active Directory. At a minimum, the Cluster service account needs to be able to:

- Reset the password on the virtual computer object.
- Write the DnsHostName attribute on the object.
- Write the ServicePrincipalName attribute on the object.
- Create Message Queuing Configuration objects if the network name resource is the dependent resource of an Message Queuing resource.

The ability to write all properties is needed if it is necessary to allow the virtual computer object to be renamed or disabled. The following table identifies the permissions needed by the Cluster service account for a virtual computer object.

| Permission | Description | Reference |
|---|---|---|
| **Add workstations to domain** | This is given by default to the Cluster service account (and all domain accounts). With this access right, the Cluster service is allowed to create computer objects in Active Directory. | Add workstations to domain |
| **Write all Properties** | Allows changes to the properties of the computer objects. For example, if you need to rename the computer object, you must give the Cluster service this access right. | |
| **Create Computer Objects** | Overrides the default limit of 10 virtual server computer objects in Active Directory. | Add workstations to domain |

You cannot rename the computer object for a virtual server using Active Directory tools. Instead, you must use Cluster Administrator or cluster.exe to rename the Network Name for the virtual server. The Cluster service will then automatically change the name of the computer object.

For more information on the concepts in this topic, see:

- Server Cluster Resources
- Nodes
- Active Directory Overview

# Failover and failback

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Failover and failback**

**Failover**
If an individual application in a server cluster fails (but the node does not), the Cluster service typically tries to restart the application on the same node. If that fails, it moves the application's resources and restarts them on another node of the server cluster. This process is called *failover*. The Cluster Administrator can use a graphical console to set various recovery policies, such as dependencies between applications, whether or not to restart an application on the same server, and whether or not to automatically rebalance, or fail back, workloads when a failed server comes back online.

The Cluster service attempts to fail over a group when:

- The node currently hosting the group becomes inactive for any reason.
- One of the resources within the group fails, and it is configured to affect the group. For more information on configuring the failure of a resource to affect the group, see View or set resource properties.
- You force failover. For more information on forcing a resource to fail over, see Initiate a resource failure.

A failover attempt consists of the following steps:

1. The Cluster service takes all the resources in the group offline in an order determined by the group's dependency hierarchy: dependent resources first, followed by the resources on which they depend. For example, if an application depends on a Physical Disk resource, the Cluster service takes the application offline first, allowing the application to write changes to the disk before the disk is taken offline.

   The Cluster service takes a resource offline by invoking, through a Resource Monitor, the resource DLL that manages the resource. If the resource does not shut down within a specified time limit, the Cluster service forcibly terminates the resource. For more information on setting the time-out value for a resource, see Specify the restart policy for a resource.

2. When all of the resources are offline, the Cluster service attempts to transfer the group to the node that is listed next on the group's list of preferred host nodes. For more information on how the Cluster service determines which node to failover or failback to, see Determining failover and move policies for groups.

3. If the Cluster service successfully moves the group to another node, it tries to bring all of the group's resources online. Failover is complete when all of the group's resources are online on the new node.

The Cluster service continues attempting to fail over a group until it succeeds or until a defined number of attempts have been made within a given time span. A group's failover policy specifies the maximum number of failover attempts that can occur in an interval of time. If the Cluster service exceeds this limit, it concludes that the group cannot be brought online anywhere in the cluster and stops trying to fail over the group. For information on how to set group failover policy, see Set group failover policy.

**Ways to control failover policy**

- Define how the Cluster service detects and responds to the failure of individual resources in the group. For more information, see Resource failure.
- Control the order in which the Cluster service takes resources offline by establishing dependency relationships between resources. For more information, see Resource dependencies.
- Specify time-out, failover threshold, and failover period for resources. The time-out controls how long the Cluster service waits for the resource to shut down. The failover threshold and period control how many times the Cluster service attempts to fail over a resource in a particular period of time. For more information on how to set these values, see

Specify the restart policy for a resource.

- Specify a possible owner list for resources. The possible owner list for a resource controls which cluster nodes are allowed to host the resource. For more information on how to set the possible owner list for a resource, see Specify which nodes can own a resource.

For more information on the Cluster service, see Cluster service.

**Failback**
When a node becomes inactive for any reason, the Cluster service fails over any groups hosted by the node. When the node becomes active again, the Cluster service can fail back the groups originally hosted by the node.

The Cluster service fails back a group using the same procedures it performs during failover. That is, the Cluster service takes all of the resources in the group offline, moves the group, and then brings all of the resources in the group online.

You can set failback to occur during a specific time period. It is important to set the failback time because you may not want failback to occur during hours of peak usage.

For more information on how to configure a group's failback policy, see Set group failback policy.

# Server Cluster Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server cluster resources**
A cluster resource is any physical or logical component that has the following characteristics:

- Can be brought online and taken offline.
- Can be managed in a server cluster.
- Can be hosted (owned) by only one node at a time.

To manage resources, the Cluster service communicates to a resource dynamic-link library (DLL) through a Resource Monitor. When the Cluster service makes a request of a resource, the Resource Monitor calls the appropriate entry-point function in the resource DLL to check and control the resource's state. For more information on Resource Monitor or resource DLL, see Resource Monitors or Resource dynamic-link libraries (DLLs) in clusters running Windows Server 2003.

**Dependent resources**
A dependent resource is one that requires another resource to operate. For example, a network name must be associated with an IP address. Because of this requirement, a Network Name resource is dependent on an IP Address resource. Dependent resources are taken offline before the resources upon which they depend are taken offline, likewise, they are brought online after the resources on which they depend are brought online. A resource can specify one or more resources on which it is dependent. Resource dependencies also determine bindings. For example, clients will be bound to the particular IP address that a Network Name resource is dependent on.

When creating resource dependencies, take into account the following: some dependencies are strictly required, while others are not required but make sense to do so. For example, a file share that is not a DFS root has no required dependencies, but if the Disk resource that holds the file share fails, the file share will be inaccessible to users. Therefore, it is logical to make the file share dependent on the Disk resource.

A resource can also specify a list of nodes on which it is able to run. Possible nodes and dependencies are important considerations when administrators organize resources into groups. For more information on preferred nodes and groups, see Server Cluster groups. For more information on nodes, see Nodes.

The following topics describe important concepts related to resources:

- Quorum resource
- Resource failure
- Resource dependencies
- Cluster resource visibility

# Quorum resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Quorum resource**
In every cluster, a single resource is designated as the quorum resource. This resource maintains the configuration data necessary for recovery of the cluster. This data, in the form of recovery logs, contains details of all of the changes that have been applied to the cluster database. This provides node-independent storage for cluster configuration and state data.

**Quorum resource and the cluster database**
The cluster database is an integral part of the formation of a server cluster. When a node joins or forms a cluster, the Cluster service must update the node's private copy of the cluster database. When a node joins an existing cluster, the Cluster service can retrieve the data from the other active nodes. However, when a node forms a cluster, no other node is available. The Cluster service uses the quorum resource's recovery logs to update the node's cluster database. To ensure cluster unity, Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition use the quorum resource to ensure that only one set of active, communicating nodes is allowed to operate as a cluster. A node can form a cluster only if it can gain control of the quorum resource. A node can join a cluster or remain in an existing cluster only if it can communicate with the node that controls the quorum resource.

For more information on the cluster database, see Cluster database.

For more information on cluster resources, see Server Cluster Resources.

**Scenarios**
To illustrate the importance of the quorum resource, consider these situations in a simple two-node cluster:

- Node 1 fails. Node 2 continues operating, writing changes to the cluster database. But before node 1 can be restarted, node 2 fails. When node 1 becomes active, it must update its private copy of the cluster database with the changes made by node 2. The Cluster service uses the quorum resource's recovery logs to perform the update.

- The networks providing communication between nodes 1 and 2 fail. Each node assumes the other node has failed and attempts to continue operating as the cluster. If both could succeed, the result would be two separate clusters using the same cluster name and competing for the same resources. Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition use quorum resource ownership to prevent this problem and maintain cluster unity. In this scenario, the node that gains control of the quorum resource is allowed to form a cluster, and the other fails over its resources and becomes inactive.

The quorum resource can be any resource with the following attributes:

- The resource must enable a single node to gain physical control of it and defend its control.

- The resource must provide physical storage that can be accessed by any node in the cluster.

- The resource must use the NTFS file system.

**Types of quorum resources**
There are two resources that come with the operating system that can act as a quorum resource for multinode clusters. They are:

- The Physical Disk resource

- The Majority Node Set resource

For single-node clusters, the Local Quorum resource acts as a quorum resource. However, other developers can create their own quorum resource types for any resources that meet the arbitration and storage requirements. For more information, see the Microsoft Software Development Kit (SDK).

# Resource failure

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource failure**

The Cluster service considers a resource to be failed when the resource is not operational and cannot be restarted on the current host node. The Cluster service detects resource failure as follows:

- At periodic intervals, the Cluster service checks to see whether the resource appears operational. It does this by periodically invoking the Resource Monitor. The Resource Monitor, in turn, relies on the resource dynamic-link library (DLL) for each resource to implement a procedure to detect whether the resource is functioning properly. The resource DLL communicates the results back through the Resource Monitor to the Cluster service. You can specify how frequently the Cluster service checks for failed resources by setting the Looks Alive and Is Alive poll intervals. The Cluster service requests a more thorough check of the resource's state at each Is Alive interval than it does at each Looks Alive interval; therefore, the Is Alive poll interval is typically longer than the Looks Alive poll interval. For more information on how to set poll intervals, see Specify the restart policy for a resource.

  For more information on Resource Monitors, see Resource Monitors.

- If the resource DLL reports that the resource is not operational, the Cluster service attempts to restart the resource. You can specify the number of times the Cluster service can attempt to restart a resource in a given time interval. If the Cluster service exceeds the maximum number of restart attempts within the specified time period, and the resource is still not operational, the Cluster service considers the resource to be failed. For more information, see Set group failover policy.

You can configure whether a failed resource causes the group that contains the resource to be failed over to another node. For more information, see the section about setting advanced resource properties in Setting resource properties.

For more information on cluster resources, see Server Cluster Resources.

If the failed resource is configured to cause the group that contains the resource to fail over to another node, Cluster service will attempt a failover. If the number of failover attempts exceeds the group's threshold and the resource is still in a failed state, Cluster service will attempt a restart of the resource. The restart attempt will be made after a period of time specified by the resource's Retry Period On Failure property, a property common to all resources. It first tries to restart and then to fail over a resource.

Even though the unit value of this property is in milliseconds, choose a value that is in the order of minutes. Also, choose a value that is greater or equal to the value of the resource's restart period property and enforce this rule.

# Resource dependencies

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resource dependencies**
A dependent resource requires, or depends on, another resource to operate. For example, if a Generic Application resource requires access to clustered physical storage, it would depend on a Physical Disk resource.

The following terms describe resources in a dependency relationship:

- A dependent resource depends on other resources (the dependencies).
- A dependency is a resource on which another resource depends.
- A dependency tree is a series of dependency relationships such that resource A depends on resource B, resource B depends on resource C, and so on.

Resources in a dependency tree obey the following rules:

- A dependent resource and all of its dependencies must be in the same group.
- The Cluster service takes a dependent resource offline before any of its dependencies are taken offline, and brings a dependent resource online after all of its dependencies are online, as determined by the dependency hierarchy.
- Resource dependencies determine bindings. For example, clients will be bound to the particular IP address that a Network Name resource is dependent on.

Some of the resource types provided with the operating system have required dependencies. For more information, see Setting resource properties.

For more information on the concepts in this topic, see:

- Server Cluster Resources
- Resource types

# Cluster resource visibility

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster resource visibility**

When users browse the network, they can see more resources associated with a network name than you might have intended.

This happens because the browsing the network is a two-stage process. First, you locate the computer associated with a network name. Second, you ask that computer to list all of the resources that it owns. If that computer is a cluster node that hosts multiple virtual servers, you can get unintended results. For example, suppose the node called ClusterNode hosts two virtual servers, PrintServer and FileServer. In the PrintServer resource group, you have a network printer named ClusterPrinter, and in the FileServer resource group, you have a file share named ClusterFileShare. When users browse the network, all three network names (ClusterNode, PrintServer, and FileServer) are associated with the same cluster node, and that cluster node owns two resources (ClusterPrinter and ClusterFileShare). Therefore, when users browse the network, they see ClusterPrinter and ClusterFileShare associated with all three network names.

This allows users to circumvent your intended usage of network names. In the previous example, you place PrintServer and ClusterPrinter in the same resource group because you want both the network name and the printer resource to fail over as a unit to other cluster nodes; users who connect to ClusterPrinter through the network name PrintServer can maintain the connection in the event of a failover. However, users in the previous example can connect to ClusterPrinter through the network names ClusterNode and FileServer as well. If users do this, they will lose their connection to ClusterPrinter in the event of a failover because the resource ClusterPrinter will no longer belong to the computer named by ClusterNode or FileServer.

You can minimize the potential for problems by:

- Using cluster and node names that are easily identifiable by administrators, but not users.
- Defining virtual server names that are easily identifiable by users.
- Associating the virtual server names with the resources hosted by the virtual server (for example, ClusterPrintServer is a good name for a virtual server that hosts a printer named ClusterPrinter).

For more information on virtual servers, see Virtual servers.

# Server Cluster Networking

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server cluster networking**
This section covers:

- The Cluster service and TCP/IP
- The Cluster service and name resolution
- Network communication between nodes

# The Cluster service and TCP/IP

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The Cluster service and TCP/IP**
The Cluster service requires the TCP/IP suite for its internal and client communication.

TCP/IP is an industry-standard suite of protocols, providing communication in a heterogeneous environment. Although TCP/IP is best known for its access to the Internet and Internet resources, TCP/IP is also well suited as an enterprise networking protocol because it provides interoperability between different types of computer systems. For more information on TCP/IP, see TCP/IP Core Networking Service.

**The Cluster service and DHCP**
The Windows Server 2003 family supports the use of DHCP addresses as public or private node addresses (you configure public and private node addresses through the Network Connections folder, not through cluster management software). The Cluster service uses the Plug and Play network support to handle the events that occur when a DHCP-allocated Internet protocol (IP) address changes. For more information about public and private networks, see Server cluster networks.

However, it is highly recommended that you use static IP addresses for each network adapter on each node. Using DHCP leases for node addresses has some disadvantages:

- First, when the address lease expires for a network, the node cannot communicate over that network until it obtains a new address. This makes the node's availability dependent on the availability of the DHCP server; the node cannot communicate over the network until it obtains its address from the DHCP server.

- Second, if an address lease expires on a network configured for public communication (communication between cluster nodes and clients), it might trigger failover for resource groups that used an IP Address resource on that network.

**Caution**

- The Cluster service does not support the use of IP addresses assigned from a DHCP server for the cluster administration address (which is an IP address resource associated with the cluster name) or any other IP address resources. If possible, it is recommended that you use static IP addresses for all public and private node addresses.

# The Cluster service and name resolution

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The Cluster service and name resolution**

Clients use name resolution services to find network resources. Clients use these same services to find resources in a server cluster. The Cluster service also uses these services when a node joins one or more other nodes to form a cluster.

In both cases, name resolution is the process of translating computer names to Internet protocol (IP) addresses. You can use the Windows Internet Name Service (WINS), the Domain Name System (DNS), or both. You can also use IP broadcast name resolution. However, because IP broadcast name resolution increases network traffic, and is ineffective in routed networks, the following sections on the Cluster service and name resolution assume you are using WINS or DNS.

The Cluster service registers a Cluster resource network name and its associated Host (A) and PTR records with a DNS server if the network adapter associated with the resource has a DNS server address specified and the DNS zone accepts dynamic updates. If the zone is also integrated with Active Directory, the zone can be configured to accept only secure updates. In a secure Active Directory-integrated zone, a Cluster resource network name has the Cluster service account associated with the Host (A) and PTR records. This registration can be deleted only by the Cluster service account or the DNS administrator. If a cluster is decommissioned but might have its name reused with a different service account, the Cluster name records must be deleted from the DNS server. If not, new records will not be registered with the DNS server and the resource will fail to go online. The Event Viewer will contain an entry indicating the resource failure along with the text "DNS operation refused" in the log entry.

For more information on resource records, see Resource records reference.

For more information on dynamic updates, see Understanding zones and zone transfer.

For more information on zones and security, see the section about secure dynamic update in Dynamic update.

The Cluster service does not require any special configuration of either WINS or DNS. If you use WINS, all cluster network resource names that have associated IP addresses are registered with WINS.

Do not use static WINS mappings for cluster resources. If you do, the clustering software cannot update the WINS entries in the event of a failover.

For more information on static versus dynamic WINS entries, see Using static mappings.

# Network communication between nodes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network communication between nodes**
Communication between the nodes of a cluster enables the Cluster service to detect node failures and status changes, and to manage the cluster as a single entity. You can set up multiple networks for this node-to-node communication so as to eliminate a single point of failure.

**Heartbeats**
The Cluster service, running on each node of the cluster, keeps track of the current state of the nodes within a cluster and determines when a group and its resources fail over to an alternate node. This communication takes the form of messages that are sent regularly between each node's Cluster service. These messages are called heartbeats.

In addition to heartbeat traffic, some network traffic occurs whenever changes are made to the cluster. For example:

1. During startup, node-to-node communication occurs for the purpose of synchronizing the cluster databases that reside on each node. The cluster database stores configuration information about the cluster resources.

2. Node-to-node communication to verify node failures during cluster configuration changes.

As the number of nodes in a server cluster increases, the node-to-node communication rises significantly. In Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, for server clusters with 3 or more nodes, multiple unicast messages for two classes of intracluster traffic are replaced by single multicast messages. This reduces the intracluster traffic, resulting in lower network bandwidth consumption and improved node performance. The configuration of the server cluster must meet the following conditions for heartbeat multicasting:

- The number of nodes that are members of the server cluster (rather than the number of nodes that are currently up and actively participating in the cluster) must be 3 or greater.

- All the nodes in the server cluster must be running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition.

**Important**

- Both conditions above refer to nodes configured in the cluster membership rather than nodes that are currently up and actively participating in the cluster.

- 2-node server clusters use unicast, not multicast, messaging for all intracluster traffic.

- If you operate a server cluster of 3 or more nodes as a mixed version cluster (that is, Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition is installed on some nodes, and Windows 2000 on others), then the cluster as a whole will send unicast, not multicast, intracluster messages.

The two kinds of intracluster traffic affected by heartbeat multicasting are:

- Heartbeat messages sent between nodes.

- Node-to-node communication to verify node failures during cluster configuration changes.

# Planning Your Server Cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning your server cluster**
This section covers the options to consider as you plan how to set up server clusters to work most efficiently in your organization:

- Choosing a Cluster Model
- Cluster deployment and operation options
- Storage configuration options
- Planning your networking hardware
- Addressing risks using server clusters
- Limitations of server clusters
- Choosing applications to run on a server cluster
- Determining failover and move policies for groups
- Choosing a domain model
- Capacity Planning for Server Clusters
- Planning for Fault-Tolerant Disks
- Planning for unattended Setup
- Optimizing Your Clusters

# Choosing a Cluster Model

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Choosing a cluster model**

Clusters can be categorized in three configuration models in order of increasing complexity. Each cluster model uses a different quorum resource type. This section describes each model and gives examples of the types of applications that are suited to each. The three models are:

| Cluster Model | Typical Deployments | Where is the Cluster Configuration Data Maintained? |
|---|---|---|
| Single node cluster | Development and testing platforms. | The quorum resource maintains the definitive copy of the cluster configuration data either on a cluster storage device or locally on the single node. Uses a Local Quorum resource type. |
| Single quorum device cluster | Highly available applications on a cluster storage device. | The quorum resource maintains the definitive copy of the cluster configuration data on the single cluster storage device connected to all nodes. Uses a Physical Disk resource type (or other storage class resource type). |
| Majority node set cluster | Geographically dispersed server clusters. | Each node maintains its own copy of the cluster configuration data. The quorum resource ensures that the cluster configuration data is kept consistent across the nodes. Uses a Majority Node Set resource type.<br>**Important**<br>• A majority node set cluster is best used in controlled, targeted scenarios, as part of a cluster solution offered by your Original Equipment Manufacturer (OEM), Independent Software Vendor (ISV), or Independent Hardware Vendor (IHV). The single quorum device server cluster, the standard cluster model available in Windows NT and Windows 2000, will still cover the vast majority of your cluster deployment needs. |

For information on cluster deployment options, see Cluster deployment and operation options.

# Model 1: Single node server cluster configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Model 1: Single node server cluster configuration**
Model 1 shows how you can use the virtual server concept with applications on a single node server cluster.

This cluster model does not make use of failover. It is merely a way to organize resources on a server for administrative convenience and for the convenience of your clients. The main advantage of this model is that both administrators and clients can readily see descriptively named virtual servers on the network rather than having to navigate a list of actual servers to find the file shares they need. You can also use this model to provide a platform for developing and testing cluster-aware applications.

Other advantages of this model include the following:

- The Cluster service automatically restarts the various application and dependent resources after a computer has been restored following a resource failure. This is useful for applications that benefit from an automatic restart function but do not have their own mechanisms for accomplishing it.

- You can cluster the single node with other nodes at a future time, and the resource groups will already be in place. After you configure failover policies for the groups, the virtual servers are ready to operate.

The following figure represents an example of a single-node cluster that does not make use of failover.

For example, you can use this model to locate all the file and print resources in your organization on a single computer, establishing separate groups for each department. When clients from one department need to connect to the appropriate file or print share, they can find the share as easily as they would find an actual computer.

**Note**

- Some applications, such as Microsoft SQL Server versions 6.5 and 7.0, cannot be installed on a single-node cluster.

# Model 2: Single quorum device server cluster configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Model 2: Single quorum device server cluster configuration**
Model 2 shows how you can configure multiple nodes in a single quorum device server cluster.

In this cluster model the quorum resource maintains the cluster configuration data on a single cluster storage device. This is the traditional cluster model that was available in previous versions of Windows.

The following figure represents an example of a multinode server cluster that uses a quorum device configuration.

**Note**

- An inaccurate perception of this model is that the cluster storage device can be a single point of failure. This is not true, especially for clusters that use Storage Area Networks (SANs) where there are often multiple, redundant paths from the cluster nodes to the storage device. It is recommended that you implement a hardware RAID solution for your cluster storage devices to guard against disk failure.

# Model 3: Majority node set server cluster configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Model 3: Majority node set server cluster configuration**

Model 3 shows how you can configure multiple nodes in a majority node set server cluster.

In this cluster model, each node maintains its own copy of the cluster configuration data. The Majority Node Set resource, acting as the Quorum Resource, ensures that the cluster configuration data is kept consistent across the different nodes. The quorum traffic travels unencrypted over Server Message Block (SMB) file shares. The main advantage of this model is that cluster nodes do not have to be physically connected to one or more cluster disks.

**Important**

- Use a majority node set cluster only in targeted scenarios. Do not configure your cluster as a majority node set cluster unless it is part of a cluster solution offered by your Original Equipment Manufacturer (OEM), Independent Software Vendor (ISV), or Independent Hardware Vendor (IHV). The single quorum device server cluster, the standard cluster model available in Windows NT and Windows 2000, will still cover the vast majority of your cluster deployment needs.

For detailed instructions on creating a majority node set cluster, see Create a cluster.

The following figure represents an example of a majority node set server cluster.

For example, in an 8-node cluster, you could use this model to physically locate 5 nodes of the server cluster in one data center (for example, in Seattle) and the other 3 nodes in another data center some distance away (for example, in Los Angeles) while still presenting a single point of access to clients.

Other advantages of this model include the following:

- If an application inadvertently corrupts one of the local quorum disks or if you need to take a quorum disk offline for maintenance, the cluster still remains available.

- You can create clusters without cluster disks. This configuration is useful if you need to host applications that can failover, but where there is some other, application-specific way, to replicate or mirror data between nodes.

**Number of nodes in a majority node set cluster**

The main disadvantage of this model is that, for *n*-node clusters, if more than half the nodes fail at any one time, then the cluster itself fails. The cluster is then said to have lost quorum. This is in contrast to the *n*-node single quorum device server cluster model which will not fail even if only a single node remains in the cluster. The table below shows the maximum number of node failures allowed in a majority node set cluster before the cluster fails.

| Number of nodes, *n*, in the cluster | Maximum number of node failures before the cluster loses quorum |
|---|---|
| 1 | 0 |
| 2 | 0 |
| 3 | 1 |
| 4 | 1 |

| | |
|---|---|
| 5 | 2 |
| 6 | 2 |
| 7 | 3 |
| 8 | 3 |

**Note**

- If the server cluster loses quorum, you can restore it by forcing the quorum. For more information, see Force quorum in a majority node set server cluster.

# Cluster deployment and operation options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster deployment and operation options**

For the single quorum device and majority node set server cluster models, there are many ways of deploying and operating your server cluster to best match the needs of your organization. These modes of operation (specified by defining the failover policies of the server cluster) are outlined in the table below.

For more information on these different modes of operation and example scenarios, see the Windows Deployment Guide.

For more information on cluster models, see Choosing a Cluster Model.

| Operation Mode | Description | Implementation Guide |
|---|---|---|
| N-node Failover Pairs | In this mode of operation, each application is set to fail over only between 2 specified nodes. | Limit the possible owner list for each resource group to a given pair of nodes.<br><br>For more information, see Specify which nodes can own a resource. |
| Hot-Standby Server<br><br>/N+I | Hot-standby server operation mode reduces the overhead of failover pairs by consolidating the "spare" node for each pair into a single node, providing a hot-standby server that is capable of running the applications from each node pair in the event of a failure. This mode of operation is also referred to as *active/passive*.<br><br>For larger clusters, N+I mode provides an extension of the hot-standby server mode where N cluster nodes host applications and I cluster nodes are spare nodes. | Use a combination of the preferred owners list and the possible owners list. Set the preferred node to the node that the application will run on by default and set the possible owners for a given resource group to the preferred node and the spare node.<br><br>For more information, see Specify preferred owners of a group and Specify which nodes can own a resource.<br><br>For N+I configurations, see article Q296799, "How to Configure Windows Clustering Groups for Hot Spare Support" in the Microsoft Knowledge Base. |
| Failover Ring | In this mode of operation, each node in the cluster runs an application instance. In the event of a failure, the application on the failed node is moved to the next node in sequence. | Define the order of failover for a given resource group using the preferred owner list. Choose a node order, with the preferred node list for each group starting at a different node.<br><br>For more information, see Specify preferred owners of a group. |
| Random | For large clusters running multiple applications, the best policy in some cases is to allow the server cluster to choose the fail over node at random. | Do not define a preferred owners list for the resource groups. Each resource group that has an empty preferred owners list will be failed over to a random node in the cluster in the event that the node currently hosting that group fails. |

# Storage configuration options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Storage configuration options**
You can configure your cluster storage devices in two ways when you use the cluster management tools (Cluster Administrator or cluster.exe) to create a new cluster or add nodes by selecting either the Typical (full) Configuration or Advanced (minimum) Configuration options.

**Typical Configuration**
The Typical Configuration option is appropriate for most installations and results in a completely configured cluster. When you choose this configuration option, the cluster configuration wizards (Add Nodes Wizard and New Server Cluster Wizard) automatically:

- Configure all disks on the shared bus as cluster disks to be managed by the cluster.
- Create cluster disk resources for all identified cluster disks.

### Important

- The storage validation heuristics used in the Typical Configuration option assumes that all nodes see the same target IDs and Logical Unit Numbers (LUNs). For some complicated storage devices, using the Typical Configuration option could result in an error during set up. For example, when you create the first node of the cluster, the Typical Configuration option could fail if some disks, which are not on the same storage bus as the system disk, cannot be remounted. The Typical Configuration option could also fail when nodes are added to the cluster if the target IDs and LUNs do not match on all the cluster nodes. For more information about target IDs and LUNs, see the documentation for your storage devices.

**Advanced Configuration**
If you do not want the cluster configuration wizards to automatically set up your cluster storage, select the Advanced Configuration option. This configuration option is appropriate for clusters that have complex storage configurations or for configurations in which you do not want the cluster to manage all of the storage.

**Creating a new cluster**
When you create a cluster and select this option, the New Server Cluster Wizard automatically:

- Configures only one disk to be managed by the cluster.
- Provides you with the option to create either a Local Quorum resource, a Physical Disk (or other storage-class type) resource, or a Majority Node Set resource as the quorum resource, and then create the quorum resource.

  ### Important

  - If you do not select a quorum resource type, the local quorum resource will be selected by default; however, you will be able to later switch to another quorum resource type. A local quorum cluster can only support a single node; additional nodes cannot be joined to a local quorum cluster. For more information on the three types of quorum resources, see Choosing a Cluster Model.

For information on using cluster.exe to create a cluster using the Advanced Configuration option, see Cluster.

Once the initial cluster is set up, you can configure additional cluster disks using Cluster Administrator or cluster.exe.

**Adding nodes to a cluster**
When you add nodes to a cluster and select this option, the Add Nodes Wizard does not configure the cluster storage devices. Each device on the shared bus remains as a storage device that is local to the node. You can later use Cluster Administrator or cluster.exe to configure these local storage devices as cluster storage devices.

For more information on configuring cluster storage, see Checklist: Installing a Physical Disk resource.

**Recommendations**

The following table summarizes these configuration options:

| **Storage scenario** | **Configuration option** | **Reason** |
|---|---|---|
| SCSI or Fiber channel | Typical Configuration | Simple configuration where the storage devices have the identical identity as seen from the Device Manager MMC snap-in on each node. |
| Fiber channel switched fabric with multiple switches (or other complex storage configurations) | Advanced Configuration (Add Node Wizard) | One storage unit on the fabric may have a different identity (target ID, LUN) on each node in the cluster. This configuration is illustrated in the diagram below.   |
| Private storage | Advanced Configuration (New Server Cluster Wizard) | One or more of the storage devices (on a different storage bus than the system disk) will not be managed by the cluster storage. |

It is important that you correctly configure the storage topology (for example, SCSI, Fibre Channel, Storage Area Networks) and the storage interconnects (for example, multiple paths) used in your server cluster. Before deploying your server cluster, contact your hardware vendors to ensure that your particular cluster storage configuration is supported at the hardware level. For descriptions of supported cluster storage topologies, best practices for deploying and managing cluster storage, and a list of cluster storage-related Knowledge Base articles, see the cluster storage information at the Microsoft Web site.

# Planning your networking hardware

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning your networking hardware**

Implementing the correct networking infrastructure is integral to trouble-free operation of your server cluster. This section offers the following guidelines for planning your networking hardware:

**Requirements**

- Your network hardware must be selected from the Windows Catalog. For information about hardware compatibility and the Windows Catalog, see Support resources.
- The nodes of a cluster must be connected by two or more local area networks (LANs); at least two networks are required to prevent a single point of failure. A server cluster whose nodes are connected by only one network is not a supported configuration. The adapters, cables, hubs, and switches for each network must fail independently. This usually implies that the components of any two networks must be physically independent.
- At least two networks must be configured to handle **All communications (mixed network)** or **Internal cluster communications only (private network)**. For more information, see Change how the cluster uses a network.
- Each network connecting the nodes of a cluster must be configured as a single IP subnet. The IP subnet numbers for the networks connecting the cluster nodes must be different. If a cluster node has multiple adapters attached to the same cluster network, only one adapter will be used by the Cluster service; the others will be ignored. Multiple adapters connected on one node to the same network will not provide fault tolerance or load balancing and is not recommended.
- Teaming network adapters on all cluster networks concurrently is not supported. At least one of the cluster networks that is enabled for internal communication between cluster nodes (typically a private network) must not be teamed. The use of teaming network adapters on other cluster networks is acceptable; however, if communication problems occur on a teamed network, Microsoft Product Support Services will require that teaming be disabled. If this action resolves the problem or issue, then you must seek further assistance from the manufacturer of the teaming solution.
- Use a virtual LAN (VLAN) to connect the nodes of a cluster as long as all of the nodes view it as the same IP subnet. The one-way communication latency between any pair of cluster nodes on the VLAN must be less than 0.5 second. The VLAN must fail independently of all other LANs or VLANs used to connect the nodes of a cluster. Again, this usually implies that the VLAN must be constructed of components that are physically independent from other networks used in the cluster. Both the hardware and software configuration of a VLAN must be certified and listed on the Windows Catalog.

**Recommendations**

- Make sure that the network adapters used in all cluster nodes are identical, that is, each is the same make, model, and firmware version.
- Reserve one network exclusively for internal communications between nodes; that network must not be teamed.

# Addressing risks using server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Addressing risks using server clusters**

When you configure a cluster, identify the possible failures that can interrupt access to resources. A single point of failure is any component in your environment that would block data or applications if it failed. Single points of failure can be hardware, software, or external dependencies, such as power supplied by a utility company and dedicated wide area network (WAN) lines.

In general, you provide maximum reliability when you:

- Minimize the number of single points of failure in your environment.
- Provide mechanisms that maintain service when a failure occurs.

With Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition, you can use server clusters and new administrative procedures to provide increased reliability. However, server clusters are not designed to protect all components of your workflow in all circumstances. For example, clusters are not an alternative to backing up data; clusters protect only availability of data, not the data itself.

The following table lists common points of failure and describes whether the point of failure can be protected, either by server clusters or by other means.

| Failure point | server cluster solution | Other solutions |
|---|---|---|
| Network hub | Redundant networks. For more information, see Configuring cluster network hardware. | -- |
| Utility company power | -- | Uninterruptible power supply (UPS).<br><br>Put each cluster node on a separate circuit. |
| server connection | Failover | -- |
| Disk | -- | Hardware RAID, to protect the data on the disk. For more information, see Hardware redundant array of independent disks (RAID). |
| Other server hardware, such as CPU or memory. | Failover | -- |
| server software, such as the operating system or specific applications. | Failover | -- |
| Wide area network (WAN) links, such as routers and dedicated lines. | -- | Redundant links over the WAN, to provide secondary access to remote connections. |
| Dial-up connection | -- | Multiple modems. |
| Client computer within your organization | -- | Configuring multiple clients for the same level of access. If one client fails, you still have access through other clients. |
| Authentication of the cluster service account | -- | Redundant networks.<br><br>Configure individual nodes as domain controllers. |

To further increase the availability of network resources and prevent the loss of data:

- Consider having replacement disks and controllers available at your site. Always make sure that any spare parts you keep on hand exactly match the original parts, including network and SCSI components. The cost of two spare SCSI controllers can be a small fraction of the cost of having hundreds of clients unable to use data.

- Consider providing UPS protection for individual computers and the network itself, including hubs, bridges, and routers. Computers running Windows Server 2003, Standard Edition support UPS. Many UPS solutions provide power for 5 to 20 minutes, which is long enough for the operating system to do an orderly shutdown when power fails.

# Limitations of server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Limitations of server clusters**

This topic covers important limitations of server clusters.

- **Disk configuration**

  You cannot configure cluster storage devices as dynamic disks or spanned volumes (volume sets) if they will be used as cluster resources.

  Disks to be used for cluster storage must be configured as basic disks and must be formatted using the NTFS file system. Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition do not support the use of dynamic disks or the features of dynamic disks, such as spanned volumes (volume sets), for cluster storage. You cannot change an existing cluster disk, such as the quorum disk, to a dynamic disk. You can, however, use the DiskPart.exe utility to extend the volume of a basic cluster disk. for more information, see DiskPart.

  **Note**

  - Various third party products allow for dynamic disks in a cluster. For more information, search the Microsoft Knowledge Base using the keywords *server cluster dynamic disks*.

  You cannot use Remote Storage on the cluster storage device. You cannot enable Shadow Copies of Shared Folders for the quorum resource, although you can enable Shadow Copies of Shared Folders for a File Share resource.

  You can enable write caching on disks on any of the products in the Windows Server 2003 family. It is highly recommended that you do not enable this feature on cluster disks; otherwise, cached data will be lost during failover.

  Disable write back cache (write through only) on an internal redundant array of independent disks (RAID) controller because the data in the cache will be lost during failover. An example of an internal controller is a Peripheral Component Interconnect (PCI) card inside the node. Enable write cache on an external RAID controller. An external RAID controller is usually inside the disk cabinet and the data in the cache will fail over.

  You cannot use software RAID. You can use hardware RAID to protect the data on your cluster disk.

  You must partition cluster disks on the cluster storage device as master boot record (MBR) and not as GUID partition table (GPT) disks.

- **Network configuration**

  The Cluster service functions only with IP-based protocols.

  The private and public networks must be on the same subnet.

# Choosing applications to run on a server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Choosing applications to run on a server cluster**
Many, but not all, applications can be adapted to run on a server cluster. Of those that can, not all need to be set up as cluster resources. This section offers guidelines for making these decisions.

**Important**

- All applications running in a server cluster must be from a trusted source and all files, registry checkpoints, and other resources needed for those applications must be in a secure location. For more information, see Best practices for securing server clusters.

Three criteria determine whether an application can adapt to server clustering failover mechanisms:

- The application must use an IP-based protocol.

  Client/server applications must use an IP-based protocol (TCP, UDP, DCOM, Named Pipes, or RPC over TCP/IP) for their network communications to run on a server cluster. Any application that uses only NetBEUI or IPX protocols cannot take advantage of cluster failover.

- The application must be able to specify where the application data is stored.

  Any application you run on a server cluster must be able to store its data in a configurable location, that is, on the disks attached to shared buses. Some applications that cannot store their data in a configurable location can still be configured to fail over. However, in such cases access to the application data is lost at failover because the data is available only on the disk of the failed node.

- Client applications that connect to the server application must retry and recover from temporary network failures.

  During failover, client applications will experience a temporary loss of network connectivity. If the client application is configured to recover from temporary network connection problems, it will be able to continue operating after a server failover.

Applications that can be failed over can be further divided into two groups: those that support the Cluster API and those that do not.

Applications that support the Cluster API (for example, Microsoft SQL Server 2000) are defined as *cluster aware*. These applications can register with the Cluster service to receive status and notification information, and they can use the Cluster API to administer clusters.

**Important**

- Only Microsoft SQL Server 2000 Failover Clusters and subsequent versions are supported in a server cluster running Windows Server 2003, Enterprise Editionor Windows Server 2003, Datacenter Edition.

Applications that do not support the Cluster API are defined as *cluster unaware*. If cluster-unaware applications meet the TCP/IP and remote storage criteria, they can still be used in a cluster and often can be configured to fail over.

In either case, applications that keep significant state information in memory are not the best applications for clustering because information that is not stored on disk is lost at failover.

Finally, it is important to note that in order for an application to be certified by Microsoft as cluster compliant, the application must meet certain requirements. Those requirements are as follows:

**Summary of Cluster service requirements**
**Note**

- Applications that do not meet these requirements are eligible for the Windows Server 2003, Standard Editioncertification only.

**Rationale**

A server cluster is a group of independent servers managed as a single system for higher availability. Cluster service is a set of system services in Windows Server 2003, Enterprise Editionand Windows Server 2003, Datacenter Editionthat enable you to form server clusters by connecting multiple servers together, making them appear to network clients as a single, highly available system.

Cluster service can automatically detect the failure of an application or server, and restart the application, either on the same server if it is still alive, or on another surviving server.

These requirements help ensure that your application will run properly with Cluster service enabled, so that:

- Your server application can fail over to other servers.
- The client side of your application properly handles failure of the server application.

**Customer benefits**

Customers who run your application in a clustered environment can achieve higher availability because your application can continue to provide service during both planned downtime (such as hardware and software upgrades) and unplanned outages (such as hardware or software failure).

When one of the systems, or nodes, in the cluster fails or becomes unavailable, Cluster service transfers its workload to another system in the cluster. Users experience only a momentary pause in service. You can also configure Cluster service to provide failback so that when the failed server comes back online, the workload is rebalanced across the server cluster.

**Requirements**

- Applications must be able to be installed on up to eight nodes for certification on Windows Server 2003, Enterprise Editionor Windows Server 2003, Datacenter Edition.
- Applications must support failover to all cluster members.
- Clients must survive failure of the server application without failing or affecting the stability of the system.

**How to comply with Cluster service requirements**

- Applications must be able to be installed on up to eight nodes for certification on Windows Server 2003, Enterprise Editionor Windows Server 2003, Datacenter Edition.

  **Note**

  - Make certain your application setup does not make any assumptions about the number of nodes in the cluster. Verify that it enumerates all nodes in the cluster and allows installing your application on any node, even if the disks where your application data is stored are not physically located on that node.

- Applications must support failover to all cluster nodes.

  When a node in the cluster fails, Cluster service will move the resource group from that node to a new node. A resource group is a collection of resources that provide services to clients and can depend on each other.

  Resources that represent the primary functionality of your application must be able to start up (come online) on any other node in the cluster. After a failover is complete, very that clients are able to access all data exposed by primary functions.

  **Note**

  - Cluster service operates under a "shared nothing" architecture in which each server owns its own disk resources.

In the event of a server failure, ownership of the clustered disk is transferred from one server to another. For applications to properly support failover, the application's data must be stored on the clustered disk.

- Clients must survive failure of the server application without failing or affecting the stability of the system.

  Any client that ships with your server application must gracefully handle both cluster node failures and application failures. Cluster and application failures may cause clients to temporarily lose their connection to the server application (see the next item). Your client must survive both the failure of the server application and node failure as follows:

  - When a connection to the server application is lost, your client application must not stop responding or compromise the stability of the client operating system.

  - After the failover is complete and the application is restarted on a cluster node, your client must reconnect to the cluster in one of the following ways:

Reestablish the lost connection without user intervention and with no loss of data

--or--

Offer the user a chance to reconnect and retry the operation that failed; for example, prompt the user to refresh the data in the client

- If the server application is not able to restart, the client must inform the user that the connection could not be reestablished.

Connections to the server application can be lost for any of the following reasons:

- The application fails and is then restarted on the same node.

- The application fails and is restarted on a new node.

- The node fails, and all resources fail over to a new node.

- The administrator moves the resource group containing the application to a new node.

- The administrator shuts down the server application.

- All nodes in the cluster fail.

- The client's network connection to the cluster is interrupted, even though the cluster and the server application are still running.

These failures might be exposed to the client application as application time-outs, invalid handles, network failures, and connection time-outs.

**Development guidelines**
The guidelines in this section are not requirements that will be tested individually for certification. However, following these guidelines will help you meet the requirements described previously:

- Use TCP/IP protocol

  Services that communicate with clients (as well as their clients) must use TCP/IP to be able to take advantage of IP address failover provided by Cluster service. servers that do not communicate with clients do not need to use TCP/IP.

- Make sure that applications use a virtual server name and IP address to connect to the node hosting the server application.

  Clients communicating with the cluster resources must use the virtual server IP address or virtual server network name

to support failover.

If the server application publishes a network name or IP address to clients, it must publish an IP virtual server IP address or network name. A server application that depends on a computer name or an IP address is supposed to use a network name or an IP address of a virtual server that is used by clients to access this application. Make sure that your server application does not fail to restart on another node because the computer name on this node is different.

The following code example illustrates how to set the server application environment as part of your resource DLL online routine.

```
//
// Create the new environment with the simulated net name when the
// services queries GetComputerName.
//
if ( ! ClusWorkerCheckTerminate( pWorker ) )
{
nStatus = ResUtilSetResourceServiceEnvironment(
YOUR_SERVICE_NAME,
pResourceEntry->hResource,
g_pfnLogEvent,
pResourceEntry->hResourceHandle
);
if ( nStatus != ERROR_SUCCESS )
{
break;
} // if: error setting the environment for the service
}
```

**About IP address failover**

Client applications use a virtual server IP address to access services running on a server Cluster. A virtual server is a cluster resource group containing an IP address and a network name. A virtual server can be brought online on any node in the cluster. However, it appears to clients accessing it as the same physical computer.

The IP address of the virtual server has to be configured as a cluster resource in the same resource group where the server application was created. In case of a node failure, all resource groups running on this node are moved to another node in the cluster. The IP address of the virtual server is now available on another node and all connections with the clients can be reestablished.

- Upon failure, clients must preserve user data.

  The client application must be able to reconnect and resume an operation in the event of cluster node failure. It must either offer the user a chance to retry the connection, or it must retry the connection automatically until it succeeds or can determine that the server application could not be brought online.

  In case of a node failure, all resource groups running on the failed node are moved to another node in the cluster. Cluster service requires some time to bring all resources online and restart services on the other node. The time needed to fail over a server application depends on many factors. The most significant is the time required to restart the application.

- The location of application data must be configurable.

  Cluster service can fail over only disks managed by the cluster that are on the storage bus shared among all nodes in the cluster. Make sure that your application setup allows for selecting the drive and installing application data on any drive. Cluster-aware setup should allow installing the application data only on a shared drive managed by the cluster.

- Checkpoint either automatically or manually the state information required for a clean restart.

  If a server application maintains any state information required for a clean restart, make sure that it checkpoints this state information frequently to a cluster disk managed by a cluster. It is supposed to use this data to recover quickly after a failure.

- Upon failure, an application can be restarted and, if applicable, recover to the last checkpoint.

  The server application must recover from a node failure. Make sure that a sudden node failure (for example, a power blackout) will not leave your application in a state in which it cannot restart.

  After a node failure, Cluster service moves the server application running on the node to another node along with any other resources it may depend on. The server application must restart, recover, and resume operation in the time you specified in your product literature.

- At least one instance of the application can run as a cluster resource.

  Cluster service manages applications as cluster resources. A cluster resource is a physical or logical entity that can be owned by a node, brought online and taken offline, moved between nodes, and managed as a server cluster object. A resource can be owned only by a single node at any point in time. A resource is associated with, and managed by, a resource type.

  If the resource supports it, Cluster service can manage multiple instances of the same resource, but it is acceptable to support only one instance.

  To take advantage of clustering, your application has to be configured as a cluster resource. Make sure you can create at least one instance of your application. Your application must function properly as a cluster resource. Cluster service must be used to start your application (bring it online) and stop it (take it offline).

- Can be configured at least as a generic service or application.

  The monitoring and failover capabilities of Cluster service can be extended to support any application. Cluster service uses resource DLLs to extend its failover support to other resource types.

  Applications that do not offer an application-specific resource DLL can still take advantage of clustering by using a generic application or generic service resource type. These resource types offer failover protection against most failures, notably node failure. However, they cannot detect your application failures. If your application stops responding, Cluster service will not be able to detect this failure and either restart or fail over your application.

  It is acceptable to use a generic application or a generic service type to manage your application as a cluster resource.

**How to pretest applications for Cluster service requirements**

**How to pretest whether your application is cluster ready.**
If your application's setup is cluster aware, use setup to configure all nodes.

If your application's setup is not cluster aware, install your server application on at least two nodes in the cluster. Use the Cluster Administrator console to create a virtual server and configure your server application as a generic service or application. Use the Cluster Administrator console to move your resource to either node in the cluster. If your application is cluster-ready, it is supposed to come online on any node in the cluster. Clients should be able to access the service provided by your application no matter which node hosts it.

For certification on Windows Server 2003, Enterprise Editionor Windows Server 2003, Datacenter Edition, repeat this procedure for three-node, four-node, five-node, six-node, seven-node, and eight-node configurations.

**How to pretest whether your application supports failover**

1. After you have installed the application on all nodes in the cluster, run functionality tests to verify that the application is fully functional and stable.

2. Cause the node running your application to fail so that failover of the application is triggered.

   Following are suggestions for triggering failure:

   - **Hardware failure.** Simulate by doing a hard reset.
   - **Operating system failure.** Simulate by emitting a CTRL+C command followed by a ".reboot" command from a remote kernel debugger.
   - **Application failure.** Simulate using the End Process feature in Task Manager or Process Viewer (Pview.exe in the Platform SDK).

     Note that normal shutdown of the computer is not a valid test for failover because the application will have the opportunity to shut down gracefully.

3. Verify that the application restarts on a new node in the cluster.
4. Run functionality tests to verify that all functionality is again available on the new node. The application must have access to all data to which it previously had access.
5. For testing on Windows Server 2003, Enterprise Editionor Windows Server 2003, Datacenter Edition, repeat steps 2 through 4 to verify that the application subsequently fails over to each of the remaining nodes.

**How to pretest whether clients you provide survive failure and subsequent restart of the server application**
Cause the server application to fail using each of the following scenarios:

- Shut down the server application using the normal shutdown sequence and leave all nodes in the cluster running.
- Terminate the application process (do not use the normal shutdown sequence), but leave the node running.
- Stop the node.

  Do not use normal shutdown. The node and application must not have time to exit gracefully. Following are suggestions for various failure modes:

  - **Hardware failure.** Simulate by doing a hard reset.
  - **Operating system failure.** Simulate by emitting a CTRL+C command followed by a ".reboot" command from a remote kernel debugger.
  - **Application failure.** Simulate using the End Process feature in Task Manager or Process Viewer (Pview.exe in the Platform SDK).

For each case:

- Verify that the client does not stop responding or lose stability when the server application fails.
- After the server application is restarted, either on the same node or a different node, verify that the client either:

  - Reestablishes the connection with no user intervention and no loss of user data.

    --or--

  - Prompts the user to retry the connection and the application then establishes the connection.

**Note**

- If you need to manually configure the client to access the server application, configure it to use the virtual server, not the node name.

**How to pretest whether clients you provide survive failure without subsequent restart of the server application**

- Cause the application to fail in a way that does not allow it to restart on the cluster. To do this, you can take the resource offline, or stop all nodes.
- Verify that the clients do not stop responding or lose stability.
- Verify that the clients notify the user in a reasonable time that the connection to the server application was lost.
- Verify that the client can be closed without failing or affecting the stability of the client's workstation, and that the user can preserve data, if appropriate.

# Determining failover and move policies for groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Determining failover and move policies for groups**
For every resource group, the Cluster service maintains a prioritized list of the nodes that are supposed to act as its host. To fully exploit the processing power of a cluster, it is recommended that you understand how the Cluster service uses this prioritized list to move, failover, and failback resource groups. This will allow you to better balance groups among all nodes and maximize the performance of your server cluster.

**Failover policies**
You can assign the failover policies for each group of resources in your cluster. These policies determine exactly how a group behaves when failover occurs. You can choose which policies are most appropriate for each resource group you set up. For more information on setting failover policies, see Setting group properties.

Failover policies for groups include three settings:

Failover timing

Preferred nodes list

Failback timing

**Failover timing**
You can set a group for immediate failover when a resource fails, or you can instruct the Cluster service to try to restart the failed resource a number of times before failover occurs. If it is possible that the resource failure can be overcome by restarting all resources within the group, then set the Cluster service to restart the group.

Verify that the failover threshold does not exceed the number of nodes in the cluster. For example, if the cluster contains three nodes, set the failover threshold to three.

**Preferred nodes list**
The Cluster service maintains an ordered, internal list of available nodes for resource group moves, failovers, and failbacks. Optionally, you can set up a prioritized list of nodes that are preferred owners for a group so that the Cluster service can choose the best available node on that list rather than choose a node at random. This list, known as the preferred nodes list, is useful if one or more of the nodes is better equipped to host the group.

### Important

- When setting up a preferred nodes list for a resource group, it is highly recommended that you define a **complete** preferred nodes list, that is, one listing all nodes in your server cluster, in order of priority.

**Failback timing**
You can set a group to fail back to its preferred node as soon as the Cluster service detects that the failed node has been restored, or you can instruct the Cluster service to wait until a specified hour of the day, such as after peak business hours.

### Important

- Failback only occurs when you have defined a preferred nodes list for a resource group and failback is allowed for that resource group.

  If you specify that a group failback to a preferred node and then restart the node to test the failback policy you set, the resource group will not failback. A resource group will not failback when a node is restarted after a planned shutdown and restart. To test the failback policy, you must press the reset button on the node. For more information on testing failback policies, see Test node failure.

**Moving groups**
You can use Cluster Administrator or cluster.exe to manually move a resource group from one node to another. If you specify the destination node for the move, the Cluster service will move the group to the node you specify. However, if you do not specify the destination node, but instead select the **Best Possible** option, the Cluster service will select a destination node. The

logic that the Cluster service uses to select the destination node will be different for each of these scenarios:

- You **have** specified a list of nodes as preferred owners for that resource group.
- You **have not** specified a list of nodes as preferred owners for that resource group.

For more information on moving resource groups, see Move a group to another node.

The table below summarizes the move, failover, and failback logic that the Cluster service uses depending on whether the user defines a preferred nodes list.

| Scenario | Move group | Resource or node failures | Failback enabled |
|---|---|---|---|
| Preferred Nodes List Defined | Fails over to the **first** node on the list that is available. | Fails over to the **next** node on the list. | Fails back to the **original** node. |
| Preferred Nodes List Not Defined | Fails over to a randomly selected node. | Fails over to a randomly selected node. | No failback. |

The section below provides details on the logic behind manual moves, failovers, and failbacks.

**Moves, failovers, and failbacks**

**Preferred nodes list not defined**
If you have not set up a preferred owners list for a group, the Cluster service creates an internal list of nodes ordered by their node IDs. In general, this is the same as the order in which the nodes were added to the server cluster. It may, however, be ordered differently if nodes have been evicted from the server cluster. When a resource group or node fails and you have not defined a preferred list of owners for that group, the Cluster service randomly selects a node from the internal list of nodes and attempts to transfer the group to that node.

If you manually move a resource group off a node without specifying a destination node, the Cluster service transfers the group to a randomly selected node.

**Preferred nodes list defined**
If you define a complete preferred nodes list for a group (that is, one listing all the nodes in the cluster), then the Cluster service uses this defined list as its internal list. However, if you define a partial preferred nodes list for a group, then the Cluster service uses this defined list as its internal list and appends any other installed nodes not on the preferred list, ordered by their node IDs. For example, if you created a 5-node cluster (installing the nodes in the order *Node1*, *Node2*, *Node3*, *Node4*, and *Node5*) and defined *Node3*, *Node4*, and *Node5* as preferred owners for the resource group, PRINTGR1, the Cluster service would maintain this ordered list for PRINTGR1: *Node3*, *Node4*, *Node5*, *Node1*, *Node2*. How the Cluster service uses this list depends on whether the resource group move is due to a resource/node failure or a manual move group request.

### Important

- When setting up a preferred nodes list for a resource group, it is recommended that you define a **complete** preferred nodes list, that is, one listing all nodes in your server cluster, in order of priority.

**Preferred lists and resource or node failures**
For resource group or node failures, the group fails over to the node **next** to the current owner on the preferred nodes list. In the example above, if the resource group PRINTGR1 on *Node3* fails, then the Cluster service would fail that group over to the next node on the list, *Node4*. If you allow failback for that group, then when *Node3* comes up again, the Cluster service will fail back PRINTGR1 to that node.

**Preferred lists and manual moves**
If you manually move a resource group without specifying a destination node, the Cluster service fails over that group to the **first** node listed on the preferred nodes list that is available.

# Choosing a domain model

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Choosing a domain model**

Nodes in a server cluster can be either member servers or domain controllers. However, in either case, all nodes must belong to the same domain.

If you configure your cluster nodes as domain controllers, you must first make sure you have the hardware to support them. For more information, see Capacity Planning for Server Clusters.

If you configure all of the cluster nodes as member servers, then the availability of the cluster will depend on the availability of the domain controller. The Cluster service requires that the nodes be able to contact the domain controller to function correctly, so the domain controller must be highly available. To avoid a single point of failure, the domain must have at least two domain controllers. For more information on increasing availability, see Addressing risks using server clusters.

At least two domain controllers must be configured to be global catalog servers.

**DNS considerations**

If DNS is used to resolve names in the domain, then you must deploy at least two Domain Name System (DNS) servers. If your cluster nodes are the only domain controllers in their domain, they must be configured as Domain Name System (DNS) servers. Make sure that the DNS servers support dynamic updates. For more information on DNS, see DNS.

Each domain controller and cluster node must be configured with a primary and at least one secondary DNS server. If the domain controllers are also DNS Servers, then make sure each points to itself for primary DNS resolution and to the other DNS servers for secondary resolution.

**Performance considerations**

Take into account the additional overhead that is incurred by the domain controller services. In large networks running on Windows Server 2003 family operating systems, substantial resources can be required by domain controllers for performing directory replication and server authentication for clients. For this reason, many applications, such as Microsoft SQL Server and Message Queuing, recommend that, for best performance, you not install the application on domain controllers. However, if you have a very small network in which account information rarely changes and in which users do not log on and off frequently, you can use domain controllers as cluster nodes.

# Capacity Planning for Server Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Capacity planning**
After you assess your clustering needs, you are ready to determine how many servers you need and with what specifications, such as memory and hard disk storage.

This section covers:

- Planning your groups
- Determining server-capacity requirements

# Planning your groups

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning your groups**
You can take six steps to organize your applications and other resources into groups:

**List all your server-based applications**
Most groups contain one or more applications. Make a list of all applications in your environment, regardless of whether or not you plan to use them with the Cluster service. Your total capacity needs are determined by the sum of the total number of groups (virtual servers) that will run in your environment and the total amount of other software you will run independently of groups.

**Sort the list of applications**
Determine which of your applications can use failover. For more information, see Choosing applications to run on a server cluster.

Also list applications that will reside on cluster nodes but that will not use the failover feature because it is inconvenient, unnecessary, or impossible to configure the applications for failover. Although you do not set failover policies for these applications or arrange them in groups, they still use a portion of the server capacity.

Before clustering an application, review the application license, or check with the application vendor. Each application vendor sets its own licensing policies for applications running on clusters.

**List all other resources**
Determine which hardware, connections, and operating-system software a server cluster can protect in your network environment. For more information, see Addressing risks using server clusters.

For example, the Cluster service can fail over print spoolers, to protect client access to printing services. Another example is a file-server resource, which you can set to fail over, maintaining client access to files. In both cases, capacity is affected, such as the random access memory (RAM) required to service the clients.

**List all dependencies for each resource**
When you create this list, include all resources that support the core resources. For example, if a Web-server application fails over, the Web addresses and cluster storage devices containing the files for that application must also fail over if the Web server is to function. All these resources must be in the same group. This ensures that the Cluster service keeps interdependent resources together at all times.

Two guidelines for quantifying resources are:

- A resource and its dependencies must be together in a single group.
- A resource cannot span groups.

For example, if several applications depend on a particular resource, you must include all of those applications with that resource in a single group.

**Make preliminary grouping decisions**
Another factor in the way you assign groups is administrative convenience. For example, you might put several applications into one group because viewing those particular applications as a single entity makes it easier to administer the network.

A common use of this technique is to combine file-sharing resources and print-spooling resources in a single group. All dependencies for those applications must also be in the group. You can give this group a unique name for the part of your organization it serves, such as "Accounting File&Print." Whenever you need to intervene with the file- and print-sharing activities for that department, you would look for this group in Cluster Administrator.

Another common practice is to put applications that depend on a particular resource into a single group. For example, suppose a Web-server application provides access to Web pages, and that those Web pages provide result sets that clients access by querying a Microsoft SQL Server 2000 database application, through the use of Hypertext Markup Language (HTML) forms. By putting the Web server and the Microsoft SQL Server 2000 database in the same group, the data for both core applications can reside on a specific disk volume. Because both applications exist within the same group, you can also create an Internet

protocol (IP) address and network name specifically for this resource group.

**Make final grouping assignments**
After you list the resources that you want to group together, assign a different name to each group, and create a dependency tree. A dependency tree is useful for visualizing the dependency relationships between resources.

To create a dependency tree, first write down all the resources in a particular group. Then draw arrows from each resource to each resource on which the resource directly depends.

A direct dependency between resource A and resource B means that there are no intermediary resources between the two resources. An indirect dependency occurs when a transitive relationship exists between resources. If resource A depends on resource B and resource B depends on resource C, there is an indirect dependency between resource A and resource C. However, resource A is not directly dependent on resource C.

The figure shows the resources in a final grouping assignment in a dependency tree.

In the diagram, the File Share resource depends on the Network Name resource, which, in turn, depends on the IP Address resource. However, the File Share resource does not directly depend on the IP Address resource.

For information on using Cluster Administrator to set resource dependencies, see Setting resource properties.

# Determining server-capacity requirements

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Determining server-capacity requirements**

After you choose a cluster model, determine how to group your resources, and determine the failover policies required by each resource, you are ready to determine the hardware capacity required for each server in the cluster. This topic explains the criteria for choosing computers for use as cluster nodes.

- **Cluster storage requirements**

  Each node in a cluster must have enough persistent storage capacity to store permanent copies of all applications and other resources required to run all groups. Calculate this for each node as if all of these resources in the cluster were running on that node, even if some or all of those groups run on other nodes most of the time. Plan these disk space allowances so that either node can efficiently run all resources during failover.

- **CPU requirements**

  Failover can strain the CPU processing capacity of a node when it takes control of the resources from a failed node. Without proper planning, the CPU of a surviving node can be pushed beyond its practical capacity during failover, slowing response time for users. Plan your CPU capacity on each node so that it can accommodate new resources without unreasonably affecting responsiveness.

- **Random access memory (RAM) requirements**

  When planning your capacity, make sure that each node in your cluster has enough RAM to run all applications that might run on either node. Also, make sure your paging files are set appropriately for each node's RAM.

  For more information about paging files, see Optimizing the paging file size and location and Change the size of the virtual memory paging file.

**Note**

- You can use the Windows DNA Performance Kit to test and tune the performance of your applications in your server cluster. For more information about the Windows DNA Performance Kit or about how to download the kit, see the Windows DNA Performance Kit link in Web Resources at the Microsoft Windows Resource Kits Web site.

# Planning for Fault-Tolerant Disks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning for fault-tolerant disks**
Many groups include disk resources for disks on shared buses. In some cases, these are simple physical disks, but in other cases they are complex disk subsystems containing multiple disks. Resources depend on the physical disk resource that represents the storage device. An unrecoverable failure of a disk resource results in certain failure of all resources that depend on that disk.

For these reasons, you might decide to use special methods to protect your disks and disk subsystems from failure. One common solution is the use of a hardware-based redundant array of independent disks (RAID). RAID support ensures the high availability of data contained on disk sets in your clusters. Some of these hardware-based solutions are considered fault tolerant, which means that data will not be lost if a member of the disk set fails.

**Important**

- You cannot use software fault-tolerant disk sets for cluster storage.

This section covers:

- Hardware redundant array of independent disks (RAID)
- Error recovery

# Hardware redundant array of independent disks (RAID)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Hardware redundant array of independent disks (RAID)**
The Windows Catalog contains many different hardware RAID configurations for clusters. Because many hardware RAID solutions provide power, bus, and cable redundancy within a single cabinet, and track the state of each component in the hardware RAID firmware, they provide data availability with multiple redundancy, protecting against multiple points of failure. Hardware RAID solutions can also use an on-board processor and cache.

Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition can use these disks as standard disk resources.

For more information on the different hardware RAID configurations, see the Microsoft Windows Catalog at Support resources.

**Important**

- You cannot use software fault-tolerant disk sets for cluster storage.

# Error recovery

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Error recovery**

With transaction logging and recovery, the NTFS file system ensures that the volume structure will not be corrupted, so all files remain accessible after a system failure. The NTFS file system also uses the recovery technique called cluster remapping. When the operating system returns a bad-sector error to the NTFS file system, NTFS dynamically replaces the disk cluster containing the bad sector and allocates a new disk cluster for the data. If the error occurs during a read, NTFS returns a read error to the calling program, and the data is lost (unless protected by RAID fault tolerance). When the error occurs during a write, NTFS writes the data to the new disk cluster, and no data is lost. NTFS puts the address of the disk cluster containing the bad sector in its Bad Sector file so that the bad sector is not reused.

Even with transaction logging and recovery and disk cluster remapping, user data can be lost due to hardware failure if you do not use a fault-tolerant-disk solution. For more information, see Planning for Fault-Tolerant Disks.

# Planning for unattended Setup

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning for unattended Setup**

This topic provides general information about unattended Setup. For detailed instructions on running unattended Setup (also called automated installation), see "Automating and Customizing Installations" at the Microsoft Windows Server System Web site. Also see the Windows XP Professional Resource Kit at the Microsoft Windows XP Resource Kits Web site. For information about the Windows Deployment and Resource Kits, see Using the Windows Deployment and Resource Kits.

To simplify the process of setting up a product in the Windows Server 2003 family on multiple computers, you can run Setup unattended. To do this, you create and use an *answer file*, a customized script that answers the Setup questions automatically. Then, you run Winnt32.exe or Winnt.exe with the appropriate options for unattended Setup. Choose the command according to the operating system that is running when you start unattended Setup:

- To start unattended Setup on a computer running MS-DOS or Windows 3.*x*, use Winnt.exe (with the appropriate options).
- To start unattended Setup on a computer running Windows 95, Windows 98, Windows Millennium Edition, Windows NT, Windows 2000, Windows XP, or a product in the Windows Server 2003 family, use Winnt32.exe (with the appropriate options). With Windows NT 4.0, before starting unattended Setup, apply Service Pack 5 or later.

To learn about unattended Setup, see the following sources:

- **For detailed instructions on running unattended Setup (also called automated installation):** See the Windows Deployment and Resource Kits listed in the first paragraph of this topic.
- **To view the command options available for Winnt.exe:** On a computer running Windows 3.*x* or MS-DOS, insert the Setup CD for a product in the Windows Server 2003 family in the CD-ROM drive and open the command prompt. Then, change to the CD-ROM drive, change to the I386 directory, and type:

  **winnt /?**
- **To use an x86-based or x64-based computer to view the command options available for Winnt32.exe:** On a computer running Windows 95, Windows 98, Windows Millennium Edition, Windows NT, Windows 2000, Windows XP, or a product in the Windows Server 2003 family, insert the Setup CD for Windows Server 2003, Standard Edition, in the CD-ROM drive, and open the command prompt (click **Start**, click **Run**, and then type **cmd**). Then, change to the CD-ROM drive, change to the I386 directory, and type:

  **winnt32 /?**
- **To use an Itanium-based computer to view the command options available for Winnt32.exe:** On an Itanium-based computer running Windows XP 64-Bit Edition; the Itanium-based version of Windows Server 2003, Enterprise Edition; or the Itanium-based version of Windows Server 2003, Datacenter Edition, insert the Setup CD for the product in the CD-ROM drive and open the command prompt (click **Start**, click **Run**, and then type **cmd**). Then, change to the CD-ROM drive, change to the IA64 directory, and type:

  **winnt32 /?**

For information about using Winnt.exe or Winnt32.exe for interactive setup (not unattended Setup), see How to install and upgrade the operating system.

# Optimizing Your Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Optimizing your clusters**

Because Cluster service uses an adaptable architecture, it is able to allocate resources as needed to meet changing usage requirements. However, there are some hardware and configuration choices you can make to improve cluster performance. These choices are explained in the following sections:

- Focusing on the right hardware resources for server clusters
- Optimizing the paging file size and location for server clusters
- Using additional TCP/IP services for server clusters

# Focusing on the right hardware resources for server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Focusing on the right hardware resources**

The goal in tuning the Cluster service and hosted applications is to determine which hardware resource will experience the greatest demand, and then to adjust the configuration to relieve that demand and maximize total throughput. Structure a system so that its resources are used efficiently.

For example, if the primary role of the cluster is to provide high availability of file and print services, high disk I/O usage will be incurred due to the large number of files being opened and closed. File and print services also cause a heavy load on network adapters because of the large amount of data that is being transferred. It is important to make sure that your network adapter can handle the load. In this scenario, memory typically does not carry a heavy load (although memory usage can be heavy if a large amount of system memory is allocated to file-system cache). Processor utilization is also typically low in this environment. In such cases, memory and processor utilization usually do not need the optimizing that other components need.

In contrast, a server-application environment (such as one running Microsoft SQL Server, Microsoft Exchange Server, Microsoft Systems Management Server, and Microsoft Systems Network Architecture (SNA) Server) is much more processor- and memory-bound than a typical file and print server environment because much more processing is taking place at the server. In these cases, it is best to use high-end multiprocessor computers. The disk and network loads tend to be less used because the amount of data being sent over the wire and to the disk is smaller. The Cluster service itself uses few of the system resources either for intracluster communication or for the operation of the cluster itself.

# Optimizing the paging file size and location for server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Optimizing the paging file size and location**

The location and size of the paging files can greatly affect performance. Paging files cannot be located on the shared bus, but if multiple unshared drives are available on the individual servers, placing the paging file on a separate, fast, low-use drive can boost performance. The size setting of the paging file is also critical to performance. A paging file that must constantly expand and shrink requires additional processor and I/O overhead.

# Using additional TCP/IP services for server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using additional TCP/IP services**

WINS, DHCP, and DNS Services use additional system resources, which you must consider before implementing any of these services on a cluster. In particular, WINS can require substantial overhead during peak logging on times in large networks. In such cases, make sure that your system has the necessary capacity to perform adequately.

**Important**

- DNS is not clustered, but the node acts as the server of the service. If you run DNS on a node of a cluster, make sure to implement backup servers to provide redundancy, just as you would normally do on your network.

# Using Server Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using server clusters**

This section provides information on how to use a server cluster to provide high availability application support.

- Server cluster rules
- Applying administrative procedures to server clusters
- Cluster automation interface
- General storage configuration tips for server clusters
- Backing up and restoring server clusters
- Uninstalling a server cluster
- Cluster Hardware Configuration
- Standard Resource Types
- Managing Security in a Cluster
- Using Cluster Administrator
- Using a server cluster with large numbers of file shares
- Using Shadow Copies of Shared Folders in a server cluster
- Setting Properties
- Network Management

# Server cluster rules

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Server cluster rules**

Following these rules will help you solve the most common problems associated with clusters.

- Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition must be installed on each node.
- All nodes of the cluster must belong to the same Windows Server 2003 family operating systems domain; see Choosing a domain model.
- When you first create the cluster or add nodes to the cluster, you must be logged on to the domain that has administrative user rights and permissions on all nodes.
- Each cluster node can belong to only one cluster.
- The shared drive must be formatted using the NTFS file system.
- Cluster disks on a shared bus must be partitioned as master boot record (MBR) and not as GUID partition table (GPT) disks.
- Do not change the computer name of a cluster node after configuring the first node of your cluster.
- Do not repartition disks on the shared bus without first deleting the corresponding disk resources.
- If you start the node using an operating system other than Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, do not run any diagnostic tools that make low-level writes to a physical disk.
- Do not reassign the drive letters of the system disks on the nodes.
- Verify that either the WINS or DNS service is accessible from all nodes.
- Verify that TCP/IP is installed on all nodes and clients.
- Verify that all cluster nodes can detect one another over the network. Use the TCP/IP **ping** utility or the Windows Server 2003 family operating system **net view** command.
- Check all event logs on all affected computers for error messages.

For information about how to obtain product support, see Technical support options.

# Applying administrative procedures to server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Applying administrative procedures to server clusters**
Typically, an administrator follows a set of server operating procedures when performing administrative tasks on a server, such as restarting a server, backing up applications and data, and installing new hardware or software. For a server cluster, reexamine these operating procedures; some will have to be modified in a server cluster environment.

**Reexamining procedures that take a server cluster offline**
Because you install Cluster Administrator on more than one computer, the tasks of administering servers and performing common server operating procedures are less disruptive to users. There are some administrative tasks that make a server unavailable to users. A server cluster, however, has another node that can continue to make the server resources available to users while you are performing administrative tasks. Therefore, you might not have to wait for nonpeak hours, when:

- A server must be restarted.
- New hardware must be installed.
- New software must be installed.

**Reexamining backups on a server cluster**
Make sure that your backup procedures account for clustering issues. In a server cluster, the following procedure is recommended:

1. Perform an Automated System Recovery (ASR) backup on each node in the cluster.

   **Note**

   - By default, Backup Operators do not have the user rights necessary to create an Automated System Recovery (ASR) backup on a cluster node. However, Backup Operators can perform this procedure if that group is added to the security descriptor for the Cluster service. You can do that using Cluster Administrator or cluster.exe. For more information, see Give a user permissions to administer a cluster and Cluster.

2. Back up the cluster disks from each node.
3. Back up each individual application (for example, Microsoft Exchange or Microsoft SQL Server) running on the nodes.

For more information, see Backing up and restoring server clusters.

# Cluster automation interface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster automation interface**

The cluster automation interface is a Component Object Model (COM) interface to the Cluster API. You can use the Cluster Automation Interface with the Windows Script Host (WSH) to automate many administrative tasks.

For more information on the Cluster API, see the Microsoft Platform Software Development Kit (SDK).

# General storage configuration tips for server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**General storage configuration tips for server clusters**

Before adding or removing hardware from a server cluster, make sure the drive letter assigned to the system partition (typically C or D) is fixed. The drive-letter assignment must remain constant because references to this drive letter are recorded in the system registry, and your server cluster is affected by these references.

It is also necessary for drive letters on the cluster storage device to remain constant and for the drive-letter assignments to be the same on each cluster node. In addition, drive letters for the cluster storage device must not conflict with any local drive letters.

If you assign drive letters to the shared cluster storage devices, the Windows Server 2003 family operating system limits the total number of such devices to 23. Mounted drives are not subject to this limit, so you can use mounted drives to access more than 23 shared cluster storage devices in your server cluster.

For more information on using mounted drives, see Using NTFS mounted drives.

For information about how to obtain product support, see Technical support options.

# Backing up and restoring server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Backing up and restoring server clusters**
Performing regular backups of your server cluster is imperative for high availability. This topic explains how you can use the Backup or Recovery Wizard to back up cluster nodes, describes ten cluster failure scenarios, and offers data restore solutions for each scenario using the Backup or Restore Wizard and recovery utilities from the *Microsoft Windows Server 2003 Resource Kit*.

For more information on backup and restore procedures, see Backing up and restoring data.

**Backing up cluster data**
In a server cluster, there are four groups of data critical to the proper operation of the cluster; the disk signatures and partitions of the cluster disks, the cluster quorum data, the data on the cluster disks, and the data on the individual cluster nodes.

- Cluster disk signatures and partitions
- Cluster quorum data
- Data on the cluster disks
- Data on the individual cluster node

**Cluster disk signatures and partitions**
Before you begin to back up any data on the server cluster nodes, make sure you backup the cluster disk signatures and partitions using Automated System Recovery in the Backup Wizard. This step is necessary if you later need to restore the signature of the quorum disk, for example, if you experience a complete system failure, and the signature of the quorum disk has changed since you last backed up.

### Note

- By default, Backup Operators do not have the user rights necessary to create an Automated System Recovery (ASR) backup on a cluster node. However, Backup Operators can perform this procedure if that group is added to the security descriptor for the Cluster service. You can do that using Cluster Administrator or cluster.exe. For more information, see Give a user permissions to administer a cluster and Cluster.

For information, see Back up cluster disk signatures and partition layouts.

**Cluster quorum data**
When you back up data on a server cluster node, make sure you also back up the cluster quorum. The cluster quorum is important because it contains the current cluster configuration, application registry checkpoints, and the cluster recovery log.

You can use the Backup Wizard to back up the cluster quorum data if you perform a System State backup from any node provided the Cluster service is running on that node.

For information, see Back up the cluster quorum.

**Data on the cluster disks**
To back up all cluster disks owned by a node, perform a full backup from that node.

You can also back up this data through a network connection to a hidden administrative file share. For example, you might use the New Resource Wizard to create FBackup$, GBackup$, and HBackup$ file shares for the root of drives F, G, and H, respectively. These shares would not appear in the browse list and could be configured to allow access only to members of the Backup Operators group.

For information on backing up data on the cluster disks, see Back up data on cluster nodes.

### Important

- If a cluster disk owned by the node being backed up fails over to another node during the backup process, the backup set will not contain a full backup of that disk.

**Important**

- You can only backup a cluster disk on a local node. You cannot backup a cluster disk on a remote computer.

**Data on the individual cluster nodes**

After you back up the cluster quorum disk on one node, it is not necessary to back up the quorum on the remaining cluster nodes. However, you may want to back up the clustering software, cluster administrative software, system state, and application data on the remaining nodes.

**Important**

- If you back up the system state for a node, you will also automatically back up the quorum data as long as the Cluster service is running on that node.

For information on backing up data on individual cluster nodes, see Back up data on cluster nodes.

**Cluster failure and restore scenarios**

This section describes ten failure scenarios that will require restoring your cluster. The type of failure you experience determines the steps you must follow.

- Scenario 1—Cluster Disk Data Loss
- Scenario 2—Cluster Quorum Corruption
- Scenario 3—Cluster Quorum Loses Checkpoints
- Scenario 4—Cluster Disk Corruption or Failure
- Scenario 5—Cluster Quorum Disk Failure
- Scenario 6—Single Cluster Node Corruption or Failure
- Scenario 7—Cluster Quorum Rollback
- Scenario 8—Complete Cluster Failure
- Scenario 9—Majority Node Set Cluster Failure
- Scenario 10—Application Data Loss in a Server Cluster

**Scenario 1—Cluster Disk Data Loss**

If you have lost files and folders on one of your cluster disks, but not on the disk containing the cluster quorum, you can use the Backup or Restore Wizard to restore that data.

**Important**

- You must restore the cluster disk data from the node that owns the cluster disk.

For information, see Restore files from a file or a tape.

**Scenario 2—Cluster Quorum Corruption**

**Symptom:** The cluster nodes can boot up, but the Cluster service fails to start because the quorum resource cannot come online.

If this problem results from corrupted files on the quorum disk, try starting the Cluster service by opening a command prompt

and typing **net start clussvc /resetquorumlog**. This creates a new quorum log file, using information stored in the cluster database on the local node. For additional information about recovering from cluster quorum corruption, see Recover from a corrupted quorum log or quorum disk. If the cluster quorum disk needs to be replaced, see Scenario 5, below. For a majority node set cluster, see Scenario 9, below.

**Scenario 3—Cluster Quorum Loses Application Checkpoints**
**Symptom:** Some resources fail to come online and the application checkpoints are out of date.

If you have recovered from quorum corruption by creating a new quorum log as described in Scenario 2 above, you may need to restore the matching checkpoints before the quorum resource can come back online.

**Using the Microsoft Windows Server 2003 Resource Kit tools**

- Use the ClusterRecovery utility. For more information, see the *Microsoft Windows Server 2003 Resource Kit* and the Help for the ClusterRecovery utility.

**Using Windows Server 2003 family tools**

- Locate backup sets of the cluster quorum disk and system disk. The cluster quorum disk backup will contain other system state data. These backups need to be a matched set, that is make sure they were taken at the same time.
- Restore data on the system disk. For information, see Restore files from a file or a tape.
- Restore the cluster quorum. For information, see Restore the contents of a cluster quorum disk for all nodes in a cluster.

**Scenario 4—Cluster Disk Corruption or Failure**
**Symptom:** A cluster disk cannot come online. Resources that depend on that cluster disk will not be able to come online.

First, see if you can run a diagnostic utility from the disk manufacturer to determine the condition of the disk. If the cluster disk is corrupted or the disk hardware fails, you can restore the disk more quickly by using utilities in the *Microsoft Windows Server 2003 Resource Kit*. If you do not have access to these tools, you can still restore your cluster disk using the Backup and Recovery utilities included with Windows Server 2003 family operating systems.

**Using the Microsoft Windows Server 2003 Resource Kit tools**

- Use the ClusterRecovery utility. For more information, see the *Microsoft Windows Server 2003 Resource Kit* and the Help for the ClusterRecovery utility.
- Use NTBackup along with the Confdisk utility (from the *Microsoft Windows Server 2003 Resource Kit*) to restore the data on the cluster disk. For more information, see the *Microsoft Windows Server 2003 Resource Kit*.

**Using Windows Server 2003 tools**

- If necessary, replace the cluster disk. For information, see Install local storage buses and devices.
- Stop the Cluster service on all nodes of the cluster.
- Locate the data backup set for the node that owns the cluster disk. Also, locate the Automated System Recovery backup set for that node, if it is available. Perform an Automated System Recovery restore on a node. Use ASR as a last resort in system recovery, only after you have exhausted other options. For more information, see Restore a damaged cluster node using Automated System Recovery.
- After the restored node comes back online, restart the Cluster service on the remaining nodes.

**Scenario 5—Cluster Quorum Disk Failure**
**Symptom:** The cluster nodes can boot up, but the Cluster service fails to start because the quorum resource cannot come online. Entries in the Event Log indicate hardware failures.

First, try starting the Cluster service by opening a command prompt and typing **net start clussvc /fixquorum**. This starts the Cluster service with all resources offline, including the quorum resource. Then you can try switching to a new quorum

resource, with or without using the Clusterrecovery utility in the Windows Server 2003 Resource Kit. For more information, see Fixquorum command.

If the cluster quorum disk (the disk containing the quorum resource) fails, you can replace it more quickly by using utilities in the *Microsoft Windows Server 2003 Resource Kit*. If you do not have access to these tools, you can still replace your cluster quorum disk using the backup and restore utilities shipped with Windows Server 2003 family operating systems.

**Using the Microsoft Windows Server 2003 Resource Kit tools**

- Use NTBackup along with the Confdisk utility (from the *Microsoft Windows Server 2003 Resource Kit)* to restore the data on the cluster disk.

- Use the ClusterRecovery utility. For more information, see the *Microsoft Windows Server 2003 Resource Kit* and the Help for the ClusterRecovery utility.

**Using Windows Server 2003 family tools**

- If necessary, replace the cluster quorum disk. For information, see Install local storage buses and devices.

- Locate the data backup set for the cluster quorum. Also, locate the Automated System Recovery backup set for the node you used to create the cluster quorum backup set, if it is available. Perform an Automated System Recovery restore on any node in the cluster. Use ASRas a last resort in system recovery, only after you have exhausted other options. For more information, see Restore a damaged cluster node using Automated System Recovery.

- Restore data on the node. For information, see Restore files from a file or a tape.

**Scenario 6—Single Cluster Node Corruption or Failure**

**Symptom:** The node cannot join the cluster.

If the Event Log indicates that the cluster database on the local node is corrupted, you can perform a System State restore on that node to replace the local cluster database. For information, see Restore the cluster database on a local node. Alternatively, you can copy the latest checkpoint file (CHKxxx.TMP) from the quorum disk to the %systemroot%\Cluster\ directory, rename it as file CLUSDB, and restart the Cluster service on that node.

If a single node fails in the cluster due to system disk or other hardware failure, follow these steps to rebuild the node and rejoin the cluster:

- After verifying that all cluster resource groups have been successfully moved to other nodes, repair or replace the failed hardware. For information, see To Move a group to another node and To Manage Cluster Hardware.

- Perform an Automated System Recovery restore on the failed node to rebuild the node. For information, see To Restore a damaged cluster node using Automated System Recovery.

- If you have other files or application data for that node backed up on on tape or other backup medium, you can restore that now. For information, see To Restore files from a file or a tape and Scenario 8 below.

- For each cluster group and resource, verify that the newly recovered node appears as a possible owner in Cluster Administrator, then move a resource group to the newly recovered node and verify that the move is successful. For information, see To test Test whether group resources can fail over.

  **Note**

  - If you do not have an Automated System Recovery backup of the node, you can evict that node and add a new node to the cluster. For more information, see To Evict a node from the clusterand To Add additional nodes to the cluster.

**Scenario 7—Cluster Quorum Rollback**

If recent changes to your cluster have resulted in the cluster not functioning as expected, you can use the Backup or Restore Wizard to roll back your cluster to a previous configuration. For example, if a number of resources have mistakenly been

deleted from the cluster configuration, you can roll it back, using a backup that contains those resources.

For information, see Restore the contents of a cluster quorum disk for all nodes in a cluster.

**Scenario 8—Complete Cluster Failure**

**Symptom:** None of the nodes can boot up.

If all nodes fail in a cluster and the quorum disk cannot be repaired, follow these steps:

- Use Automated System Recovery on one node in the original cluster, choosing a node that was backed up recently and that was active in the cluster at the time it was backed up. This restores the disk signatures, the partition layout of the cluster disks (quorum and nonquorum), and the cluster configuration data. Do not start other nodes until the first node is restored. For more information, see To Restore a damaged cluster node using Automated System Recovery.

- Restore other nodes. For more information, see Restore a damaged cluster node using Automated System Recovery.

- Restore your applications and application data from backup data sets.

### Important

- If you do not have an Automated System Recovery backup of each node, you cannot restore the cluster. Instead, you must recreate your cluster from scratch. For more information, see Checklist: Planning and creating a server cluster.

**Scenario 9—Majority Node Set Cluster Failure**

The methods for restoring a majority node set cluster are the same as for restoring other clusters. However, in a majority node set cluster, if some of the nodes fail, and the cluster loses quorum, you can force the remaining nodes to form a quorum and restart the cluster. For more information, see To Force quorum in a majority node set server cluster.

### Note

- On a majority node set cluster, the cluster database is not stored on a cluster disk central to all nodes, but is instead stored locally on each node at %systemroot%\Cluster\MNS.%ResourceGUID%$\%ResourceGUID%$\MSCS\.

**Scenario 10—Application Data Loss in a Server Cluster**

When restoring application data in a server cluster, follow the instructions provided in the documentation that shipped with your application.

### Important

- If you are backing up Microsoft Exchange Server, a newer version of NTBackup.exe may be available from the Exchange Server section of the Microsoft Web site. Otherwise, you can use the version of NTBackup.exe that is included with Windows Server 2003 family operating systems.

# Uninstalling a server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Uninstalling a server cluster**

You can uninstall or remove a node of a server cluster at any time. Before uninstalling a node, take all groups offline or move them to one or more other nodes. Also, close Cluster Administrator.

For instructions on how to remove a node from a server cluster, see Evict a node from the cluster.

# Cluster Hardware Configuration

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster hardware configuration**
This section covers:

- Fibre Channel hardware configuration
- Network Configuration in a Server Cluster

# Fibre Channel hardware configuration

Updated: April 10, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Fibre Channel hardware configuration**

When using Fibre Channel for a cluster, note the following details:

- The Fibre Channel systems are listed in a separate section of the Windows Catalog at Support resources. To list all compatible Fibre Channel devices, select **All** in **Device Type**, then in **Model** search for **Fibre Channel**.
- Your Fibre Channel disks are managed just like any other disk connected to a storage bus.
- The Fibre Channel controller ID is preconfigured with a unique ID. This simplifies your hardware setup because you do not need to manually configure each cluster node with a separate ID.

The figure shows a Fibre Channel cluster with a fiber switch or hub. Fiber optic cable runs between a node's Fibre Channel controller and the fiber switch or hub. The device bus between the switch or hub is fiber.

For more information about the types of storage you can use in a server cluster running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, see Server clusters overview.

# Network Configuration in a Server Cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network configuration in a server cluster**
This section covers:

- Configuring cluster network hardware
- Private network addressing options

# Configuring cluster network hardware

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring cluster network hardware**

**Planning your cluster network hardware and network infrastructure**
Before you configure your cluster network hardware, make sure that your networking hardware and domain infrastructure meets all the requirements for a server cluster. For more information, see Planning your networking hardware and Choosing a domain model.

**Network Interface Controller (NIC) configuration**
Follow the guidelines below to correctly configure your cluster networking hardware:

**Requirements**

- Your network adapters must use the same configuration settings.
- Each network is on a single subnet.
- At least one of the cluster networks enabled for internal communication (for example, either a private or mixed network) must be configured using static addresses.

**Recommendations**

- If an adapter is set to use Auto Select, it may drop packets while automatically negotiating the network settings. Manually set the speed and duplex mode for multiple speed adapters to the same values and settings (set these properties on the **Advanced** tab of the network adapter's Property Page). If the adapters are connected to a switch, ensure that the port settings of the switch match those of the adapters. For more information, see Change network adapter settings.
- Use static IP addresses for all adapters. Choose private IP addresses following the guidelines at Private network addressing options (that is, specify a class A, B, or C private address for each). For public networks, also use static IP addresses. It is recommended that you do not use DHCP leases for public network addresses because cluster operations might be disrupted. For more information, see The Cluster service and TCP/IP.

  The use of Automatic Private IP Addressing (APIPA) to configure a cluster network is not supported. APIPA is not designed for use in computers that are attached to multiple networks. For more information, see TCP/IP configuration methods.
- Do not configure a default gateway or DNS or WINS server on the private network adapters.
- Configure WINs and/or DNS servers and a default gateway on the public network adapters. If Network Name resources are used on the public networks, set up the DNS server to support dynamic updates; otherwise the Network Name resources may not fail over correctly. For more information, see Configure TCP/IP settings.
- Set the order of the network adapter binding as follows:

  1. External public network
  2. Internal private network (Heartbeat)
  3. [Remote Access Connections]

  For more information, see Modify the protocol bindings order.

- Clearly identify each network by changing the default name. For example, you could change the name of the private network connection from the default *Local Area Connection* to *Private Cluster Network*.

  For more information on networks and network roles, see Server cluster networks.

**Configuring logically multihomed network adapters**

A logically multihomed network adapter is one that has two IP addresses assigned to it. These adapters can be used only for node-to-node cluster communication if their primary addresses are on the same IP subnet. If the primary addresses on all nodes are not on the same IP subnet, reorder the IP addresses assigned to the adapter by using the Network Connections folder.

# Private network addressing options

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Private network addressing options**

If an interconnect connects only the cluster nodes and does not support any other network clients, you can assign it a private Internet protocol (IP) network address instead of using one of your enterprise's official IP network addresses.

By agreement with the Internet Assigned Numbers Authority (IANA), several IP networks are always left available for private use within an enterprise. These reserved numbers are:

- 10.0.0.0 through 10.255.255.255 (Class A)
- 172.16.0.0 through 172.31.255.255 (Class B)
- 192.168.0.0 through 192.168.255.255 (Class C)

You can use any of these networks or one of their subnets to configure a private interconnect for a cluster. For example, address 10.0.0.1 can be assigned to the first node with a subnet mask of 255.0.0.0. Address 10.0.0.2 can be assigned to a second node, and so on. Do not specify any default gateway, DNS or WINS servers for this network.

Ask your network administrator which of the private networks or subnets you can use within your enterprise before configuring your cluster.

Never route these private network addresses. For more information on private IP network addresses, see Resources for Server Cluster information.

# Standard Resource Types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Standard resource types**
Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition come with numerous resource types that you can use to manage cluster resources.

Internet Information Services (IIS) can be installed on a server cluster. For more information on how IIS runs on a server cluster, view the IIS online documentation.

If you have IIS installed, you can view the online documentation by typing **http://localhost/iisHelp/** in your browser address bar and pressing ENTER.

You can install Message Queuing on a server cluster. For more information on the Message Queuing and Message Queuing Triggers resource types and how they run on a server cluster, see Microsoft Message Queuing.

You can install Distributed Transaction Coordinator (DTC) on a server cluster. For more information on the Distributed Transaction Coordinator resource type and how it runs on a server cluster, see Distributed Transaction Coordinator.

**Note**

- IIS Server Instance, Simple Mail Transfer Protocol (SMTP) Server Instance, and Network News Transfer Protocol (NNTP) Server Instance resource types, previously available on Windows 2000 cluster nodes, are not supported on Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition cluster nodes.

This section also covers the following resource types and topics:

- Physical Disk resource type
- DHCP Service and WINS Service resource types
- Print Spooler resource type
- File Share resource type
- Internet Protocol Address resource type
- Local Quorum resource type
- Majority Node Set resource type
- Network Name resource type
- Generic Application resource type
- Generic Script resource type
- Generic Service resource type
- Volume Shadow Copy Service resource type

# Physical Disk resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Physical Disk resource type**

You use the Physical Disk resource type to manage disks that are on a cluster storage device.

You can assign drive letters to the disks that are on a cluster storage device or create mounted drives. If you assign drive letters, the disks must have the same drive letters on all cluster nodes.

To prevent data corruption, it is important that only one node at a time use a cluster disk. Normally, the Cluster service prevents more than one node from using a disk at the same time. However, there are two circumstances in which the ordinary cluster safeguards do not work: when you install a new disk, and when you remove a disk from control by the cluster.

For information on replacing disks in a server cluster, see Updated technical information and article Q305793, "How to Replace a Disk with Windows 2000 or Windows Server 2003 family Clusters" in the Microsoft Knowledge Base.

# DHCP Service and WINS Service resource types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**DHCP Service and WINS Service resource types**

Dynamic Host Configuration Protocol (DHCP) and Windows Internet Name Service (WINS) provide network services to clients. DHCP leases Internet protocol (IP) addresses to clients. This lets you centrally manage IP addresses and related configuration details. For more information on DHCP, see DHCP. WINS provides a dynamic database service that can register and resolve NetBIOS names to IP addresses used on your network. For more information on WINS, see WINS.

Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition provide resource types that allow you to manage DHCP and WINS services in a cluster. Each of these resources stores a database on disk. In order for these resources to fail over, the database must be kept on a disk that is on cluster storage.

You must configure a location for the DHCP and WINS database files and for the backup of these files.

The path to the DHCP or WINS database files and backup of these files must:

- End with a backslash (\).
- Use a drive letter of a disk resource on which the DHCP or WINS resource depends.
- Cannot begin with *systemroot*, although you can use other environment variables.

The path for the DHCP or WINS database will be of the form f:\dhcp\ or f:\wins\.

The path to the backup of the DHCP database files will be of the form f:\dhcp\backup\.

For WINS, you provide a root path, and the backup of the WINS database files is created in a subdirectory of this path. The path will be of the form f:\wins\.

# Print Spooler resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Print Spooler resource type**

You use the Print Spooler resource to cluster your print services. You can only cluster a printer that is connected to your servers by way of a network. If the printer is connected by way of a local port, such as LPT1, there is no way to fail over control of that printer in the case of failure of the server to which it is connected.

You cluster print services using the Print Spooler resource. Multiple Print Spooler resources can exist in a cluster, but there can be no more than one Print Spooler resource per group. Clients access clustered printers in exactly the same way they access nonclustered printers. Clients can use either the network name or Internet protocol (IP) address as the server name.

When a group containing a Print Spooler resource fails over to another node, the document that is currently being spooled to the printer is restarted from one of the other nodes after failover. When you move a Print Spooler resource or take it offline, the Cluster service waits until all jobs that are spooling to the printers are finished (or until the configured wait time has elapsed). Documents that are spooling from an application to a Print Spooler resource are discarded and must be respooled (or reprinted) to the Print Spooler resource if the group containing the Print Spooler resource fails over before the application has finished spooling.

In addition to creating a Print Spooler resource, you must properly configure your printer ports and printer drivers to function on a cluster. To properly set up a printer on a cluster, you must install printer drivers and a printer port on the same virtual server as the Print Spooler resource. The Cluster service will replicate the printer drivers from the virtual server to all cluster nodes the first time the Print Spooler resource fails over to another node.

For more information on the entire printing process in Windows Server 2003 family operating systems, see Understanding Printing. For detailed instructions on how to configure a printer to operate in a cluster, see Create a cluster-managed printer.

# File Share resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**File Share resource type**

If you want to use a server cluster to provide a high availability file server you need to use the File Share resource type. You can use this resource type in three major ways:

- Normal file share

  You can use the File Share resource type to provide a basic file share. Using this method, a single file folder is published to the network under a single name and functions much as an Server Message Block (SMB) share does.

- Share or hide subdirectories

  You can also use the File Share resource to publish several network names: one each for a file folder and all of its immediate subfolders. This is an efficient way to create large numbers of related file shares on a single file server. An example application for this is creating a file share for each user who has files on the server. For more information on why you would want to share subdirectories, see Using a server cluster with large numbers of file shares. You can also prevent users from seeing the subdirectory shares when they browse the network. For more information on sharing or hiding subdirectories, see Share subfolders on a File Share resource.

  **Important**

  - When you share subdirectories, do not use the same name for subfolders under different folders (for example, \folder1\name1 and \folder2\name1). The first shared subdirectory to come online will remain online, but the second shared subdirectory will not be initialized and will not come online.

- DFS root

  You can use the File Share resource type to create a resource that manages a stand-alone DFS root. Fault-tolerant DFS roots cannot be managed by this resource. The DFS root File Share resource has required dependencies on a network name and an Internet Protocol (IP) address. The network name can be either the cluster name or any other network name for a virtual server.

  A cluster-managed DFS root is very different from an Active Directory (or domain-based) DFS root. If the data that needs to be replicated is not changed very often, using a domain-based DFS root with replicas can be a better choice than a cluster-managed DFS root for providing high availability. If the data set changes frequently, replication is usually undesirable, and a cluster-managed DFS root is recommended.

  In Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition, server clusters support multiple standalone DFS roots. These multiple DFS roots can exist in multiple resource groups and each group can be hosted on a different node.

  **Important**

  - Clusters running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition on some nodes and Windows 2000 on others will only support one DFS root per cluster.

  - Do not make DFS configuration changes (for example, by adding new links) while operating a mixed-version cluster.

  If you create multiple DFS roots in a single cluster, be aware of the following restrictions:

  - The name you specify for one DFS root cannot overlap with the names for other DFS roots in the same cluster. For example, if you named one DFS file share c:\dfsroots\root1, you could not share out other roots using names

derived from the first DFS root, for example, c:\dfsroots, c:\dfsroots\root1, or c:\dfsroots\root1\root2.

- The DFS roots must be hosted on NTFS partitions.
- The name you give a non-clustered DFS root on a node's local storage must be different from the name you give a clustered DFS root on the cluster storage.

For more information on DFS in a server cluster, see article Q301588, "Using DFS on a Server Cluster to Maintain a Single Namespace" in the Microsoft Knowledge Base.

For more information on DFS, see Distributed File System (DFS).

When you create a new File Share resource, permissions for the Everyone group for that file share are automatically set by default to Read only. You can use Cluster Administrator or Cluster.exe to change the default permissions. For more information about using Cluster Administrator for this purpose, see View or set resource properties. For more information about using Cluster.exe for this purpose, see information about private property names for a File Share resource in Cluster resource.

You can also cache files from a cluster file share onto client computers. Clients can then have access to these files even when the client computer is disconnected from the network. For more information, see Set client-side caching for a File Share resource.

For more information on creating a highly available file share, see Create a cluster-managed file share.

You can also encrypt the data on your clustered file shares using Encrypting File System (EFS). For more information, see Create a cluster-managed encrypted file share.

# Internet Protocol Address resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet Protocol Address resource type**

You use the Internet Protocol (IP) Address resource type to manage IP network addresses as cluster resources. When an IP Address resource is included in a group with a Network Name resource, the group can be accessed by network clients as a virtual server.

For more information on virtual servers, see Virtual servers.

# Local Quorum resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Local Quorum resource type**

You use the Local Quorum resource type to manage the system disk on the local node as the quorum resource. The Local Quorum resource cannot fail over to another node. If you create a new cluster on a node that is not connected to a cluster disk , the New Server Cluster Wizard will, by default, create a single-node cluster using the Local Quorum resource .

One scenario where a single-node cluster can be useful is in the development and testing of cluster-aware applications or custom resource types. For more information on how to create a cluster-aware application or custom resource type, see the *Microsoft Platform Software Development Kit* (SDK).

You can migrate an existing multinode cluster to a single-node cluster by creating a Local Quorum resource on one node, evicting all other nodes, and using the Local Quorum resource as the quorum resource. This can be useful if you need to troubleshoot cluster problems, for example on the cluster disk.

# Majority Node Set resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Majority Node Set resource type**
You use the Majority Node Set resource type to manage cluster configuration data that may or may not be on a cluster storage device. For example, the Majority Node Set resource type can manage cluster configuration data that is actually stored on multiple nodes in a cluster at the same physical location or in a geographically dispersed cluster. The Majority Node Set resource ensures that the cluster configuration data is kept consistent across the different nodes. In contrast, in a single quorum device server cluster, the quorum resource maintains the definitive copy of the cluster configuration data on the cluster storage device.

**Important**

- Only one Majority Node Set resource can exist in a server cluster.
- Do not use the **net use** command to connect to the share containing the cluster database files (%systemroot%\Cluster\MNS.%ResourceGUID%$\%ResourceGUID%$\MSCS) in a majority node set server cluster. Otherwise, the Majority Node Set resource (the quorum resource) may be unable to connect to the share and may fail to come online.

For detailed instructions on creating a majority node set cluster, see Create a cluster.

For information on differences between a single quorum device server cluster and a majority node set server cluster, see Choosing a Cluster Model.

# Network Name resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network Name resource type**

You use the Network Name resource type to provide an alternate computer name for an entity that exists on a network. When included in a group with an Internet Protocol (IP) Address resource, a Network Name resource provides an identity to the group, allowing the group to be accessed by network clients as a virtual server.

For more information on virtual servers, see Virtual servers.

# Generic Application resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Generic Application resource type**
You use the Generic Application resource type to manage cluster-unaware applications.

**When to use the Generic Application resource type**
Not all applications will function effectively in a cluster. The minimum requirements for an cluster-unaware application are:

- The application must be able to store its data in a configurable location.
- The application must use TCP/IP to connect with clients.
- Clients must reconnect in the event of intermittent network failure.

**Installing a generic application**
If your cluster-unaware application is to work during failover, you must make sure the application can run from all cluster nodes. There are two strategies for accomplishing this:

1. Install the application onto a cluster disk. Because all nodes use the same drive letters for cluster disks, this solution guarantees that the application can be started from all nodes using the same command line.
2. Install separate copies of the application on all cluster nodes. Make sure that the application is installed in a folder on each node that has the same drive letter and path as all other nodes. Although this solution uses more disk space, it is the only way you can install an application that will allow you to perform a rolling upgrade of that application.

# Generic Script resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Generic Script resource type**

You use the Generic Script resource type to manage Windows Server 2003 family operating system scripts as cluster resources. Similar to the Generic Application resource type, the Generic Script resource type provides only the most basic functionality. If the script is running, it is presumed to be online. For more information on creating a generic script using Windows Script Host, see the *Microsoft Platform Software Development Kit* (SDK). To provide greater functionality, you can define a custom resource type. For more information on how to create a custom resource type, see the *Microsoft Platform Software Development Kit* (SDK).

# Generic Service resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Generic Service resource type**

You use the Generic Service resource type to manage Windows Server 2003 family operating system services as cluster resources. Similar to the Generic Application resource type, the Generic Service resource type provides only the most basic functionality. For example, the failure of a Generic Service resource is determined by a query of the Service Controller. If the service is running, it is presumed to be online. To provide greater functionality, you can define a custom resource type. For more information on how to create a custom resource type, see the *Microsoft Platform Software Development Kit* (SDK).

# Volume Shadow Copy Service resource type

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Volume Shadow Copy Service Task resource type**

With the Volume Shadow Copy Service Task resource type, you can create jobs in the Scheduled Task folder that must be run on the node that is currently hosting a particular resource group. In this way, you can define a scheduled task that can failover from one cluster node to another. However, in the Microsoft® Windows Server 2003 family of products, the Volume Shadow Copy Service Task resource type has limited capabilities for scheduling tasks and serves primarily to support Shadow Copies of Shared Folders in a server cluster. If you need to extend the capabilities of this resource type, consider using the Generic Script resource type. For more information on the Generic Script resource, see Checklist: Installing a Generic Script resource.

For more information on shadow copies, see Shadow Copies for Shared Folders.

For more information on using the Volume Shadow Copy Service Task resource to manage shadow copies, see Using Shadow Copies of Shared Folders in a server cluster.

# Managing Security in a Cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing security in a cluster**
The Cluster service relies on Windows Server 2003 family security at all levels for securing communication between nodes, and controlling authentication and access, including client access to the cluster and cluster resources. You can use Cluster Administrator to specify which users or groups can:

- Administer the cluster.
- Access files or folders on File Share resources.

For more information on setting server cluster administration permissions, see Give a user permissions to administer a cluster.

For information on how to change the account or the password for the Cluster service, see Change the account under which the Cluster service runs and Change the Cluster service account password.

This section covers common security tasks:

- Limiting client access to cluster resources
- Securing shared data in a cluster
- Domain accounts and the Cluster service
- Disk resource security
- Using Windows Firewall with a server cluster

# Limiting client access to cluster resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Limiting client access to cluster resources**

The following table lists the Windows Server 2003 family security features you can use to control client access to cluster resources.

**Important**

- In general, grant permissions to the individual applications and services as you would normally. However, always use Cluster Administrator to set File Share resource security policies. File Share security policies configured using Windows Explorer are lost when the File Share resource fails over.

| Resource type | Windows Server 2003 family security |
|---|---|
| Dynamic Host Configuration Protocol (DHCP) Service | Windows Server 2003 family DHCP security. |
| File Share | NTFS or share-level security configured with a cluster management application. NTFS file permissions strongly preferred. Only NTFS file permissions for subfolder shares. For information about administering DFS shares, see the DFS documentation. |
| Generic Application | Windows Server 2003 family network authentication and NTFS security applied to the shared file system.<br><br>Note that when using Cluster Administrator to configure the parameters for a Generic Application resource, we recommend that you avoid selecting **Allow application to interact with desktop** unless it is necessary. |
| Generic Service | Determined by Windows Server 2003 family service configuration. |
| Generic Script | NTFS file-level security for execute permissions on files and permissions for APIs called in the script. |
| IP Address | N/A |
| Distributed Transaction Coordinator | Controlled by Microsoft Distributed Transaction Coordinator (MS DTC). |
| Message Queue Service | Controlled by Message Queue Service. |
| Network Name | N/A |
| Physical Disk/Local Quorum | NTFS file-level security. |
| Print Spooler | Windows Server 2003 family network and print-level permissions. |
| WINS Service | Windows Server 2003 family WINS security. |

# Securing shared data in a cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Securing shared data in a cluster**

**Securing data on cluster disks**
You can control access to folders and files of File Share resources on a user or group basis. You must set access to File Share resources through Cluster Administrator. The account used to start the Cluster service must have appropriate access to the directories with File Share resources. At minimum, this account must have NTFS Read permissions.

By default, access to cluster file shares is disabled to anonymous users. To allow anonymous access to specific file shares you can either enable Kerberos authentication on the Network Name resource associated with the file share or change the local security policy setting. For more information on configuring these Kerberos properties, see Enable Kerberos authentication for virtual servers.

**Important**

- If you change file share permissions using Windows Explorer or My Computer instead of using **Permissions** on the **Parameters** tab in Cluster Administrator, the permissions are lost when the resource is taken offline.

When setting access permission on File Share resources, specify permissions based on, at minimum, a local Administrator group account; do not specify permissions based on local user or local group accounts. On member servers, local users and local groups have security context only on the local computer. The security context of these accounts and groups is meaningless when failed from one node to another. For this reason, you cannot give local users or local groups permissions to administer the cluster. The single exception to this rule is the local Administrators group. This is not a problem on domain controllers because the local accounts and groups have security context on all member servers in the domain.

**Important**

- The Cluster service must always have full access to the folder on the quorum disk containing the quorum log (the folder is named MSCS by default). (The quorum log file is used to write all cluster state and configuration changes that cannot be committed to the other nodes.)

**Encrypting shared data**
You can further secure the contents of the data on your cluster disks by using Encrypting File System (EFS). EFS prevents unauthorized users that may gain physical access to your cluster disks from reading the data on those disks. For more information, see Create a cluster-managed encrypted file share.

**Auditing access to shared data**
Use standard security features to audit access to files and folders that reside on drives on the cluster storage. Use either My Computer or Windows Explorer to set file or directory auditing. You cannot do this using Cluster Administrator. For more information on auditing, see Auditing Security Events.

Security events are written to the security log on the node that owns the File Share resource.

Audit settings are specific to a node. Therefore, if you enable auditing on one node but not on another, you only see security events when the node with auditing enabled owns the File Share resource. If you want to audit access to shared data, it is a best practice to enable auditing on all cluster nodes.

**Taking ownership of files or folders**
Use either My Computer or Windows Explorer to set file or directory ownership. You cannot do this using Cluster Administrator.

# Domain accounts and the Cluster service

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Domain accounts and the Cluster service**

You must log on using an account that is a member of an Administrators group to create the first node in a cluster or add additional nodes. All nodes must have joined a domain (instead of a workgroup) and be members of the same domain. When you create a cluster or join nodes to a cluster, you specify the domain user account under which the Cluster service runs. It is best if the Cluster service user account is a new account. The account must have local administrative rights and permissions on the cluster nodes. In addition, make sure that applications (for example, Microsoft SQL Server 2000) do not use the same account as the Cluster service account. Be sure to keep the password from expiring on the account (follow your organization's policies for password renewal).

When you install the operating system on a member server, Setup adds the Cluster service account as a member of the local Administrators group. When you install the operating system on a domain controller, Setup gives cluster-administrative permissions to the Domain Administrators group.

When you use Cluster Administrator to administer a cluster from a remote location, such as from another server or a computer running Windows XP Professional, or to administer a cluster locally from a node, you must use an account that is a member of the local Administrators group on all nodes. For more information, see Give a user permissions to administer a cluster.

**Note**

- You can use an account that is a domain user account or a member of a global group to remotely or locally administer a cluster if you use cluster.exe or cluster scripting tools. For more information, see Cluster and the Microsoft Platform Software Development Kit (SDK).

If you have administrative permissions on all nodes of the cluster, you can fully administer the cluster. However, if you have only specific permissions to administer the cluster, you cannot change the cluster description, change cluster security, or register extensions to Cluster Administrator.

For information on changing the account used to run the Cluster service, see Change the account under which the Cluster service runs.

For information on changing the password for the Cluster service account, see Change the Cluster service account password.

# Disk resource security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Disk resource security**

There are two disk subsystems in a cluster environment: The first is the shared bus or buses, including the cluster disks, and the second is theWindows Server 2003 family operating system files. Keep these two systems separate. Do not put Windows Server 2003 family system files on the cluster disks. In addition, you can locate Windows Server 2003 family system files on either file allocation table (FAT) or NTFS drives, but you must locate the cluster disks on the shared bus only on NTFS-formatted drives.

**Securing access to the cluster disks**

Restrict access to the cluster disks to applications that are managed as a cluster resource. If there are other applications on a cluster node that are not managed by the cluster, install those applications either on the system disk or on a local disk. To help reduce the risk of unauthorized reads and writes to the quorum disk, it is recommended that you give access to the quorum disk only to the Cluster service account and members of the local Administrators group.

**Securing disk resources on cluster disks**

All standard Windows Server 2003 family file security options apply to the disk resources on the cluster disk. You can use Windows Explorer to set permissions on disk resources.

# Using Windows Firewall with a server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Windows Firewall with a Server Cluster**
For a server cluster running Windows Server 2003 Service Pack 1, if you enable Windows Firewall, you must carry out the following steps on each cluster node:

- Learn about how to install and run the Security Configuration Wizard, an optional component that can be installed through Control Panel, by opening a command prompt and typing **hh scwhelp.chm**.

- Install and run the Security Configuration Wizard. Select the appropriate server roles, client features, and administration options for that server. Select only what is necessary, but be sure to include the following:

  - Among server roles, select **Cluster server** and any server roles that correspond to the clustered resources for that node. For example, for a node with a File Share resource, select **Cluster server** and **File server**.

  - Among client features, select those necessary for the node to function. Examples of client features are **Domain member**, **Microsoft networking client**, **DHCP client**, **DNS client**, and **WINS client**.

  - Among administration and other options, select **Join a cluster** and any other appropriate options.

  The Security Configuration Wizard helps ensure that ports needed by the Cluster service are open and the Cluster service and other necessary services can operate normally.

- In the Services snap-in, make sure that the Recovery action for the Cluster service is set to **Restart the Service** (the default setting). For more information, see Set up recovery actions to take place when a service fails.

  Note that this step will set the recovery action but will not immediately restart the Cluster service. If necessary, after taking the step, type **net start clussvc** to restart the service.

Help: Windows Firewall

# Using Cluster Administrator

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Cluster Administrator**
Cluster Administrator shows you information about the groups and resources on all of your clusters and specific information about the clusters themselves. A copy of Cluster Administrator is automatically installed on your computer when you install Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition.

**Important**

- Cluster nodes must be running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. You cannot create a cluster or add nodes to an existing cluster on computers running Windows Server 2003, Standard Edition.

For remote administration, you can install copies of Cluster Administrator on other computers on your network running Windows server 2003 family operating systems. Cluster Administrator is available through Windows server 2003 Administration Tools, included on the Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition compact disc sets. The remote and local copies of Cluster Administrator will be identical. It is also possible to administer a Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition server cluster remotely from a computer running Windows NT 4.0 Service Pack 3 or later using the Windows NT server, Enterprise Edition 4.0, Cluster Administrator tool or from a computer running Windows 2000.

This section describes the uses of Cluster Administrator, including the ways in which it changes procedures you might have been familiar with in a noncluster environment.

- Identifying failovers
- Installing Cluster Administrator on a remote computer

# Identifying failovers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Identifying failovers**

Failover can occur in one of two situations: An entire node fails, or a resource on a node fails (such as a network interface). Node failure is easily identifiable in Cluster Administrator. When you are connected to a cluster, Cluster Administrator displays a list of all nodes and their current status. Resource failure that does not bring down a node, but does result in group failover, can be harder to detect. Use Cluster Administrator or another cluster management application to periodically check the owner of all cluster groups to see if a group has failed over.

It is important to use Cluster Administrator to routinely monitor the status of all clusters and check for failover activities that diminish either the performance or the availability of resources. Failover is supposed to be easily tolerated. Your work flow will not suffer if all applications are working, failover policies have been correctly set, and you have provided sufficient capacity for all situations. If any of these three criteria are not met, you must take action to meet them. For information on how to plan your server cluster, failover policies, and capacity requirements, see Planning Your Server Cluster.

Serious failover situations can affect performance and availability. If a node fails and its companion node is unable to serve clients efficiently, the situation must be resolved immediately. If groups persistently fail over and fail back without surviving on either node for very long, availability to clients is completely lost.

**Responding to a failover**

When investigating possible problems with failovers, answer the following questions:

- How serious is the problem?

  For example, other resources could be suffering due to the increased load placed on the alternate node.

- What caused the failover?

  Many types of failure can cause failovers. Usually, these occur at the operating system and hardware levels. For help with determining the exact type of a failure, see Server Cluster Troubleshooting.

  To review what happened prior to and during a group failure, run Event Viewer and look at the application log, system log, and the security log (if applicable). This helps you determine what types of errors occurred.

- Are any changes needed to prevent this kind of event in the future?

  If your performance has seriously suffered as a result of a failover, review the capacity planning issues presented in Capacity Planning for Server Clusters.

  If you determine that the nodes did not efficiently transfer control of various groups and resources during failover, review the failover policies you have set. For example, the Cluster service could be attempting to bring a File Share resource online before the corresponding Physical Disk resource was brought online. This type of error is easily fixed by configuring dependencies.

The Cluster service records error messages about resource failure in the system log. The system log is found in Event Viewer. The **Event Properties** dialog box contains error message information. Information about a resource failure might appear as follows:

```
Date: 9/8/2001

Time: 3:22:49 PM

Type: Error

Source: ClusSvc

Category: Failover Mgr

Event ID: 1069
```

```
User: N/A

Computer: DTCENTER3

Description: "Cluster resource 'Disk V:' in Resource Group 'SQL' failed.

For more information, see Help and Support Center at http://go.microsoft.com/fwlink/events.asp."
```

Other applications can keep track of such errors and notify appropriate parties as necessary.

For more information about diagnosing and resolving specific kinds of failures and errors, see Server Cluster Troubleshooting. For more information on resource dependencies, see Server Cluster groups.

For information on how to solve failover problems, see Server Cluster Troubleshooting.

# Installing Cluster Administrator on a remote computer

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing Cluster Administrator on a remote computer**
You can use Cluster Administrator to remotely administer a server cluster. Cluster Administrator runs on any computer that is running Windows NT 4.0 Service Pack 3 or later, Windows 2000, or a Windows Server 2003 family operating system. You can use Cluster Administrator on any computer running Windows 2000 or Windows Server 2003 family operating system to remotely create, join nodes, or manage a server cluster. On computers running Windows NT 4.0 Service Pack 3 or later, you can use Cluster Administrator just to remotely manage a server cluster.

**Important**

- Computers used to remotely administer a server cluster must be secure and restricted to trusted personnel. For more information, see Best practices for securing server clusters.
- When you remotely manage a cluster using Cluster Administrator or cluster.exe, you must verify that NetBIOS over TCP/IP (NetBT) is enabled on the client. For more information on enabling NetBIOS over TCP/IP, see Configure TCP/IP settings.

You use Windows Server 2003 Administration Tools to install Cluster Administrator on computers that are running Windows Server 2003 family operating systems that are not cluster nodes. On Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition, Cluster Administrator is installed when you install the operating system. For more information on Windows Server 2003 Administration Tools, see Windows Server 2003 Administration Tools Pack Overview.

You cannot use Windows Server 2003 Administration Tools to install Cluster Administrator on a computer running Windows NT 4.0. However, if you have the version of Cluster Administrator that was provided with Windows NT Server, Enterprise Edition 4.0, you can use that version from any Windows NT 4.0, Service Pack 3 or later computer to administer a cluster running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. Because Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition provide resource types that were not supported in Windows NT 4.0, you might see error messages if you administer a cluster running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition from a computer running Windows NT 4.0.

If you are adding or removing users from the list of those who can administer a cluster, or otherwise changing the cluster security descriptor, the server from which you run Cluster Administrator must run one of the following versions of the operating system and service pack:

- Windows Server 2003
- Windows Server 2003 with Service Pack 1
- A product in the Windows 2000 Server family with Service Pack 2 or later

**Caution**

- When remotely managing a server cluster from another computer, the system default locale on that remote computer can be different from the system default locale on all the nodes in the cluster only if the names of the cluster and all the cluster nodes use English language characters. For more information on changing the system default locale, see Change number, currency, time, and date settings.

# Using a server cluster with large numbers of file shares

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using a server cluster with large numbers of file shares**

Every cluster resource you create has a performance impact; the Cluster service must periodically poll all resources to determine whether they have failed. Because of this, you may notice that your cluster's performance decreases as you increase the number of resources that it manages.

If you want to use a cluster to create a high availability file server that will have hundreds of file shares, consider managing those file shares using a single File Share resource. You can do this if the folders that you want to share on the network are all subfolders of a common folder. For example, if you use your file server to support hundreds of users, and each user has a private folder that is a subfolder of the Users folder, you can manage individual file shares for each user using a single File Share resource. You also have the option to hide the file shares that you create for each user so that they will not be visible when browsing. For information on sharing the subfolders of a folder and hiding the files shares you create, see Share subfolders on a File Share resource.

The maximum number of resources supported by the default Resource Monitor is 1674 (the default Resource Monitor creates a maximum of 62 threads, each thread monitoring up to 27 resources). Additional Resource Monitors can each monitor one resource.

For more information on how the Cluster service checks for failed resources, see Resource failure.

# Using Shadow Copies of Shared Folders in a server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Shadow Copies of Shared Folders in a server cluster**
Shadow Copies of Shared Folders provides point-in-time copies of files that are located on shared resources, such as a file server. You can use Shadow Copies of Shared Folders as part of your overall disaster recovery strategy to quickly recover files that were accidentally deleted or overwritten, as well as to compare different versions of files. However, there are several important considerations to keep in mind if you want to use Shadow Copies of Shared Folders on a cluster disk:

- Cluster-managed shadow copies can only be created in a single quorum device cluster on a disk with a Physical Disk resource. In a single node cluster or majority node set cluster without a shared cluster disk, shadow copies can only be created and managed locally.
- You cannot enable Shadow Copies of Shared Folders for the quorum resource, although you can enable Shadow Copies of Shared Folders for a File Share resource.
- The recurring scheduled task that generates volume shadow copies must run on the same node that currently owns the storage volume.
- The cluster resource that manages the scheduled task must be able to fail over with the Physical Disk resource that manages the storage volume.

The Volume Shadow Copy Service Task resource type can be used to manage shadow copies in a server cluster. The Volume Shadow Copy Service Task resource used in this way has a required dependency on the Physical Disk resource.

For more information on shadow copies, see Shadow Copies for Shared Folders.

For more information on the Volume Shadow Copy Service Task resource type, see Volume Shadow Copy Service resource type.

**Best practices for using shadow copies in a cluster**

- To improve server performance, use different disks for the shadow copy volume and the storage volume.

  **Note**

  - You cannot create storage volume associations between distinct volumes on a disk managed by a single Physical Disk resource.

- If you have multiple shadow copy volumes, use a single, separate disk for the storage volume.
- Do not enable shadow copies in a deployed cluster. When you enable shadow copies, the shadow copy volumes (as well as all resources that directly or indirectly depend on the disk) go offline for a brief period while the resource dependencies are created. The shadow copy volumes are not accessible to applications and users while they are offline.
- Enable shadow copies after you have created your cluster. If you enable shadow copies before clustering your servers, you must disable, then reenable, shadow copies.

  **Note**

  - If you cluster a disk containing a previously-created shadow copy, the shadow copy may stop functioning once that disk's Physical Disk resource fails over.

**Using Cluster Administrator or cluster.exe to manage shadow copies**
**Important**

- Using Cluster Administrator or cluster.exe to completely configure and manage shadow copies in a cluster is not a supported scenario. The only supported scenario for configuring shadow copies in a cluster is described in Enable Shadow Copies for Shared Folders in a cluster.

For more information on using Cluster Administrator to create a Volume Shadow Copy Service Task resource, see Checklist: Installing a Volume Shadow Copy Service Task resource.

For more information on using cluster.exe to create a Volume Shadow Copy Service Task resource, see Cluster resource.

**Enabling shadow copies on a cluster node**

When you enable shadow copies on a cluster node (for example, by using the Configure Shadow Copy user interface through the Computer Management MMC ), a Volume Shadow Copy Service Task resource and a scheduled task for creating that shadow copy are automatically generated and configured. You do not need to explicity create the Volume Shadow Copy Service Task resource using Cluster Administrator or cluster.exe. In addition, the Configure Shadow Copy user interface automatically sets up the required resource dependencies. The default properties of the scheduled task and Volume Shadow Copy Service Task resource are described in the table below. For more information, see Enable Shadow Copies for Shared Folders in a cluster.

| **Scheduled task property** | **Volume Shadow Copy Service Task resource Cluster Administrator property (cluster.exe property)** | **Default setting** |
|---|---|---|
| **Name of task** | **Name of resource (TaskName)** | ShadowCopyVolume{*VolumeGUID*}<br><br>**Note**<br><br>• The name of the scheduled task is the same as the name of the Volume Shadow Copy Service Task resource associated with that task. |
| **Run** | **Command to run/Command parameters (ApplicationName/ApplicationParams)** | %systemroot%\system32\vssadmin.exe Create Shadow /AutoRetry=5 /For=\\?\Volume{VolumeGUID}\<br><br>For more information, see Vssadmin. |
| **Creator** | n/a | Cluster service |
| **Start in** | **Start in** | %systemroot%\system32\ |
| **Run as** | n/a | Local System |
| **Schedule** | **Schedule (TriggerArray)** | The default settings used by Shadow Copies of Shared Folders.<br><br>For more information, see Defining a schedule for shadow copies. |

# Setting Properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting properties**

After setting up your cluster, you might need to change the configuration of some resources and groups from time to time. To make changes to a selected group or resource, on the **File** menu, click **Properties**.

For detailed procedures on setting properties for groups, resources, networks, and network interfaces, see Server Cluster How To....

This section covers:

- Setting group properties
- Setting resource properties
- Setting network properties
- Setting network interface properties
- Setting node properties
- Setting resource type properties

# Setting group properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting group properties**

Using the group **Properties** dialog box, you can:

- View the state of the group (whether it is online or offline) and view which node currently owns the group.
- Change the group name, description, and preferred owner.
- Set the failover policy (using the **Failover** tab).
- Set the failback policy (using the **Failback** tab).

Do not update the properties of a cluster object on multiple nodes simultaneously. For more information on multiple and simultaneous property updates, see the Microsoft Platform Software Development Kit (SDK).

**Setting failover policy**

Use the **Failover** tab to set failover policy for the group. You can set the following:

- The failover threshold
- The failover period
- Whether or not a failure of one resource affects other resources in the group.

  By default, if one or more resources fail in a group, the Cluster service fails all other resources in the group.

The failover threshold is the number of times the group can fail over within the number of hours specified by the failover period. For example, if a group failover threshold is set to 5 and its failover period to 3, the Cluster service will fail over the group at most five times within a three-hour period. The sixth time a resource in the group fails, the Cluster service fails all other resources in the group and leaves the entire group offline instead of failing over the group. If the **Effect the Group** failover option is disabled, and a resource in the group fails for a sixth time, the Cluster service leaves the resource in the offline state instead of failing all other resources in the group. For example, if the **Effect the Group** option was disabled and a Network Name resource failed six times in three hours, on the sixth failure the Network Name would be left offline. An IP Address resource, however, would be left online.

**Setting failback policy**

By default, groups are set not to fail back. Unless you manually configure your group to fail back after failing over, it continues to run on the alternate node after the failed node comes back online.

When you configure a group to automatically fail back to the preferred node, you specify whether you want the group to fail back as soon as the preferred node is available or to fail back only during specific hours that you define. This option is useful if you want the failback to occur after peak business hours or if you want to make sure the preferred node is able to support the group when it does come back online.

The group must be configured to have a preferred owner to fail back. You can specify a preferred owner on the **General** tab of the group **Properties** dialog box.

For instructions on how to open the **Properties** dialog box, see Change the properties of a group.

# Setting resource properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting resource properties**

Using the resource **Properties** dialog box, you can:

- View or change the resource name.
- View or change the resource description and possible owners.
- Specify whether the resource runs in a separate memory space.
- View the resource type, group ownership, resource state, and which node currently owns the resource.
- View preexisting dependencies and modify resource dependencies.
- Specify whether to restart a resource and, if so, what settings to use to restart.
- Specify how often you want the Cluster service to check whether the resource is in the online state (by setting the **Looks Alive** and **Is Alive** polling intervals).
- Specify the amount of time that a resource in a pending state (Online Pending or Offline Pending) has to either resolve its status or report that it is making progress to the Resource Monitor before the Cluster service puts the resource in Failed status.
- Set specific resource parameters.

The **General**, **Dependencies**, and **Advanced** tabs are the same for every resource. Some resource types support additional tabs.

Do not update the properties of a cluster object on multiple nodes simultaneously. For more information on multiple and simultaneous property updates, see the Microsoft Platform Software Development Kit (SDK).

**Setting resource dependencies**

The Cluster service uses the dependencies list when bringing resources online and offline. For example, if a group is brought online in which a physical disk and a file share are located, it is futile to try to bring the file share online before bringing the physical disk (on which the file share is located) online. It is important to remember this when you configure resources because the groups function properly only if these dependencies are correctly configured.

The following table shows resources and their dependencies. The resources in the right column must be configured before you create the resource.

| Resource | Dependencies (required or recommended) |
|---|---|
| DHCP Service | Physical Disk or other storage class device (on which the files are located)<br><br>Internet Protocol (IP) Address (for client access to the DHCP server)<br><br>Network Name (for client access to the DHCP server) |
| Distributed Transaction Coordinator | Physical Disk or other storage class device |

| | |
|---|---|
| File Share | A file share that is configured as a DFS root has the following required dependency:<br>• Network Name<br><br>A file share that is not DFS has no required dependencies. It is recommended that file share resources have the following dependencies:<br>• Physical Disk<br>• Network Name |
| Generic Application | Network Name |
| Generic Script | None |
| Generic Service | Network Name |
| IP Address | None |
| Local Quorum | None |
| Majority Node Set | None |
| Message Queuing | Physical Disk or other storage class device<br><br>Network Name (so that remote clients can access it) |
| Network Name | IP Address (that you want to correspond to the name) |
| Physical Disk | None |
| Print Spooler | Physical Disk or other storage class device (on which the spool is located)<br><br>Network Name (so that remote clients can access it) |
| Volume Shadow Copy Service Task | A Volume Shadow Copy Service Task resource has no required dependencies. However, Volume Shadow Copy Service Task resources that manage scheduled tasks for shadow copies have a required dependency on the Physical Disk resources for the volumes on which the volume shadow copies are located. |
| WINS Service | Physical Disk or other storage class device (on which the files are located)<br><br>Network Name (for client access to the WINS server)<br><br>**Note**<br>• The Network Name will, in turn, be dependent on the IP Address which is necessary for client access to the WINS server. |

The New Resource Wizard enforces the use of resource dependencies.

**Setting advanced resource properties**

Use the **Advanced** tab of the resource **Properties** dialog box to:

- Specify whether the Cluster service attempts to restart a resource or allows the resource to fail.

- If you want the Cluster service to restart the resource, you must specify whether to affect the group. If you want the group to be failed over when this resource fails, select the **Affect the group** check box, and then enter the values you want in **Threshold** and **Period**. These values determine how many times the Cluster service attempts to restart the resource before failover and the amount of time in which the threshold number of restart attempts takes place. If the **Affect the group** check box is not selected, a failure of this resource never causes the group to fail over.

- Specify how often the Cluster service makes a cursory check (Looks Alive) or in-depth check (Is Alive) to determine if a resource is in the online state.

- Click **Use resource type value** to use the default number for the resource type.

- Specify the amount of time that a resource in a pending state (Online Pending or Offline Pending) has to either resolve its status or report that it is making progress to the Resource Monitor before the Cluster service puts the resource in Failed status.

**Setting resource parameters**

Most resources have a resource-specific **Parameters** tab in their **Properties** dialog box. The following table lists each resource and its configurable parameters.

| Resource | Configurable parameters |
|---|---|
| DHCP Service | You can enter the path to the DHCP database files and to the backup of the DHCP database files.<br><br>You can enter the path to the audit log file stored by the DHCP service. |
| Distributed Transaction Coordinator | None. |
| File Share | You can use the **Parameters** tab for the **File Share Properties** dialog box to set permissions on the file share and limit the number of simultaneous users.<br><br>**Important**<br><br>• When you create a new File Share resource, permissions for the Everyone group for that file share are automatically set by default to Read only. You can use Cluster Administrator or cluster.exe to change the default permissions. For more information, see View or set resource properties.<br><br>You can also use the **Parameters** tab to set the name of the file share (because clients will detect it in their browse or explore lists), set the file share comment, and set the path to the shared files. |
| Generic Application | You can use the **Parameters** tab in the **Generic Application Properties** dialog box to specify the application command line, current directory, whether it uses the Network Name for the computer name, and whether or not it can interact with the desktop.<br><br>**Important**<br><br>• It is recommended that you carefully consider the ways in which you interact with the server before you enable the Generic Application to interact with the desktop. This option is not valid in a number of scenarios, for example, administering a cluster either in a terminal server session or remotely using Emergency Management Services and an out-of-band connection. |
| Generic Script | You can use the **Parameters** tab for the **Generic Script Properties** dialog box to specify the path to the Visual Basic (VB) script file. |
| Generic Service | You can use the **Parameters** tab for the **Generic Service Properties** dialog box to specify the service name, startup parameters, and whether it uses the Network Name for the computer name. |

| | |
|---|---|
| IP Address | You can configure the IP address and subnet mask. You must also specify which cluster network to use and enable NetBIOS for the IP address. |
| Local Quorum | None. |
| Majority Node Set | None. |
| Message Queuing | None. |
| Network Name | You can configure the computer name parameter, enable Kerberos authentication, and indicate whether DNS registration failures are tolerated for the Network Name resource. |
| Physical Disk | You can specify only which drive to use for the Physical Disk resource. You cannot change this after the resource is created. |
| Print Spooler | You can configure the path to the Print Spooler folder and the job completion time-out for the Print Spooler resource. |
| Volume Shadow Copy Service Task | You can use the **Parameters** tab for the **Volume Shadow Copy Service Task Properties** dialog box to specify the command to run for the task (a combination of the **Command to run** and **Command parameters** fields), the working directory, and the schedule for running that command.<br>**Important**<br>• These parameters are automatically set when you enable shadow copies on cluster nodes. For more information, see Enable Shadow Copies for Shared Folders in a cluster. |
| WINS Service | You can enter the path to the WINS database files and to the backup of the WINS database files. |

# Setting network properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting network properties**

After setting up your cluster, you might need to change the configuration of the networks that support client-to-cluster communication and node-to-node communication. For detailed procedures on setting network properties, see Manage Networks.

Using the network **Properties** dialog box, you can:

- View or change the network name.
- View or change the network description.
- Enable or disable the network for cluster use. If you enable the network for cluster use, you can specify whether to use the network for only client-to-cluster communication, only node-to-node communication, or both.
- View the network's state.
- View the network ID.
- View the subnet mask.

Do not update the properties of a cluster object on multiple nodes simultaneously. For more information on multiple and simultaneous property updates, see the Microsoft Platform Software Development Kit (SDK).

**Setting network priorities**

Cluster nodes can communicate over multiple networks. You can change the network's priority to specify the order in which the nodes will attempt to communicate over the networks. For detailed instructions on changing the network priority, see Change network priority for communication between nodes.

# Setting network interface properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting network interface properties**

After setting up your cluster, you might need to change the configuration of the network interfaces. For detailed procedures on setting network interface properties, see Manage Networks.

Using the network interface **Properties** dialog box, you can:

- View the node and network object name.
- View or change the network interface description.
- View the network interface's state.
- View the name of the network adapter for the network interface.
- View the network interface's Internet Protocol (IP) address.

Do not update the properties of a cluster object on multiple nodes simultaneously. For more information on multiple and simultaneous property updates, see the Microsoft Platform Software Development Kit (SDK).

# Setting node properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting node properties**

Using the node **Properties** dialog box, you can:

- View the node object name.
- View or change the node description.
- View the node's state. A node's state can be:
  - **Down.** The node is not actively participating in cluster operations.

    **Joining.** The node is in the process of becoming an active participant in the cluster operations.

    **Paused.** The node is actively participating in cluster operations but cannot take ownership of resource groups and cannot bring resources online.

    **Unknown.** The state could not be determined.

    **Up.** The node is actively participating in all cluster operations.
- View the version and build number of the Cluster service.

Do not update the properties of a cluster object on multiple nodes simultaneously. For more information on multiple and simultaneous property updates, see the Microsoft Platform Software Development Kit (SDK).

# Setting resource type properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting resource type properties**

Using the resource type **Properties** dialog box, you can:

- View or change the resource type display name. The display name is used to manage the resource type in the cluster administration tools.
- View or change the description of the resource type.
- View the nodes on which the resource type can run.
- View or change the default poll intervals (in milliseconds) for resources of this type. The poll intervals are Looks Alive and Is Alive.

  The Looks Alive poll interval specifies how often the Cluster service checks the state of the resource to determine whether or not the resource appears to be active. You can use the default value for the resource type or specify a number in milliseconds.

  The Is Alive poll interval specifies how often the Cluster service checks whether the resource is active. You can use the default value for the resource type or specify a number in milliseconds.
- View the type name of the resource type. The type name is used internally by APIs and resource dynamic-link libraries (DLLs).
- View the DLL file that implements the behavior of this resource type.
- View whether resources of this type can be used as a quorum resource. The only quorum-capable resource types currently provided by Microsoft are the Physical Disk, Majority Node Set, and Local Quorum resource types. For more information on quorum resources, see Quorum resource. For more information on the Physical Disk, Majority Node Set, and Local Quorum resource types, see Physical Disk resource type, Majority Node Set resource type, and Local Quorum resource type.

Do not update the properties of a cluster object on multiple nodes simultaneously. For more information on multiple and simultaneous property updates, see the Microsoft Platform Software Development Kit (SDK).

# Network Management

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network management**

This topic describes features of server clusters that affect network management:

- Plug and Play network support
- Name coordination between Cluster service and Network and Dial-up Connections
- Network Failure Detection and Recovery

# Plug and Play network support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Plug and Play network support**

Using the Plug and Play technology built into Windows Server 2003 family operating systems, the Cluster service detects the addition and removal of TCP/IP networking components. For example, the Cluster service can detect the following events:

- Addition or removal of network adapters
- Binding or unbinding the TCP/IP protocol stack to a network adapter
- Addition or release of a DHCP-assigned or static Internet protocol (IP) address

When a new network adapter is added to the computer and bound to TCP/IP using a subnet not already in use by the Cluster service, the Cluster service adds a network interface object to the cluster. If the network interface is connected to a new network, the Cluster service also adds a new network object to the cluster. You do not need to restart the Cluster service for these changes to take place. By default, the newly created interface and network objects are used for mixed communication, that is for both client and internal cluster communication.

Similarly, if a TCP/IP stack is removed, the Cluster service removes the corresponding network interface object from the cluster. If that network interface is the last interface connected to a network, the Cluster service removes the network object from the cluster.

If one network adapter is removed from a node, all IP Address resources dependent on that adapter will attempt to failover to another node. If all network adapters in the cluster are removed (that is, reconfigured or connected to a different physical network), all dependent IP Address resources go offline and are "orphaned," that is, their associated network is empty. If another network adapter is then added and assigned to the same subnet as the orphaned IP Address resource, the resource is reassociated with the "new" network; it is new in the sense that it has a different GUID and is a new instance of a network that has the same properties as the "old" network.

For more information on configuring network objects, see Setting network properties. For more information on configuring network interface objects, see Setting network interface properties.

# Name coordination between Cluster service and Network and Dial-up Connections

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Name coordination between Cluster service and Network Connections**
In the Windows Server 2003 family, each physical network adapter in a computer is represented by a named icon in the Network Connections folder. The Cluster service coordinates the names of its network interface objects with the names of the icons in the Network Connections folder.

**Automatic renaming of networks**
Windows Server 2003 family operating systems automatically ensure that both a server cluster and the Network Connections folder use the same name to reference any individual network interface. For example, if you use any cluster administration tool to rename a cluster network object, the Windows Server 2003 family operating system automatically renames the corresponding icon in the Network Connections folder. Similarly, if you rename a network connection icon in the Network Connections folder, the Windows Server 2003 family operating system renames the matching cluster network object, if one exists.

The Windows Server 2003 family operating system ensures that cluster nodes also use the same name for the network object and corresponding icons in the Network Connections folder. Therefore, if you rename a cluster network object on one node of a cluster, the name of the network object on the other nodes and the icon name in the Network Connections folders on all nodes also change. The operating system does not notify you when it renames a related cluster network object or icon in a Network Connections folder.

The following table summarizes the actions the Windows Server 2003 family operating system takes in response to any renaming you perform.

| Action | Result |
|---|---|
| Set up a new cluster. | The Windows Server 2003 family operating system uses the names of the icons in the Network Connections folder as the default names for cluster network objects. If you choose to rename any of the cluster network objects, the operating system renames the corresponding icon in the Network Connections folder. |
| Add a new node to an existing cluster. | The Windows Server 2003 family operating system renames icons in the Network Connections folder to match the names of the cluster network objects. |
| Rename a network object using a cluster administration tool. | The corresponding icon in the Network Connections folder is renamed on all cluster nodes. |
| Rename an icon in the Network Connections folder. | The Windows Server 2003 family operating system renames the corresponding cluster network object. It renames the corresponding icon in the Network Connections folder on the other node. |

**Network name conflicts**
When you change the name of a network object or an icon in the Network Connections folder on one node of a cluster, you introduce the possibility of a naming conflict. For example, assume you have a cluster consisting of Node 1 and Node 2, and you change the name of a cluster network object on Node 1 from *Public Network* to *Corporate Network*. If an icon in the Network Connections folder on either Node 1 or Node 2 is already named Corporate Network, then the renaming attempt creates a name conflict.

Windows Server 2003 family operating systems prevent name conflicts by appending a number to any existing icon or network object names that would cause a name conflict with whatever new name you enter. In the previous example, the operating system renames the existing **Corporate Network** icon to **Corporate Network (2)**. This feature ensures that whenever you attempt to rename a network object or an icon in the Network Connections folder, your renaming attempt succeeds without generating any name conflicts.

# Network Failure Detection and Recovery

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network failure detection and recovery**
The Cluster service is able to detect and isolate network failures. The Cluster service uses its improved network failure detection to improve failure recovery actions.

This section describes the Cluster service network state management and failure recovery process:

- Network state management and failure detection
- Network-failure recovery

# Network state management and failure detection

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network state management and failure detection**

Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition use sophisticated algorithms to monitor the health of network interfaces in a server cluster. The following tables summarize the states that a network interface and a network can be in.

**Network interface states**

| State | Description |
|---|---|
| Failed | The node that owns the network interface is active; however, it cannot communicate through its network interface. The Cluster service has determined that the error is isolated to the network interface.<br><br>Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition use several methods to determine whether failures are isolated to network interfaces. First, the Cluster service uses a heartbeat to help detect network problems. Second, the operating system can receive hardware failure notifications from a network adapter that supports the Network Driver Interface Specification (NDIS). Using network adapters that support newer NDIS features, for example, media sense, improves cluster network state management. Finally, the Cluster service attempts to ping external hosts to estimate the scope of a network interface failure. This can cause a temporary increase in network traffic while the operating system investigates the extent of a network failure.<br><br>**Note**<br><br>• When a failed network adapter is replaced, the Cluster service will determine that the new card is the interface for an existing network if the card is on the same subnet. |
| Unavailable | The network is disabled for cluster use, or the node associated with this network interface is down. |
| Unreachable | The node cannot communicate through this network interface. The reason for the failure is unknown. |
| Up | The network interface is active and can communicate with all other interfaces on the network (except those currently in Failed or Unavailable states). Up is the normal operational state. |
| Unknown | The state cannot be determined. |

**Network states**

| State | Description |
|---|---|
| Down | The network has failed. None of the active nodes in the cluster can communicate with one another using this network. |
| Unavailable | The network is disabled for cluster use, or all of the cluster nodes attached to this network are inactive. |
| Partitioned | The network has partially failed. Some active cluster nodes cannot communicate with one another over this network. |
| Up | The network is functioning normally. Up is the normal operational state. |
| Unknown | The state cannot be determined. |

# Network-failure recovery

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Network-failure recovery**

When a network interface enters the Failed state, the Cluster service triggers the failure of all IP Address resources that use that network interface. When an IP Address resource fails, the Cluster service treats it like the failure of any other resource: All resources that depend on the IP Address resource fail, and the Cluster service uses the failover policy that you have set to determine whether or not to fail over the resource group.

The Cluster service does not trigger the failure of IP Address resources when a network interface enters the Unreachable state. If the network interface is in the Unreachable state, the Cluster service has not isolated the network problem enough to implement an appropriate recovery policy. When a network interface enters the Unreachable state, investigate the state of the network to determine whether or not to cause a manual failover of resource groups.

# Administering Server Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering server clusters**

You can use cluster commands to administer a server cluster and the Cluster service from the command prompt.

- Managing a Server Cluster from the Command Line
- Managing the Cluster Service from the Command Line

# Managing a Server Cluster from the Command Line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing a server cluster from the command line**
You can use cluster commands to create, configure, and administer server clusters from the command prompt. You can also call the program Cluster.exe from command scripts to automate many cluster administration tasks. Cluster.exe is provided on all computers running Windows Server 2003 family operating systems.

You can use Cluster.exe to create, configure, and administer clusters from a node of the cluster, from nodes of other clusters, or from other computers running Windows NT 4.0 with Service Pack 3 or later.

**Caution**

- When using cluster.exe to manage a server cluster, the locale settings for the user account must match the system default locale on the computer used to manage the cluster. If you remotely manage a server cluster from another computer, the system default locale on that remote computer can be different from the system default locale on all the nodes in the cluster only if the names of the cluster and all the cluster nodes use English language characters. For more information on changing the system default locale, see Change number, currency, time, and date settings.

**Important**

- When you remotely manage a cluster using Cluster Administrator or cluster.exe, you must verify that NetBIOS over TCP/IP (NetBT) is enabled on the client. For more information on enabling NetBIOS over TCP/IP, see Configure TCP/IP settings.

You can also start the Cluster Administration tool at a command prompt using the Cluadmin.exe command.

For information about other command-line utilities, see Command-line reference. For more information about manageability, see Management Strategies and Tools.

The following rules apply to cluster.exe and its subcommands when entering commands from the command prompt:

- You must use quotation marks around all names that contain spaces and special characters. Examples of special characters are: the minus sign (-), the slash mark (/), quotation marks ("), the colon (:), the comma (,), and the equal sign (=). For other examples, see the cluster commands in Related Topics.

- When setting properties to True or False, specify 1 (one) for True and 0 (zero) for False.

- You specify the local cluster when you enter a PERIOD (.) in the command for cluster name.

- You can specify multiple options for one command line. Cluster.exe processes options from left to right. If an option fails, the command will stop executing at the failed option.

- Use double quotation marks (") in a string that has two consecutive double quotation marks (""). The following example shows double quotation marks in a string:

  **cluster resource AResource /priv aProp="a """**

This section describes cluadmin.exe as well as the cluster.exe commands, command abbreviations, and property lists:

- Cluadmin

- Cluster

- Cluster node

- Cluster group
- Cluster network
- Cluster netinterface
- Cluster resource
- Cluster resourcetype
- Cluster command abbreviations
- Property lists

# Cluadmin

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluadmin**
The cluadmin command is used to connect to a server cluster. Used without parameters, **cluadmin** starts Cluster Administrator, the tool used to configure and manage server clusters.

**Syntax**
**cluadmin** [**/norecon**[**nect**]] [*IP Address*] [**.**] [{*ClusterName* | *NodeName*}]

**Parameters**
**/norecon[nect]**
Starts Cluster Administrator without restoring all previous cluster connections left open when you closed the previous session.

***IP Address***
Connects to either a node in the cluster or the cluster using the IP address.

**[ .]**
Connects to the local node.

**{*ClusterName* | *NodeName*}**
Connects to the cluster using a NetBIOS name. You can use either one of the node names or the cluster name.

**/?**
Displays help at the command prompt.

**Remarks**

- Using the **/norecon**[**nect**] option

  If you use this parameter, you will be prompted to enter the name of the cluster that you want to connect to.

- Using the [**.**] option

  If the cluster name or cluster Internet Protocol (IP) address does not come online, you can use this parameter to make a connection to the cluster.

- Using the {*ClusterName* | *NodeName*} option

  To use this parameter, the name resolution service must be functioning correctly.

**Examples**
To connect to cluster node NODE1, type:

**cluadmin NODE1**

To start Cluster Administrator without opening old cluster connections, type:

**cluadmin /norecon**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |

| | |
|---|---|
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

Cluster commands overview

# Cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster**
The cluster command is used to create a new cluster or administer an existing cluster.

**Syntax**
**cluster** [[**/cluster:**]*ClusterName*] **/***Option*

**Parameters**
***ClusterName* /create /ipaddr[ess]:*Static_IP_Address*[,*SubnetMask*,*NetworkConnectionName*] /pass[word]:*Password* /user:{*Domain**UserName* | *UserName@Domain*} [/node:*NodeName*] [/verb[ose]] [/unattend[ed]] [/min[imum]]**
Creates a cluster. Descriptions of the optional parameters are provided in the table below.

***ClusterName* /add[nodes][:*NodeName1*[,*NodeName2*, ...]] [/pass[word]:*Password*] [/verb[ose]] [/unattend[ed]] [/min[imum]]**
Adds one or more nodes to an existing cluster.

**/ren[ame]:*ClusterName***
Renames a cluster.

**/cluster: *ClusterName1*[,*ClusterName2*, ...] /changepass[word][:*NewPassword*[,*OldPassword*]] [/skipdc] [/force] [/test] [/quiet] [/verb[ose]] [/unattend[ed]] [/help]**
For one or more clusters, changes the Cluster service account password on the domain controller and all the cluster nodes from *OldPassword* to *NewPassword*. If not supplied as part of the command, you will be prompted to provide the *NewPassword* or the *OldPassword*. You can specify a blank password by supplying two double quotes ("""). If multiple clusters are specified in one operation, they must all use the same Cluster service account. Descriptions of the optional parameters are provided in the table below.

**/ver[sion]**
Displays the Cluster service version number.

**/listnetpri[ority]**
Lists the priority of all internal (private and mixed) networks.

**/setnetpri[ority]:*NetworkName1*[,*NetworkName2*, ...]**
Sets the priority order for all internal networks. If you use this option, you must supply all the internal networks in the cluster.

**/quorum[resource][:*ResourceName*] [/path:*Drive*:*Path*\] [/maxlogsize:*MaximumSize_in_Kilobytes*]**
Changes the name or location of the quorum resource or the size of the quorum log. If you change the location of the quorum resource, do not omit the drive letter, the colon, or any backslashes. For example, for a quorum resource on drive f: in a folder called Quorumfolder, you must specify the location with **/path:f:\Quorumfolder** not **/path:f:Quorumfolder**.

If no options are supplied, this command will display the name of the quorum resource, the path, and maximum log size.

**/reg[admin]ext:*AdminExtension_DLL* [,*AdminExtension_DLL* ...]**
Registers a Cluster Administrator extension DLL with the cluster.

**/unreg[admin]ext:*AdminExtension_DLL* [,*AdminExtension_DLL* ...]**
Unregisters a Cluster Administrator extension DLL from the cluster.

**/list:[*DomainName*]**
Displays a list of clusters in the computer's domain or a specified domain. Do not use the cluster name with this command-line option.

**/prop[erties] [*PropertyList*]**
Views or sets cluster common properties.

**/priv[properties] [*PropertyList*]**
Views or sets cluster private properties.

**/registerdns**
Registers existing Network Name resources with a DNS server in a way that does not interrupt cluster availability.

**/wiz[ard]**
Starts the Cluster Configuration Wizard. This command must be used with either the **/create** or **/add**[**nodes**] commands.

**Important**

- You cannot supply the subnet mask or network connection name when you use the **/wiz**[**ard**] command to create a cluster. The program will use the information from the network connection with the same subnet mask as the cluster to supply the subnet mask, and network connection name.

**/setfail[urereactions][:*NodeName*[,*NodeName* ...]]**
Resets the restart actions settings that the Services Microsoft Management Console snap-in uses for the Cluster service to the original values used at setup.

**/?**
Displays help at the command prompt.

**Remarks**

- Using the **cluster** command

  The cluster name is optional except when using the **/changepass**[**word**] command. If you do not specify a cluster, Cluster.exe attempts to connect to the cluster running on the node that is running Cluster.exe.

  If the name of your cluster is also a cluster command or its abbreviation, such as "cluster" or "c", use **/cluster:** to explicitly specify the cluster name. For a list of all the cluster commands, see Related Topics.

- Using command-line options with **cluster /create**

  Unless you are invoking the Cluster Configuration Wizard (by using the **/wiz**[**ard**] option), you must supply a name and static IP address for the cluster and the user name for the Cluster service account. If you do not use the **/unattend**[**ed**] option, you must also supply the password for the user account used to run the Cluster service on the first node. If possible, the program will use the information from the network connection with the same subnet mask as the node to supply the subnet mask, and network connection name. The cluster will be created in the same domain to which the first server belongs. See the table below for details on the other optional parameters.

- Using the **cluster** command for unattended setup.

  You can create and configure a cluster during an unattended setup by including the cluster.exe command in the [GuiRunOnce] section of the Unattend.txt file. The cluster.exe command must include all the command line options required for creating and configuring a cluster. For more information on unattended installs, see the Microsoft Windows Corporate Deployment Tools User's Guide (deploy.chm) in the support folder on your installation media.

- Using the **/prop**[**erties**] [*PropertyList*] command-line option

  For more information on property lists, see Related Topics.

- Using the **/priv**[**properties**] [*PropertyList*] command-line option

  For more information on property lists, see Related Topics.

- Using the **/setfail**[**urereactions**][**:***NodeName*[**,***NodeName* ...]] command-line option

  This option resets the Cluster service restart settings for one or more nodes to the following values:

| **Service Restart Option** | **Setting** |
|---|---|
| First failure | Restart the service |
| Second failure | Restart the service |

| | |
|---|---|
| Subsequent failure | Restart the service |
| Reset fail count after *N* days | 0 days |
| Restart service after *N* minutes | 1 minute |

- Command options for creating a cluster

| Option | Description | Default |
|---|---|---|
| [**/node:***NodeName*] | The name of the server to be configured as the first cluster node. | The command will use the name of the current computer if you do not supply a node name. |
| [**/min**[**imum**]] | This option creates a cluster using the Advanced (minimum) Configuration option. Use this option when creating clusters with complex storage configurations. For more information, see Storage configuration options. | n/a |
| [**/verb**[**ose**]] | This option writes all event messages to the cluster log. Use this option for troubleshooting cluster configuration issues. | n/a |
| **/unattend**[**ed**] | If you use this option, you will not be prompted for passwords not supplied at the command prompt. | n/a |

- Command options for changing the Cluster service account password

| Option | Description | Default |
|---|---|---|
| [**/skipdc**] | This option will change the Cluster service account password only on the cluster nodes. It will not change the password on the domain controller. Use this option to complete a previous password update that was only partially completed. For example, use this option if you previously issued a **cluster /changepass** command for multiple clusters and the Cluster service account password was not updated on all the clusters, for whatever reason.<br><br>**Note** If you use this option, you do not have to supply the *OldPassword*. | n/a/ |
| [**/force**] | This option will force execution of the password change command on the available nodes in a cluster even if some of the cluster nodes are not available (that is, some nodes are in the Down, Joining, or Unknown states). | n/a |
| [**/test**] | This option will open a connection to the specified cluster(s), verify that an appropriate domain controller is available, check the version of the operating system installed on each node, and verify that all the cluster nodes are online and use the same Cluster service account. | n/a |
| [**/quiet**] | This option will result in no output, unless an error occurs. | n/a |
| [**/verb**[**ose**]] | This option outputs detailed information about the cluster nodes (for example, node names and Cluster service account names) to the screen. Use this option for troubleshooting password change issues. | n/a |
| **/unattend**[**ed**] | If you use this option, you will not be prompted for passwords not supplied at the command prompt. | n/a |
| [**/help**] | This option displays help for the **cluster /changepass** command only. | n/a |

- Cluster common property names

The following table describes the common **cluster** property names, their uses, and valid settings:

| Common property names | Use |
|---|---|

| | |
|---|---|
| **AdminExtensions** | Describes one or more class identifiers (CLSIDs) of Cluster Administrator extension for the cluster object. |
| **DefaultNetworkRole** | Specifies the default role to assign to networks. |
| **Description** | Specifies administrative description of the cluster. |
| **Security** | Describes the Windows Server 2003 family-compatible security descriptor. |
| **Security Descriptor** | Describes Windows NT-SP4 and the Windows Server 2003 family-compatible security descriptor. |
| **Groups\AdminExtensions** | Describes one or more class identifiers (CLSIDs) of Cluster Administrator extensions for the groups. |
| **NetworkInterfaces\AdminExtensions** | Describes one or more class identifiers (CLSIDs) of Cluster Administrator extensions for the netinterfaces. |
| **Networks\AdminExtensions** | Describes one or more class identifiers (CLSIDs) of Cluster Administrator extensions for the networks. |
| **Nodes\AdminExtensions** | Describes one or more class identifiers (CLSIDs) of Cluster Administrator extensions for the nodes. |
| **Resources\AdminExtensions** | Describes one or more class identifiers (CLSIDs) of Cluster Administrator extensions for the resources. |
| **ResourceTypes\AdminExtensions** | Describes one or more class identifiers (CLSIDs) of Cluster Administrator extensions for the resource types. |
| **EnableEventLogReplication** | Specifies if Event Log Replication is enabled or disabled cluster wide. (True (1) means enabled; False (0) means disabled.) |
| **QuorumArbitrationTimeMin**<br>**QuorumArbitrationTimeMax** | Determines the minimum and maximum time, in seconds, a node is allowed to spend arbitrating for the quorum resource before giving up. The range of values allowed is 0 to 3600 seconds for **QuorumArbitrationTimeMin** and 1 to 3600 seconds for **QuorumArbitrationTimeMax**.<br><br>For a single quorum device server cluster, the default values are 7 seconds for **QuorumArbitrationTimeMin** and 60 seconds for **QuorumArbitrationTimeMax**.<br><br>For a majority node set server cluster, the default values are 7 seconds for **QuorumArbitrationTimeMin** and 180 seconds for **QuorumArbitrationTimeMax**. |
| **DisableGroupPreferredOwnerRandomization** | If you do not specify a preferred owner list for resource groups, the Cluster service randomizes the list it uses internally to decide which node to fail over the groups to, as described in Determining failover and move policies for groups. That is, by default, this property is set to FALSE (0). If you want to disable this randomization and instead follow the internal ordered list of nodes for failover, set the **DisableGroupPreferredOwnerRandomization** property to be TRUE (or 1). |
| **EnableEventDeltaGeneration** | When a set of events in the Event Log is replicated across cluster nodes, this property generates a delta event in the Event Log to indicate the time difference between nodes. True (1), the default, means enabled; False (0) means disabled. |
| **ClusSvcHeartbeatTimeout** | Used by the Cluster Network driver, ClusNet.sys, to monitor the health of the Cluster service. |

| | |
|---|---|
| **HangRecoveryAction** | Describes the recovery action taken if ClusNet.sys detects a failure in the Cluster service. |
| **EnableResourceDllDeadlockDetection**<br><br>**ResourceDllDeadlockTimeout**<br><br>**ResourceDllDeadlockThreshold**<br><br>**ResourceDllDeadlockPeriod** | Used by the Cluster service to monitor if the entry points to the Resource DLLs are deadlocked (a condition that occurs when two processes are each waiting for the other to complete before proceeding). |

- Using cluster private property names

  To view the private properties for a cluster, use the **/priv**[**properties**] parameter without any options. For example, to see the private properties for the cluster OpsClust, type the following at a command prompt:

  **cluster opsclust /priv**

  The following table describes a **cluster** private property for cryptographic checkpoints. This private property is useful in two scenarios:

  - If there is a third-party resource or application that uses a third-party cryptographic provider that is not supplied by Microsoft.

    For information on troubleshooting this issue, see "A third-party resource fails to come online in a mixed-version cluster or while upgrading a cluster" in Group and resource failure problems.

  - If you have security concerns about the cryptographic checkpoint data that is written to the quorum when you import resource data to a cluster node before bringing the resource online.

  You can use this private property to change the encryption levels for any of the cryptographic providers (supplied by third-party developers or by Microsoft) that are used by the Cluster service.

| **Private property names** | **Use** |
|---|---|

| | |
|---|---|
| **"*CSP*"** | Sets the encryption levels (key lengths) for a cryptographic key that is used to export (encrypt) and import (decrypt) resource data (cluster and cluster application cryptographic checkpoints). The imported and exported resource data is saved to the quorum. The cryptographic key is generated by a cryptographic provider that uses the RC2 block encryption method.<br><br>Usage: **"*CSP*"**=*key_length,effective_key_length*:**MULTISTR**<br><br>"*CSP*" is the name of the cryptographic provider. For example, one of the standard cryptographic providers supplied with the Windows Server 2003 family is "Microsoft Enhanced Cryptographic Provider v1.0." For more information, see CLUSCTL_RESOURCE_ADD_CRYPTO_CHECKPOINT in the *Microsoft Platform Software Development Kit* (SDK).<br><br>*key_length* is the RC2 key length, in bits.<br><br>*effective_key_length* is the RC2 effective key length, in bits<br><br>For example, to change the RC2 key length for a third-party cryptographic provider named "Database CSP v2.0" in cluster opsclust to 128 bits, type:<br><br>**cluster opsclust /priv "Database CSP v2.0"=128,40:MULTISTR**<br><br>**Notes**<br><br>For this property to take effect, the resource DLL must add the cryptographic checkpoint for the property. This is because the cryptographic key is exported and saved to the quorum when the checkpoint is added for the very first time; prior to the resource coming online the key is imported from the file saved in the quorum. Review the documentation for your cryptographic provider to obtain the correct procedure for adding the cryptographic checkpoint.<br><br>Review the documentation for your cryptographic provider to obtain valid values for the following RC2 encryption algorithm parameters: *key_length* and *effective_key_length*. |

**Examples**
To rename a cluster called OpsClust to OpsClust1, type:

**cluster opsclust /rename:opsclust1**

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

# Cluster node

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster node**

The cluster node command is used to administer a node in a server cluster or to view its status. Used without parameters, **cluster node** defaults to the **/status** command-line option and displays the status for all nodes is displayed.

**Syntax**

**cluster**[[**/cluster:**]*ClusterName*] **node** *NodeName* **/***Option*

**Parameters**

**/stat[us]**
Displays the cluster node status (for example, Up, Down, Paused).

**/force[cleanup] [/wait[:*Timeout_in_Seconds*]]**
Manually restores the configuration of the Cluster service on the specified node to its original state.

**/start [/wait[:*Timeout_in_Seconds*]]**
Starts the Cluster service on the specified node.

**/stop [/wait[:*Timeout_in_Seconds*]]**
Stops the Cluster service on the specified node.

**/pause**
Pauses a node.

**/resume**
Resumes a paused node.

**/evict [/wait[:*Timeout_in_Seconds*]]**
Evicts a node from a cluster.

**/listint[erfaces]**
Lists the node's network interfaces.

**/prop[erties] [*PropertyList*]**
Views or sets node common properties.

**/priv[properties] [*PropertyList*]**
Views or sets node private properties.

**/?**
Displays help at the command prompt.

**Remarks**

- Using the **cluster node** command

  The cluster name is optional. If the name of your cluster is also a cluster command or its abbreviation, such as "node", use **/cluster:** to explicitly specify the cluster name. For a list of all the cluster commands, see Related Topics.

  With **/force**[**cleanup**], **/start**, **/stop**, and **/evict,** the command-line option **/wait**[:*Timeout_in_Seconds*] specifies how long Cluster.exe waits before canceling the command if it does not successfully complete. If a time-out is not specified, Cluster.exe waits indefinitely or until the node state changes.

  The node name (node_name) is optional for all commands except for **/listint**[**erfaces**] or when you use the **/prop**[**erties**] or **/priv**[**properties**] commands to set common or private properties.

- Using the **/stat**[**us**] command-line option

  The node name is optional. The status of all nodes is displayed if you do not provide a node name.

- Using the **/evict** command-line option

  If both the node and the cluster are up, this command evicts the node and removes the cluster configuration from the node. If the cluster is up, but the node is down, this command only evicts the node. The Cluster service will then remove the cluster configuration for the node when it detects that the node no longer belongs to the cluster.

- Using the **/force**[**cleanup**], **/start**, **/stop**, **/pause**, **/resume**, or **/evict** command-line options

  If the node name is not specified, the command will take effect on the local node, that is, the node where the command is run.

- Using the **/prop**[**erties**] [*PropertyList*] command-line option

  The node name is optional. If you do not specify a node name, properties for all nodes are displayed. For more information on property lists, see Related Topics.

- Using the **/priv**[**properties**] [*PropertyList*] command-line option

  The node name is optional. If you do not provide a node name, private properties for all nodes are displayed . For more information on property lists, see Related Topics.

- Using the **/stat**[**us**], **/prop**[**erties**], or **/priv**[**properties**] command-line options

  If the node name is not specified, the command will display results for all nodes in the cluster.

- Using cluster node common property names

  The following table describes the common **cluster node** property names, their uses, and valid settings.

| Common property names | Use |
|---|---|
| **Description** | Describes a node. |
| **EventEnableLogReplication** | Specifies if Event Log Replication is enabled or disabled on a node. (True (1) means enabled; False (0) means disabled.) If the cluster Event Log Replication is disabled, Event Log Replication on a node is disabled, regardless of property setting. |
| **NodeName** | Displays the name of the node. |
| **NodeHighestVersion**<br>**NodeLowestVersion** | Displays the highest and lowest versions of the Cluster service with which a node is compatible. |
| **MajorVersion**<br>**MinorVersion** | Displays the version of the operating system installed on the node (for example, **MajorVersion**=5 and **MinorVersion**=00 indicates a version number of 5.00). |
| **BuildNumber** | Displays the build number of the operating system installed on the node. |
| **CSDVersion** | Displays the version of the latest service pack installed on the node. |

- Using cluster node private property name

  By default, there are no private properties for **cluster node**. Software vendors can add private properties to extend cluster functionality.

**Examples**

To display the status of a node named OpsNode1, type:

**cluster node opsnode1 /status**

**Formatting legend**

| Format | Meaning |
| --- | --- |
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

Cluster commands overview

# Cluster group

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster group**

The cluster group command is used to create a new cluster group or administer an existing group. Used without parameters, **cluster group** defaults to the **/status** command-line option and displays the status for a group.

**Syntax**

**cluster** [[**/cluster:**]*ClusterName*] **group** *GroupName* **/***Option*

**Parameters**

**/node: *NodeName***
Specifies the node that owns the group.

**/stat[us]**
Displays the status of a group (online, offline, or Partially Online).

**/create**
Creates a new group.

**/delete**
Deletes a group.

**/ren[ame]:*NewGroupName***
Renames a group.

**/move[to][:*NodeName*] [/wait[:*Timeout_in_Seconds*]]**
Moves a group to another node.

**/on[line][:*NodeName*] [/wait[:*Timeout_in_Seconds*]]**
Brings a group online.

**/off[line][:*NodeName*] [/wait[:*Timeout_in_Seconds*]]**
Takes a group offline.

**/prop[erties] [*PropertyList*]**
Views or sets the group common properties.

**/priv[properties] [*PropertyList*]**
Views or sets the group private properties.

**/listowners**
Displays a list of preferred owners.

**/setowners: *NodeName*[,*NodeName* ...]**
Specifies a preferred owner.

**/?**
Displays help at the command prompt.

**Remarks**

- Using the **cluster group** command

  The cluster name is optional. If the name of your cluster is also a cluster command or its abbreviation, such as "cluster" or "group," use **/cluster:** to explicitly specify the cluster name. For a list of all the cluster commands, see Related Topics.

  With **/move**[**to**], **/online**, and **/offline**, the command-line option **/wait**[**:***Timeout_in_Seconds*] specifies how long Cluster.exe waits before canceling the command if it does not successfully complete. If you do not use the **/wait** option with the **/move**[**to**] command, Cluster.exe waits 20 seconds. If you do not use the **/wait** option with the **/offline** or **/online** commands, Cluster.exe waits 10 seconds. For the **/move**[**to**], **/online**, or **/offline** commands, if you use **/wait** without specifying a time-out period, Cluster.exe waits indefinitely or until the group state changes.

If a node name is not specified, the Cluster service will automatically select a node following the move and failover logic described in Determining failover and move policies for groups.

- Using the **/stat**[**us**] command-line option

  The group name is optional. If you do not provide a group name, status for all groups is displayed.

- Using the **/prop**[**erties**] [*PropertyList*] command-line option

  The group name is optional. Properties for all groups are displayed if group name is not provided. For more information on property lists, see Related Topics.

- Using the **/priv**[**properties**] [*PropertyList*] command-line option

  The group name is optional. Private properties for all groups are displayed if you do not provide a group name. For more information on property lists, see Related Topics.

- Using cluster group common property names

  The following table describes the common **cluster group** property names, their uses, and valid settings:

| **Common property names** | **Use** |
|---|---|
| **Name** | Name of the cluster group object. |
| **Description** | Describes a group. |
| **PersistentState** | Describes the last known persistent state of a group (1, (true) means online; 0 (false) means offline). |
| **FailoverThreshold** | Specifies the number of times the Cluster service attempts to failover a group before it concludes that the group cannot be brought online anywhere in the cluster. |
| **FailoverPeriod** | Specifies the interval (in hours) over which the Cluster service attempts to fail over a group. |
| **AutoFailbackType** | Set to **ClusterGroupPreventFailback (0)** to prevent failback. Set to **ClusterGroupAllowFailback (1)** to allow failback. |
| **FailbackWindowStart** | Specifies the start time (on a 24-clock) for failback of a group to its preferred node. These values must be between 0 (midnight) and 23 (11:00 p.m.) in local time. For immediate failback, set to -1. |
| **FailbackWindowEnd** | Specifies the end time (on a 24-hour clock) for failback of a group to its preferred node. These values must be between 0 (midnight) and 23 (11:00 p.m.) in local time. For immediate failback, set to -1. |
| **AntiAffinityClassNames** | Specifies a name for a class of groups that should not be hosted on the same cluster node. This property (a string of alphanumeric characters) can be used to configure N+I server clusters. For more information on N+I server clusters, see Cluster deployment and operation options. For more information on using this property, see article Q296799, "How to Configure Windows Clustering Groups for Hot Spare Support," in the Microsoft Knowledge Base. |
| **LoadBalState** | This property is not used at this time by the Cluster service, but is reserved for future use. |

- Using Cluster group private property names

  By default, there are no private properties for **cluster group**. Software vendors can add private properties to extend cluster functionality.

**Examples**

To move a group called Disk Group 1 on the OpsClus1 cluster from OpsNode1 to OpsNode2, type:

**cluster opsclust group "disk group 1" /moveto:opsnode2**

To specify that the Cluster service not place groups "disk group 1" and "disk group 2" together on the same node, supply the same string "SEP1" for groups "disk group 1" and "disk group 2". Similarly, to specify that the Cluster service not place groups "disk group 1" and "file share 1" together on the same node, supply the same string "SEP2" for groups "disk group 1" and "file share 1". That is, type:

**cluster opsclust group "disk group 1" /prop AntiAffinityClassNames="SEP1","SEP2"**

**cluster opsclust group "disk group 2" /prop AntiAffinityClassNames="SEP1"**

**cluster opsclust group "file share 1" /prop AntiAffinityClassNames="SEP2"**

**Formatting legend**

| **Format** | **Meaning** |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

Cluster commands overview

# Cluster network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster network**
The cluster network command is used to view or change the properties of all the networks in the cluster. Used without parameters, **cluster network** defaults to the **/status** command-line option and displays the status of all cluster networks.

**Syntax**
**cluster** [[**/cluster:**]*ClusterName*] **net**[**work**] *NetworkName* **/***Option*

**Parameters**
**/stat[us]**
Displays the status for cluster network.

**/prop[erties] [*PropertyList*]**
Views or sets the network common properties.

**/priv[properties] [*PropertyList*]**
Views or sets the network private properties.

**/ren[ame]:*NewName***
Renames the network.

**/listint[erfaces]**
Lists network interfaces associated with the network.

**/?**
Displays help at the command prompt.

**Remarks**

- Using the **cluster net**[**work**] command

  The cluster name is optional. If the name of your cluster is also a cluster command or its abbreviation, such as "cluster" or "network," use **/cluster:** to explicitly specify the cluster name. For a list of all the cluster commands, see Related Topics.

- Using the **/stat**[**us**] command-line option

  The network name is optional. If you do not provide a network name, the status of all cluster networks is displayed.

- Using the **/prop**[**erties**] [*PropertyList*] command-line option

  The network name is optional. If you do not provide a network name the properties for all networks are displayed. For more information on property lists, see Related Topics.

- Using the **/priv**[**properties**] [*PropertyList*] command-line option

  The network name is optional. Private properties for all networks are displayed if you do not provide a network name. For more information on property lists, see Related Topics.

- Using cluster network common property names

  The following table describes the common **cluster network** property names, their uses, and valid settings.

| Property name | Use |
|---|---|

| | |
|---|---|
| **Name** | The name of the network. The cluster uses the same name as the Network Connections folder. For more information, see Name coordination between Cluster service and Network and Dial-up Connections. |
| **Address** | Provides the address for the entire network or subnet. |
| **AddressMask** | The subnet mask for the network. |
| **Description** | A description of the network. |
| **Role** | The communication role of the network. For more information on network roles, see Server cluster networks. |

- For more information about the private properties for **cluster network**, see Q307962, "Multicast Support Enabled for the Cluster Heartbeat," in the Microsoft Knowledge Base.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

Cluster commands overview

# Cluster netinterface

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster netinterface**
The cluster netinterface command is used to view or change the properties of all the network interface devices in the cluster. Used without parameters, **cluster netinterface** defaults to the **/status** command-line option and displays the status for cluster network interface.

**Syntax**
**cluster** [[**/cluster:**]*ClusterName*] **netint**[**erface**] **/node:***NodeName* **/net**[**work**]**:***NetworkName* **/***Option*

**Parameters**

**/stat[us]**
Displays the status for cluster network interface.

**/prop[erties] [*PropertyList*]**
Views or sets the network interface common properties.

**/priv[properties] [*PropertyList*]**
Views or sets the network interface private properties.

**/?**
Displays help at the command prompt.

**Remarks**

- Using the **cluster netint**[**erface**] command

  The cluster name is optional. If the name of your cluster is also a cluster command or its abbreviation, such as "cluster" or "c," use **/cluster:** to explicitly specify the cluster name. For a list of all the cluster commands, see Related Topics. The commands **/node:***node name***/network:***network name* are both required. You cannot supply one without supplying the other.

- Using the **/stat**[**us**] command-line option

  The network name and node name are optional. If you do not provide the network name and node name, the status of all cluster network interfaces is displayed.

- Using the **/prop**[**erties**] [*PropertyList*] command-line option

  The network name and node name are optional. Properties for all network interfaces are displayed if you do not provide a network name and node name. For more information on property lists, see Related Topics.

- Using the **/priv**[**properties**] [*PropertyList*] command-line option

  The network name and node name are optional. If you do not provide a network name and node name, the private properties for all network interfaces are displayed. For more information on property lists, see Related Topics.

- Using cluster netinterface common properties

  The following table describes the common **cluster netinterface** property names, their uses, and valid settings:

| Name | Use |
|---|---|
| **Adapter** | Uniquely identifies the adapter in the cluster. |
| **AdapterID** | A Globally Unique Identifier (GUID) for the adapter in the cluster. |

| | |
|---|---|
| **Address** | The primary network address used by the network interface. |
| **Description** | Optional description of the network interface. |
| **Name** | Name of the cluster network interface object. |
| **Network** | The name of the network to which the network interface is connected. |
| **Node** | The name of the node on which the network interface is installed. |

- Using cluster netinterface private properties

  By default, there are no private properties for **cluster netinterface**. Software vendors can add private properties to extend cluster functionality.

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

Cluster commands overview

# Cluster resource

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster resource**

The cluster resource command is used to create a new cluster resource or administer an existing resource. Used without parameters, **cluster resource** defaults to the **/status** command-line option and displays the status of a cluster resource.

**Syntax**

**cluster** [[**/cluster:**]*ClusterName*] **res**[**ource**] *ResourceName* **/***Option*

**Parameters**

**/stat[us]**
Displays the status of a cluster resource (online, offline, or failed).

**/create /group: *GroupName* /type: *ResourceType* [/separate]**
Create a new resource in a specified group.

**/delete**
Deletes a resource.

**/ren[ame]:*NewResourceName***
Renames a resource.

**/addowner: *NodeName***
Adds a node name to the list of possible owners.

**/removeowner: *NodeName***
Removes a node name from the list of possible owners.

**/listowners**
Displays a list of possible owners.

**/move[to]:*Group***
Moves the resource to a different group.

**/prop[erties] [*PropertyList*]**
Views or sets the resource common properties.

**/priv[properties] [*PropertyList*]**
Views or sets the resource private properties.

**/fail**
Initiates resource failure.

**/on[line] [/wait[:*Timeout_in_Seconds*]]**
Brings the resource online.

**/off[line] [/wait[:*Timeout_in_Seconds*]]**
Takes the resource offline.

**/maint[enancemode][:{on|off}]**
Views or controls maintenance mode (used when running a disk maintenance tool).

**/listdep[endencies]**
List the dependencies for a resource.

**/adddep[endency]:*Resource***
Adds a dependency for a resource.

**/removedep[endency]:*Resource***
Removes a dependency for a resource.

**/addcheck[points]:*Key*[*Subkey* ...][,*Key*[*Subkey* ...] ...]**
Adds a registry checkpoint for a resource.

**/removecheck[points]:*Key*[*Subkey* ...][,*Key*[*Subkey* ...] ...]**
Removes a registry checkpoint for a resource.

**/check[points]**
Lists registry checkpoints for a resource.

**/addcryptocheck[points]:*Type**Name**Key* ... [,*Type**Name**Key* ...]**
Adds a cryptographic key checkpoint for a resource.

**/removecryptocheck[points]:*Type**Name**Key* ... [,*Type**Name**Key* ...]**
Removes a cryptographic key checkpoint for a resource.

**/cryptocheck[points]**
Lists the cryptographic key checkpoints for a resource.

**/?**
Displays help at the command prompt.

**Caution**

- Incorrectly editing the registry may severely damage your system. Before making changes to the registry, you should back up any valued data on the computer.

**Remarks**

- Using the **cluster res**[**ource**] command

  The cluster name is optional. If the name of your cluster is also a cluster command or its abbreviation, such as "cluster" or "resource," use **/cluster:** to explicitly specify the cluster name. For a list of all the cluster commands, see Related Topics.

  With **/on**[**line**] and **/off**[**line**] the command-line option **/wait**[**:***Timeout_in_Seconds*] specifies how long Cluster.exe waits before canceling the command if it does not successfully complete. If you do not use the **/wait** option, Cluster.exe waits 10 seconds. If no time-out is specified, Cluster.exe waits indefinitely or until the resource state changes.

- Using the **/stat**[**us**] command-line option

  The resource name is optional. If you do not provide a resource name, the status of all cluster resources is displayed.

- Using the **/create** command-line option

  When you use cluster.exe to create a new File Share resource, permissions for the Everyone group for that file share are automatically set by default to Full Control. In contrast, if you use Cluster Administrator to create a new File Share resource, permissions for the Everyone group are set by default to Read-only. You can change the default permissions by specifying the Security private property as described below.

- Using the **/separate** command-line option

  Use **/separate** to specify that the resource should run in a separate Resource Monitor.

- Using the **/prop**[**erties**] [*PropertyList*] command-line option

  The resource name is optional. If you do not provide a resource name, properties for all resources are displayed. For more information on property lists, see Related Topics.

- Using the **/priv**[**properties**] [*PropertyList*] command-line option

  Resource name is optional. If you do not provide a resource name, private properties for all resources are displayed. For more information on property lists, see Related Topics.

- Using the **/maint**[**enancemode**][**:**{**on**|**off**}] command-line option

Maintenance mode can be run only on a disk resource and only when the resource is online. Maintenance mode allows a disk maintenance tool, such as Chkdsk, to finish running without being interrupted by failover. Maintenance mode will remain on until you turn it off, until the resource goes offline or fails, or until the node on which the resource is running restarts or loses communication with other nodes (which causes failover of all resources on that node). As soon as the maintenance tool has finished running, turn maintenance mode off. Type **/maint** to check whether maintenance mode is on or off.

- Using the **/check**[**points**] command-line option

  The resource name is optional. Checkpoints for all cluster resources are displayed if you do not provide a resource name.

- Using the **/addcryptocheck**[**points**] or **/removecryptocheck**[**points**] command-line options

  The argument for a cryptographic checkpoint is the path to a cryptographic key container (that is, *Type*****Name******Key*). *Type* is a number, *Name* is the name of the cryptographic provider, and *Key* is the key container name (usually created by an application).

- Using the **/cryptocheck**[**points**] command-line option

  The resource name is optional. If you do not provide a resource name, checkpoints for all cluster resources are displayed. The argument for a cryptographic checkpoint is the path to a cryptographic key container (that is, *Type*****Name******Key*). *Type* is a number, *Name* is the name of the cryptographic provider, and *Key* is the key container name (usually created by an application).

- Using cluster resource common property names

  The following table describes the common **cluster resource** property names, their uses, and valid settings.

| Common property names | Use |
|---|---|
| **Name** | Name of the cluster resource object. |
| **Description** | Describes a resource. |
| **Type** | Specifies the resource type. |
| **DebugPrefix** | Specifies the appropriate debugger for the resource. For more information, see the *Microsoft Platform Software Development Kit*. |
| **SeparateMonitor** | Indicates whether or not a resource shares a Resource Monitor. Valid values are True (1) and False (0). |
| **PersistentState** | Describes the last known persistent state of a resource. In order to save the resource's **PersistentState** property, the resource must be offline. |
| **LooksAlivePollInterval** | Recommended interval in milliseconds that the Cluster service polls a resource to determine if it appears operational. If a value is not specified, a default value is taken from the **LooksAlivePollInterval** property for the resource type. |
| **IsAlivePollInterval** | Interval (in milliseconds) that the Cluster service polls a resource to determine if it is operational. If a value is not specified, a default value is taken from the **IsAlivePollInterval** property for the specific resource type. **IsAlivePollInterval** cannot be zero. |

| | |
|---|---|
| **RestartAction** | Describes the action to perform if the resource fails. The choices are:<br><br>**ClusterResourceDontRestart (0)**: Do not restart following a failure.<br><br>**ClusterResourceRestartNoNotify (1)**: If the resource exceeds its restart threshold within its restart period, the Cluster service does not attempt to failover the group to another node.<br><br>**ClusterResourceRestartNotify (2)**: If the resource exceeds its restart threshold within its restart period, the Cluster service attempts to fail over the group to another node.<br><br>If you do not enter a value, the default allows the resource to affect the group, which can cause the group to fail over to another system. |
| **RestartThreshold** | Specifies how many times the Cluster service attempts to restart the resource in the **RestartPeriod** before failing over the group. |
| **RestartPeriod** | Specifies the amount of time allowed for the restart attempts to reach the **RestartThreshold** before the Cluster service fails over the group. |
| **PendingTimeout** | The amount of time that a pending online or pending offline resource has to either resolve its status or report that it is making progress to the Resource Monitor before the Cluster service puts the resource in Failed status. The default value is 3 minutes. |
| **RetryPeriodonFailure** | Specifies the interval of time (in milliseconds) that a resource should remain in a failed state before the Cluster service attempts to restart it. |
| **LoadBalStartupInterval**<br><br>**LoadBalSampleInterval**<br><br>**LoadBalMinProcessorUnits**<br><br>**LoadBalMinMemoryUnits** | These properties are not used at this time by the Cluster service, but are reserved for future use. |

- Using cluster resource private property names

  To view the private properties for a resource, use the **/priv**[**properties**] parameter without any options. For example, to see the disk signature and other private properties for the Disk L: resource, type:

  **cluster resource "disk l:" /priv**

  The following tables describe some important private **cluster res**[**ource**] property names for File Share, Physical Disk, Network Name, Local Quorum, and Volume Shadow Copy Service Task resources, their uses, and valid settings.

**File Share resource**

| Private property names | Use |
|---|---|

| | |
|---|---|
| **CSCCache** | Controls client side caching for file shares on a server cluster. Client side caching allows network users to access files on file shares, even when the client computer is disconnected from the network, because the files have been cached on the client computer. The choices are:<br><br>**CSCCache** is set to 0. Changes in only those files specifically identified on the file share will be reconciled between the client and the server cluster.<br><br>**CSCCache** is set to 16. Changes in all files opened on the client will be reconciled between the client and the server cluster.<br><br>**CSCCache** is set to 32. Client side caching is disabled for those files that are only opened, but not modified.<br><br>**CSCCache** is set to 48. Client side caching is disabled for all files on this file share.<br><br>For example, to automatically reconcile changes in all files on the shared file resource FLSH1 opened on the client, type:<br><br>**cluster resource "FLSH1" /priv CSCCache=16** |
| **Security** | Sets file share-level permissions for file shares on a server cluster.<br><br>Usage: **Security=***Security group or user,access type,access mask***:security**<br><br>Access types are grant, deny, set, or revoke. An access mask is required for the types grant, deny, or set. Access masks are R for read, C for change, and F for full.<br><br>For example, to set read-only access to File Share resource FSHR1 for the Everyone group, type:<br><br>**cluster resource "FSHR1" /priv Security=Everyone,set,R:security** |

**Physical Disk resource**

| Private property names | Use |
|---|---|
| **Signature**<br><br>**DiskInfo**<br><br>**MountVolumeInfo** | Displays the disk signature and layout details of the disk resource. |
| **SkipChkdsk**<br><br>**ConditionalMount** | Controls if and how the chkdsk program runs on a corrupt shared cluster disk or inaccessible quorum disk. The choices are:<br><br>**SkipChkdsk** is set to 1. The Cluster service does not run Chkdsk against the drive and mounts the disk for immediate use. This setting overrides any setting for **ConditionalMount**.<br><br>**SkipChkdsk** set to 0, and **ConditionalMount** is set to 1. The Cluster service fails the disk resource and leaves it offline.<br><br>**SkipChkdsk** set to 0, and **ConditionalMount** is set to 1. The Cluster service runs the command **chkdsk /f** against the disk and then mounts it.<br><br>For example, to bypass **chkdsk** for a corrupt disk resource Disk Q: and mount it directly, type:<br><br>**cluster resource "Disk Q:" /priv SkipChkdsk=1** |

**Network Name resource**

| Private property names | Use |
|---|---|

| | |
|---|---|
| **RequireDNS** | Controls whether or not the network name must be registered with a DNS server so that the Network Name resource can be brought online. The choices are:<br><br>**RequireDNS** is set to 1. The DNS Host (A) record must be registered in DNS in order for the Network Name resource to be brought online. If the DNS server accepts dynamic updates but the DNS Host (A) record could not be updated, the Network Name resource will fail. If the DNS server does not accept dynamic updates, or if there are no DNS servers associated with the network, the Network Name resource will still come online.<br><br>**RequireDNS** is set to 0. Disables this option. The network name does not have to be registered in DNS in order for the Network Name resource to be brought online. |
| **RequireKerberos** | Controls whether or not the Network Name resource can be brought online without Kerberos authentication. The choices are:<br><br>**RequireKerberos** is set to 1. The next time this resource is brought online, clients using this resource will be authenticated using Kerberos. That is, a computer object for the Network Name resource will be created or updated before that resource comes online.<br><br>**RequireKerberos** is set to 0. Disables this option, that is, no computer object is created for the Network Name resource. This is the default. The Cluster service will try to detect if a computer object already exists for the Network Name resource; if a computer object is present, the resource will fail to come online. If this property were previously set to 1, setting it back to zero will disable the computer object created for this Network Name resource, if any.<br><br>Do not rename a Network Name resource and change the Kerberos authentication setting at the same time. Instead, allow time for changes to replicate after performing each action. |
| **CreatingDC** | Displays the fully qualified DNS name of the domain server on which the computer object for the Network Name resource was created. |
| **StatusDNS** | Displays the error status when the Network Name resource is registered with the DNS servers. If the value is zero, the action was successful; otherwise the value returned is the error code encountered. To view the text for the error code, *ErrorCode*, from the command prompt, type, **net helpmsg** *ErrorCode*. |
| **StatusKerberos** | Displays the error status when the computer object associated with the Network Name resource is created or updated. If the value is zero, the action was successful; otherwise the value returned is the error code encountered. |
| **StatusNetBIOS** | Displays the error status when the Network Name resource is registered with NetBIOS. If the value is zero, the action was successful; otherwise the value returned is the error code encountered. |

**Local Quorum resource**

| Private property names | Use |
|---|---|
| **Path** | Displays the default location for the quorum files if the Local Quorum resource is chosen as the quorum resource. You can override the default location of quorum files by explicitly specifying another local file path or a Server Message Block (SMB) path denoting a file share.<br><br>**Important**<br><br>If the path is not local, quorum logging is turned off. This can result in an out-of-date cluster database. |

| | |
|---|---|
| **Debug** | Specifies whether or not a server cluster that uses a Local Quorum resource as the quorum resource can have more than one node. The choices are:<br><br>Debug is set to 0. This is the default and specifies that the server cluster using a Local Quorum resource as the quorum resource can have only one node.<br><br>Debug is set to 1. This specifies that the server cluster using a Local Quorum resource as the quorum resource can have more than one node (that is, it can be a multi-node server cluster).<br><br>**Important**<br><br>If you have a multi-node server cluster that uses a Local Quorum resource as the quorum resource, you cannot set the Debug property to 0. |

**Volume Shadow Copy Service Task resource**

| Private property names | Use |
|---|---|
| **TaskName** | Specifies the name of the task created in the Scheduled Task folder.<br><br>**Caution**<br><br>If the name you provide for TaskName is the same as an existing scheduled task, that scheduled task will be deleted when the Volume Shadow Copy Service Task resource is brought online. |
| **ApplicationName** | Specifies the path to the executable program to be run for the scheduled task. |
| **ApplicationParams** | Specifies the parameters for the executable program to be run for the scheduled task. This property is used in combination with the **ApplicationName** property to create the full command line that will be run. For example, if the **ApplicationName** property is C:\WINDOWS\SYSTEM32\defrag.exe and the **ApplicationParams** property is -a C:, then the command run when the scheduled task is executed is: C:\WINDOWS\SYSTEM32\defrag.exe -a C:. |
| **TriggerArray** | Displays the schedule information for the scheduled task. This property cannot be specified using cluster.exe, but can be specified using Cluster Administrator or the Cluster APIs. For more information, see Checklist: Installing a Volume Shadow Copy Service Task resource. |

**Examples**

To create a Print Spooler resource in the Ops Print Spoolers group, type:

**cluster resource /create /group:"Ops Print Spoolers" /Type:"print spooler"**

To require that the Network Name resource CLUS N1 be authenticated by Kerberos before being brought online, type:

**cluster resource "CLUS N1" /priv RequireKerberos=1**

To give user accounts USR1 and USR2 in domain DOMAIN1, read-only access to File Share FSHR1, type:

**cluster resource "FSHR1" /priv Security=DOMAIN1\USR1,set,R,DOMAIN1\USR2,set,R:security**

**Formatting legend**

| Format | Meaning |
|---|---|
| *Italic* | Information that the user must supply |
| **Bold** | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| `Courier font` | Code or program output |

Cluster commands overview

# Cluster resourcetype

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster resourcetype**

The cluster resourcetype command is used to create a new cluster resource type or administer an existing resource type. Used without parameters, **cluster resourcetype** defaults to the **/list** command-line option and displays available installed cluster resource types.

**Syntax**

**cluster** [[**/cluster:**]*ClusterName*] **resourcetype** *ResourceType_DisplayName* **/***Option*

**Parameters**

**/list**
Lists the available installed cluster resource types.

**/listowners**
Displays a list of preferred owners.

**/create /Dll[Name]:*DLL_Name* [/type:*TypeName*] [/IsAlive:*Interval_in_Milliseconds*] [/LooksAlive:*Interval_in_Milliseconds*]**
Creates a resource type.

**/delete [/type]**
Deletes a resource type.

**/properties [*PropertyList*]**
Views or sets the resourcetype common properties.

**/privproperties [*PropertyList*]**
Views or sets the resourcetype private properties.

**/?**
Displays help at the command prompt.

**Remarks**

- Using the **cluster resourcetype** command

  The cluster name is optional. If the name of your cluster is also a cluster command or its abbreviation, such as "cluster" or "c," use **/cluster:** to explicitly specify the cluster name. For a list of all the cluster commands, see Related Topics.

- Using the **/list** command-line option

  Resource type display name is optional. If you do not provide a resource type display name, all installed resource types are listed.

- Using the **/delete** [**/type**] command-line option

  If the resource DLL cannot be accessed by the Cluster service, specify the resource type name with the /type command-line option instead of specifying the resource type display name.

- Using the **/prop**[**erties**] [*PropertyList*] command-line option

  Resource type display name is optional. Properties for all resourcetypes are displayed if you do not provide a resource type display name. For more information on property lists, see Related Topics.

- Using the **/priv**[**properties**] [*PropertyList*] command-line option

  The resource type display name is optional. If you do not provide a resource type display name, the private properties for

all resourcetypes are displayed. For more information on property lists, see Related Topics.

- Using cluster resourcetype common property names

  The following table describes the common **cluster resourcetype** property names, their uses, and valid settings.

| Common Property Names | Use |
|---|---|
| **Name** | Changes a resource type display name. |
| **Description** | Changes the text that describes a resource type. |
| **DllName** | Specifies the name of the dynamic-link library (DLL) for a specific resource type. |
| **DebugPrefix** | Specifies the appropriate debugger for the resource type. For more information, see the *Microsoft Platform Software Development Kit*. |
| **DebugControlFunctions** | Specifies if debugger breakpoint is set at the resource control function. (True (1) it is set; False (0) it is not set.) |
| **AdminExtensions** | Describes one or more class identifiers (CLSID) for Cluster Administrator extensions. |
| **LooksAlivePollInterval** | Specifies the interval (in milliseconds) that the Cluster service polls resources of a particular resource type to determine if the resources appear operational. |
| **IsAlivePollInterval** | Specifies the interval (in milliseconds) that the Cluster service polls resources of a particular resource type to determine if the resources are operational. |

- Using cluster resourcetype private property name

  By default, there are no private properties for **cluster resourcetype**. Software vendors can add private properties to extend cluster functionality.

**Examples**

To display the properties of the Generic Application resource type on the OpsClust1 cluster, type:

**cluster opsclust1 resourcetype "generic application" /properties**

**Formatting legend**

| Format | Meaning |
|---|---|
| Italic | Information that the user must supply |
| Bold | Elements that the user must type exactly as shown |
| Ellipsis (...) | Parameter that can be repeated several times in a command line |
| Between brackets ([]) | Optional items |
| Between braces ({}); choices separated by pipe (\|). Example: {even\|odd} | Set of choices from which the user must choose only one |
| Courier font | Code or program output |

# Cluster command abbreviations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster command abbreviations**

The following table lists keyword abbreviations supported by Cluster.exe.

| Keyword | Supported abbreviations |
|---|---|

# Property lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Property lists**

You specify property lists on the Cluster.exe command line in the following ways:

- *Name* **=** *Value*[**,***Value* ...][**:***Format*][*Name*=*Value*[**,***Value* ...][**:***Format*] ...]

  For example:

  **cluster opsclust node mynode /priv prop1=string1,string2:multistring prop2=0xa,0xb:binary**

- **:** *PropertyName1*[**,PropertyName2,** ...]**/usedefault**

  For example:

  **cluster opsclust node mynode /priv:prop1,prop2 /usedefault**

To revert to the default value of a common property or to delete a private property, use the **/usedefault** command-line option.

The following table describes the available format options.

| Format | Description | Example |
|---|---|---|
| **Binary** | Separated list of values from 0 to 255 | myBinary = 12,0xab,255:binary |
| **DWord** | Double word | myDWord=2346:dword |
| **String** | Double quotation marks are required around strings with spaces | myString="string value":string |
| **ExpandString** | Expanded by Cluster.exe | myExpandString=^%windir^%:expandstr |
| **MultiString** | List of strings separated by commas | myMultiString="string value 1", "string value 2":multistr |
| **Security** | Set access permissions. Access types are grant, deny, set, or revoke. An access mask is required for the types grant, deny, or set. Access masks are R for read, C for change, and F for full. | mySecurity= devgroup \ user1, grant, RC, devgroup \ user2, revoke, everyone, set, F:security |
| **ULarge** | Unsigned 64-bit value | myULarge = 12345678901234567890:ularge |

Cluster commands overview

# Managing the Cluster Service from the Command Line

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing the Cluster service from the command line**
You can use cluster service commands to troubleshoot or debug the Cluster service from the command prompt. The Cluster service command line can only be run locally from the cluster directory:

%systemroot%\cluster

Do not use the **clussvc** command under normal conditions, but only as a temporary diagnostic tool if the Cluster service fails to start (because of a system-related error, for example).

**Important**

- If you use the clussvc command to start the Cluster service in a server cluster with 3 or more nodes, the Cluster service will be unable to authenticate any intracluster messages sent in multicast mode. The intracluster traffic in the server cluster will then revert to unicast mode. However, this will not affect the ability of any node to participate in the server cluster. For information, see Network communication between nodes.

- Do not change the Cluster service account password while running the Cluster service from the command line. For information on changing the Cluster service account password, see Change the Cluster service account password

For information about other command-line utilities, see Command-line reference. For more information about manageability, see Management Strategies and Tools.

The following rules apply when entering commands from the command prompt:

- When entering commands from the command prompt, you can specify multiple options for one command line. Clussvc.exe processes options from left to right. If an option fails, the command stops running at the failed option.

- To use the Cluster service commands, you must be logged on with administrative rights.

- To stop the Cluster service, at the command prompt, press CTRL+C.

The command line for starting the Cluster service has the following syntax:

**clussvc /debug** [*command*]

The Cluster service runs in the command prompt window and displays all output recorded in the cluster log in the window.

| Cluster service command | Action |
|---|---|
| **/debugresmon** | Enables the debugging of the resource dynamic-link libraries (DLLs) that are loaded by the resource monitor process. |
| **/fixquorum** | Allows the Cluster service to start up, despite problems with the quorum device. |
| **/resetquorumlog** | If the quorum log file is not found or is corrupted, creates a new quorum log file based on information in the local node's cluster database file. If the quorum log file is found and is not corrupted, this command has no effect. |
| **/norepevtlogging** | Allows no replication of event log entries. |

| | |
|---|---|
| **/forcequorum** | Restores quorum for a majority node set server cluster that has lost quorum.<br><br>**Note**<br><br>• It is recommended that you use the method described in Force quorum in a majority node set server cluster instead of the clussvc /debug /forcequorum command option described here. |

For more information on commands for the Cluster service, see:

- Debugresmon command
- Fixquorum command
- Resetquorumlog command
- Norepevtlogging command
- Forcequorum command

# Debugresmon command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Debugresmon command**

The **debugresmon** command helps you to debug the resource monitor process and, therefore, the resource dynamic-link libraries (DLLs) that are loaded by the resource monitor. You can use any standard Windows-based debugger, such as Microsoft Developer Studio.

The syntax is:

**clussvc /debug /debugresmon**

**Note**

- The **debugresmon** command can be used only when starting the cluster service in the command prompt window. The **debugresmon** command cannot be used as a start parameter when starting the cluster service in the Computer Management console.

Just before the resource monitor process is started up, the cluster service issues the message:

"Waiting for debugger to connect to the resmon process *x*"

where *x* is the process identification number (PID) of the resource monitor process.

After the resource monitor process has started and you have attached a debugger to the resource monitor process, the Cluster service continues with its initialization.

For more information on the Resource Monitor, see Resource Monitors.

For more information on resource DLLs, see Resource dynamic-link libraries (DLLs) in clusters running Windows Server 2003.

For more information on debugging resource DLLs, see the Microsoft Software Development Kit (SDK).

# Fixquorum command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Fixquorum command**

The **fixquorum** command allows you to start the cluster service even if there are problems with the quorum resource. Only one node at a time can be started with this command. You cannot join any other nodes to the node started using this command.

The syntax is:

**clussvc /debug /fixquorum**

Preferably, you can use the **fixquorum** command as a start parameter when starting the cluster service in the Computer Management console. For more information, see Set the Cluster service to only start manually.

When the **fixquorum** command is issued on a particular node, the Cluster service starts, but all the resources, including the quorum resource, remain offline. This allows you to then manually bring the quorum resource online and more easily diagnose quorum device failures. You can use this command, for example, if you need to switch from a problematic quorum disk to another quorum resource. For more information, see Use a different disk for the quorum resource.

# Resetquorumlog command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resetquorumlog command**

The **resetquorumlog** command creates a new quorum log file, if missing or corrupted, using information stored in the local node's cluster database and creates a new registry checkpoint file. The new quorum file is created using information in the cluster database located in %systemroot%\cluster\CLUSDB. If the quorum log file is not missing or corrupt, this command has no effect.

The syntax is:

**clussvc /debug /resetquorumlog**

The **resetquorumlog** command can also be set as a start parameter when starting the cluster service in the Computer Management console.

**Caution**

- The information retrieved from the cluster database might be outdated. Therefore, use this command only if there are no backups of the quorum log file available. You must use the Backup or Restore Wizard even if you do not have a backup of the quorum log. For more information on restoring server cluster data using the Backup or Restore Wizard, see Backing up and restoring server clusters.

  For more information on recovering from a corrupted quorum log, see Recover from a corrupted quorum log or quorum disk.

**Note**

- The registry checkpoint file created by the **resetquorumlog** command has the format CHKxxx.TMP.

# Norepevtlogging command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Norepevtlogging command**

The **norepevtlogging** command prevents replication of those events recorded in the event log. This command is useful in reducing the amount of information displayed in the command window by filtering out events already recorded in the event log.

The syntax is:

**clussvc /debug /norepevtlogging**

The **norepevtlogging** command can also be set as a start parameter when starting the cluster service in the Computer Management console.

For example, to start the cluster service and log those events not recorded in the event log to a local file, Debugnorep.log:

```
clussvc /debug /norepevtlogging > c:\DEBUGNOREP.log\
```

For more information on event logs, see Event Viewer.

# Forcequorum command

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Forcequorum command**

The **forcequorum** command restores quorum for a majority node set server cluster that has lost quorum. This command is useful if a partition of a geographically dispersed server cluster (for example all the nodes in one location) has lost communication with the nodes at another location.

The syntax is:

**clussvc /debug /forcequorum** *node list*

For example, to start the cluster service on nodes Node1, Node2, and Node3, type:

```
clussvc /debug /forcequorum Node1,Node2,Node3
```

**Important**

- When you force quorum in a majority node set cluster, an error message from the Service Control Manager may appear, indicating that the Cluster service failed to start. You can safely ignore this message at this time; the Cluster service will continue startup after the end of the startup timeout period for Service Control Manager.

**Note**

- It is recommended that you use the method described in Force quorum in a majority node set server cluster instead of the clussvc /debug /forcequorum command option described here.

# Resources for Server Cluster information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

- For a good technical reference on clustering technologies, see Pfister, Gregory F. *In Search of Clusters*. Upper Saddle River, NJ: Prentice Hall, 1998.

- For information on Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, see the Microsoft Web site.

- Microsoft maintains up-to-date Windows Server 2003 family product documentation at the Microsoft Web site. This site has information that is more current than the Help documentation on your product CD.

- For technical support information on server clusters, see Updated technical information.

- The Microsoft Windows Resource Kits contain additional technical, planning, and deployment information on server clusters. For more information about server cluster deployments, see "Planning for High Availability" at the Microsoft Windows Resource Kits Web site.

- For a detailed description of how a business has used Network Load Balancing clusters and server clusters to improve performance and availability of their Web site and other services, refer to the clustering scenario at the Microsoft Web site.

- Requests for Comments (RFCs) are an evolving series of reports, proposals for protocols, and protocol standards used by the Internet community. Standards are defined in RFCs published by the Internet Engineering Task Force (IETF) and other working groups. For more information on private IP network addresses, see RFC 1918: Address Allocation for Private Internets.

  You can obtain RFCs from the RFC Editor Web site.

  Web addresses can change, so you might be unable to connect to the Web site or sites mentioned here.

- Cluster Administrator supports command-line parameters. If you start Cluster Administrator from the command line, you can connect to one or more clusters by specifying the cluster name, the name of one of the cluster nodes, or the name of a cluster IP address.

  When you specify the clusters to connect to using the Cluster Administrator command line, Cluster Administrator will not try to restore your most recent cluster connections. You can also prevent Cluster Administrator from restoring your most recent cluster connections by specifying the **cluadmin /noreconnect** command at the command line.

  For more information on administering a cluster from the command line, see Managing a Server Cluster from the Command Line.

- The following links point to information that may help you better understand server clusters within the overall context of Windows Clustering.

  For information on the solutions that make up Windows Clustering, see Windows Clustering.

  For information on Network Load Balancing clusters, see Network Load Balancing Clusters.

  For information on server clusters and how they work with Network Load Balancing clusters, see Updated technical information.

- Server clusters support unattended setup, a feature of Windows Server 2003 family operating systems.

For information about unattended setup, see Planning for unattended Setup.

# Server Cluster Troubleshooting

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**

This section provides symptom-based diagnostic procedures for troubleshooting clustering problems. You can also use the Cluster Diagnostics and Verification Tool (ClusDiag) to run diagnostic tests. These tests will help you verify the functionality of a cluster and troubleshoot cluster failures using the generated log files. ClusDiag is available in the *Microsoft Windows Server 2003 Resource Kit* and at the Microsoft Download Center at the Microsoft Web site . For information about how to obtain product support, see Technical support options.

This section covers:

- Additional New Server Cluster Wizard information
- Cluster installation problems
- Cluster disk and drive connection problems
- Node-to-node connectivity problems
- Client-to-cluster connectivity problems
- Group and resource failure problems
- File and print server cluster problems
- General administrative problems

# Additional New Server Cluster Wizard information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Additional New Server Cluster Wizard Information**
Problems that occur when you use the New Server Cluster Wizard to create a new server cluster are usually the result of misconfigured cluster networks and hardware or permissions issues with the Cluster service account. You can use the information in this topic to help diagnose and troubleshoot these problems.

This topic contains overviews of clustering technology, additional information on error and event log messages, step-by-step implementation guides, scenarios, top troubleshooting issues, and relevant Knowledge Base (KB) articles from the Microsoft Product Support Services Web site.

**Top Troubleshooting Issues**

- Cluster installation problems
- Cluster disk and drive connection problems
- Node-to-node connectivity problems
- Client-to-cluster connectivity problems
- Group and resource failure problems
- General administrative problems

**Error and Event Log Messages**
To search for additional information on error and event log messages, click **Error and Event Log Messages** in Help and Support Center.

**Top Knowledge Base (KB) articles**
For information about server clusters, see the following key articles in the Microsoft Knowledge Base.

| Problem Area | Key KB Article # | Title |
|---|---|---|
| Understanding virtual servers | Q257932 | Using Microsoft Cluster Server to Create a Virtual Server |
| Event 1034 occurs when replacing a shared SCSI disk | Q280425 | Recovering from an Event ID 1034 on a Server Cluster |
| Network configuration errors | Q259267 | Microsoft Cluster Service Installation Resources |
| Creating clustered home folders | Q256926 | Implementing Home Folders on a Server Cluster |
| Setting up clustered printers | Q197046 | How to Set up a Print Spooler on Microsoft Cluster Server |
| Starting the Cluster service | Q262962 | Cluster Service Does Not Start with Event ID 7000: Not Responding to Control Function |
| Accessing cluster disks | Q275704 | Cluster Disks May Be Incorrectly Accessible from All Nodes |
| Setting up "heartbeat" configurations for private networks | Q258750 | Recommended Private "Heartbeat" Configuration on Cluster Server |
| Setting up Cluster service account permissions | Q269229 | How to Manually recreate the Cluster Service Account |

- For a list of the top server cluster support issues, see the Microsoft Web site
- To find other relevant articles, search the Microsoft Knowledge Base using the keywords *server cluster*.

**Help Topics**

- For a checklist of the steps to follow when creating a new server cluster or adding a node to an existing cluster, see Checklist: Planning and creating a server cluster.
- For an overview of server clusters, see Server clusters overview.
- For an overview of the three complementary Microsoft Windows Clustering technologies (server clusters, Network Load Balancing, and Component Load Balancing), see Windows Clustering.

**Step-by-Step Implementation Guides and Scenarios**

- For a tutorial on Cluster Installation, see the Microsoft Web site.
- For example deployments of Windows Clustering, see "Planning for High Availability" at the Microsoft Windows Resource Kits Web site.

# Cluster installation problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster installation problems**

For help in diagnosing and solving problems with creating a cluster or adding one or more nodes to an existing cluster, see Troubleshooting cluster node installations.

For more information about troubleshooting cluster installation issues, see Knowledge Base article 266274, "How to Troubleshoot Cluster Service Startup Issues" in the Microsoft Knowledge Base.

For information about how to obtain product support, see Technical support options.

# Cluster disk and drive connection problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cluster disk and drive connection problems**
What problem are you having?

- When the physical disks are not powering up or spinning, Cluster service cannot initialize any quorum resources.
- The Cluster service fails to start and generates an Event ID 1034 in the Event log after you replace a failed hard disk, or change drives for the quorum resource.
- Drive on the shared storage bus is not recognized.
- Configuration cannot be accessed through Disk Management.
- SCSI or fibre channel storage devices do not respond.
- Disk groups do not move or stay online pending after move.
- Disks do not come online or Cluster service does not start when a node is turned off.
- Drives do not fail over or come online.
- Mounted drives disappear, do not fail over, or do not come online.
- The cluster quorum disk (containing the quorum resource) becomes disconnected from all nodes in a cluster and you are later unable to add the nodes back to the cluster.

**When the physical disks are not powering up or spinning, Cluster service cannot initialize any quorum resources.**
**Cause:** Cables are not correctly connected, or the physical disks are not configured to spin when they receive power.

**Solution:** After checking that the cables are correctly connected, check that the physical disks are configured to spin when they receive power.

**The Cluster service fails to start and generates an Event ID 1034 in the Event log after you replace a failed hard disk, or change drives for the quorum resource.**
**Cause:** If a hard disk is replaced, or the bus is reenumerated, the Cluster service may not find the expected disk signatures, and consequently may fail to mount the disk.

**Solution:** Write down the expected signature from the Description section of the Event ID 1034 error message. Then follow these steps:

1. Backup the server cluster.
2. Set the Cluster service to start manually on all nodes, and then turn off all but one node.
3. If necessary, partition the new disk and assign a drive letter.
4. Use the confdisk.exe tool (available in the *Microsoft Windows Server 2003 Resource Kit*) to write that signature to the disk.
5. Start the Cluster service and bring the disk online
6. If necessary, restore the cluster configuration information.

7. Turn on each node, one at a time.

For information on replacing disks in a server cluster, see Knowledge Base article Q305793, "How to Replace a Disk with Windows 2000 or Windows Server 2003 family Clusters" in the Microsoft Knowledge Base.

**Drive on the shared storage bus is not recognized.**
**Cause:** Scanning for storage devices is not disabled on each controller on the shared storage bus.

**Solution:** Verify that scanning for storage devices is disabled on each controller on the shared storage bus.

Many times, the second computer you turn on does not recognize the shared storage bus during the BIOS scan if the first computer is running. This situation can manifest itself in a "Device not ready" error being generated by the controller, or in substantial delays during startup.

To correct this, disable the option to scan for devices on the shared controller.

### Note

- This symptom can manifest itself as one of several errors, depending on the attached controller. It is normally accompanied with a one- to two-minute start delay and an error indicating the failure of some device.

**Configuration cannot be accessed through Disk Management.**
Under normal cluster operations, the node that owns a quorum resource locks the drive storing the quorum resource, preventing the other nodes from using the device. If you find that the cluster node that owns a quorum resource cannot access configuration information through Disk Management, the source of the problem and the solution might be one of the following:

**Cause:** A device does not have physical connectivity and power.

**Solution:** Reseat controller cards, reseat cables, and make sure the drive spins up when you start.

**Cause:** You attached the cluster storage device to all nodes and started all the nodes before installing the Cluster service on any node.

**Solution:** After you attach all servers to the cluster drives, you must install the Cluster service on one node before starting all the nodes. Attaching the drive to all the nodes before you have the cluster installed can corrupt the file system on the disk resources on the shared storage bus.

**SCSI or fibre channel storage devices do not respond.**
**Cause:** The SCSI bus is not properly terminated.

**Solution:** Make sure that the SCSI bus is not terminated early and that the SCSI bus is terminated at both ends.

**Cause:** The SCSI or fibre channel cable is longer than the specification allows.

**Solution:** Make sure that the SCSI or fibre channel cable is not longer than the cable specification allows.

**Cause:** The SCSI or fibre channel cable is damaged.

**Solution:** Make sure that the SCSI or fibre channel cable is not damaged. (For example, check for bent pins and loose connectors on the cable and replace it if necessary.)

**Disk groups do not move or stay online pending after move.**
**Cause:** Cables are damaged or not properly installed.

**Solution:** Check for bent pins on cables and make sure that all cables are firmly anchored to the chassis of the server and drive cabinet.

**Disks do not come online or Cluster service does not start when a node is turned off.**
**Cause:** If the quorum log is corrupted, the Cluster service cannot start.

**Solution:** If you suspect the quorum resource is corrupted, see the information on the problem "Quorum log becomes corrupted" in Node-to-node connectivity problems.

**Drives do not fail over or come online.**
**Cause:** The drive is not on a shared storage bus.

**Solution:** If drives on the shared storage bus do not fail over or come online, make sure the disk is on a shared storage bus, not on a nonsystem bus.

**Cause:** If you have more than one local storage bus, some drives in **Shared cluster disks** will not be on a shared storage bus.

**Solution:** If you do not remove these drives from **Shared cluster disks**, the drives do not fail over, even though you can configure them as resources.

**Shared cluster disks** is in the Cluster Application Wizard.

**Mounted drives disappear, do not fail over, or do not come online.**
**Cause:** The clustered mounted drive was not configured correctly.

**Solution:** Look at the Cluster service errors in the Event Log (ClusSvc under the Source column). You need to recreate or reconfigure the clustered mounted drive if the description of any Cluster service error is similar to the following:

Cluster disk resource "*disk resource*": Mount point "*mount drive*" for target volume "*target volume*" is not acceptable for a clustered disk because *reason*. This mount point will not be maintained by the disk resource.

When recreating or reconfiguring the mounted drive(s), follow these guidelines:

- Make sure that you create unique mounted drives so that they do not conflict with existing local drives on any node in the cluster.
- Do not create mounted drives between disks on the cluster storage device (cluster disks) and local disks.
- Do not create a mounted drive from a clustered disk to the cluster disk that contains the quorum resource (the quorum disk). You can, however, create a mounted drive from the quorum disk to a clustered disk.
- Mounted drives from one cluster disk to another must be in the same cluster resource group, and must be dependent on the root disk.

For more information on viewing the Event Log, see View Event Logs.

For more information on creating mounted drives in a server cluster, see Add drives on the shared storage bus.

**The cluster quorum disk (containing the quorum resource) becomes disconnected from all nodes in a cluster and you are later unable to add the nodes back to the cluster.**
See the solution for the identically titled problem in Node-to-node connectivity problems.

For information about how to obtain product support, see Technical support options.

It is important that you correctly configure the storage topology (for example, SCSI, Fibre Channel, Storage Area Networks) and the storage interconnects (for example, multiple paths) used in your server cluster. Before deploying your server cluster, contact your hardware vendors to ensure that your particular cluster storage configuration is supported at the hardware level. For descriptions of supported cluster storage topologies, best practices for deploying and managing cluster storage, and a list of cluster storage-related Knowledge Base articles, see the cluster storage information at the Microsoft Web site.

# Node-to-node connectivity problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Node-to-node connectivity problems**
What problem are you having?

- I cannot complete a cluster on the first node.
- When the resources fail over and the nodes do not detect each other, there is no connectivity between the nodes or with the cluster storage device.
- Quorum resource does not start.
- Quorum resource fails.
- Quorum log becomes corrupted.
- Additional node cannot join the cluster.
- Nodes cannot connect to the cluster drives.
- The cluster quorum disk (containing the quorum resource) becomes disconnected from all nodes in a cluster and you are later unable to add the nodes back to the cluster.

**I cannot complete a cluster on the first node.**
**Cause:** Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition is incorrectly installed.

**Solution:** Make sure that Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition is correctly installed.

**Cause:** Your hardware is not listed in the Cluster category on the Microsoft Windows Catalog.

**Solution:** Make sure that your hardware is listed on the Microsoft Windows Catalog. See the Windows Catalog at Support resources. Search for "Cluster".

If any of the hardware you are using for your cluster is not on this list, consider replacing those components with hardware that is listed.

**Cause:** You have chosen individual components from the Windows Catalog instead of systems.

**Solution:** Do not choose individual *components* of your cluster from the Microsoft Windows Catalog. Microsoft supports only *systems* chosen from this list.

**Cause:** Your primary Internet protocol (IP) address is invalid.

**Solution:** If the node uses DHCP to obtain noncluster IP addresses, use Ipconfig.exe to verify that you have a valid primary IP address for all network adapters. If the second IP address listed (the subnet mask) is 0.0.0.0, your primary address is invalid.

**When the resources fail over and the nodes do not detect each other, there is no connectivity between the nodes or with the cluster storage device.**
**Cause:** The Remote Procedure call (RPC) service is not running.

**Solution:** On each node, use **Services** in Control Panel to confirm that the RPC service is running.

**Cause:** The nodes do not have RPC connectivity.

**Solution:** Verify that the nodes have RPC connectivity.

You can determine this by using a network analyzer (such as Network Monitor), or you can use RPCPing (available on the Microsoft Exchange Server CD)

**Quorum resource does not start.**
**Cause:** The resource is not physically connected to the server.

**Solution:** Make sure that the resource is physically connected to the server.

**Quorum resource fails.**
**Cause:** The disk on the shared bus holding the quorum resource has failed.

**Solution:** If the disk on the shared bus holding the quorum resource fails and cannot be brought online, the Cluster service cannot start. To correct this situation, you must use the **fixquorum** option to start the Cluster service on a single node, and then use Cluster Administrator to configure the Cluster service to use a different disk on the shared bus for the quorum resource.

When **fixquorum** is specified, the Cluster service starts without a quorum resource, and does not bring the quorum disk online. A node cannot join a cluster when the Cluster service is running with the **fixquorum** option.

For instructions on how to change the disk that the Cluster service uses for the quorum resource, see Use a different disk for the quorum resource.

**Quorum log becomes corrupted.**
**Cause:** This may occur for a variety of reasons.

**Solution:** If the quorum log is corrupted, the Cluster service attempts to correct the problem by resetting the log file. In this case, the Cluster service writes the following message in the system log:

The log file [*name*] was found to be corrupt. An attempt will be made to reset it.

If the quorum log cannot be reset, the Cluster service cannot start.

If the Cluster service fails to detect that the quorum log is corrupted, the Cluster service may fail to start. In this case, there may be an "ERROR_CLUSTERLOG_CORRUPT" message in the system log.

To correct this, you must use the **noquorumlogging** option when starting the Cluster service to temporarily run the Cluster service without quorum logging. You can then correct the disk corruption and delete the quorum log, as necessary. When **noquorumlogging** is specified, the Cluster service brings the quorum disk online, but disables quorum logging. You can then run Chkdsk on your quorum disk to detect and correct disk corruption.

For instructions on how to recover from a corrupted quorum log or quorum disk, see Recover from a corrupted quorum log or quorum disk.

**Additional node cannot join the cluster.**
**Cause:** The cluster configuration on the node may not have been completely removed if the node was previously evicted.

**Solution:** At a command prompt, type **cluster** [*cluster name*] **node***node name***/forcecleanup**.

When an additional node fails to join a cluster, improper name resolution is often the cause. The problem may exist because of invalid data in the WINS cache. You may also have the wrong binding on the WINS or DNS Services for the additional node.

If WINS or DNS is functioning correctly on all nodes:

**Cause:** You may not be using the proper cluster name, node name, or IP address.

**Solution:** Confirm that you are using the proper cluster name, node name, or IP address.

When joining a cluster, you can specify the cluster name, the computer name of the first node, or the IP address of either the cluster or the first node.

**Cause:** The Cluster Name resource may not have started.

**Solution:** Confirm that the Cluster Name resource started.

Use Cluster Administrator on the first node to ensure that the Cluster Name resource is running.

**Cause:** The Cluster service may not be running on the first node.

**Solution:** Confirm that the Cluster service is running on the first node and that all resources within the Cluster Group are online before installing a second node.

The Cluster service may not have yet started when you attempted to join the cluster.

**Cause:** Network connectivity may not exist between the nodes.

**Solution:** Confirm that network connectivity exists between the nodes.

Make sure TCP/IP is properly configured on all nodes.

**Cause:** You may not have IP connectivity to the cluster address.

**Solution:** Confirm that you have IP connectivity to the cluster address and that the IP address is assigned to the correct network.

If you cannot ping the IP address of the cluster, run Cluster Administrator on the first node and ensure the cluster IP Address resource is running. Also, use Cluster Administrator to ensure that the cluster has a valid IP address and subnet mask (click **Cluster Group**, right-click **Cluster IP Address**, and click **Properties**), and that the IP address does not conflict with an IP address that is already in use on the network. If the address is not valid, change it, take the Cluster IP Address resource offline, and then bring it online again. If the IP address is not assigned to the correct network, use Cluster Administrator to correct the problem.

If your cluster nodes use DHCP to obtain noncluster IP addresses, use Ipconfig.exe to verify that you have a valid primary IP address for the networks in question. If the second IP address listed (the subnet mask) is 0.0.0.0, your primary address is invalid.

**Cause:** The network role may have changed from **Use for all communication**.

**Solution:**Confirm that the network role has not been changed from **Use for all communication**.

A network role is initialized to **Use for all communications** but can be changed by the administrator. After verifying that you have IP connectivity to the cluster address and that the IP address is assigned to the correct network, use Cluster Administrator to confirm that at least one of the networks connected between the nodes is enabled to **Use for all communications**. To verify the role in Cluster Administrator, open the Networks folder, right-click **Network**, and then click **Properties**. **Use for all communications** enables the network to have both node-to-node communication and client-to-cluster communication.

For more information on networks, see Server cluster networks. For more information on network roles, see Configuring cluster network hardware. To use Cluster Administrator to reset the network's role to **Use for all communications**, see Enable a network for cluster use.

**Nodes cannot connect to the cluster drives.**

**Cause:** The same drive letters may not have been assigned to the cluster drives on all nodes.

**Solution:** Confirm that the cluster drives are assigned the same drive letters on all nodes.

To do so, run Disk Management on each node and make sure that identical drive letters are assigned to all cluster drives.

**Where?**

- Computer Management/Storage/Disk Management

**Cause:** The node may not be physically connected to the cluster drive.

**Solution:** Confirm that the node is physically connected to the cluster drive.

If it is not, shut down all nodes and the cluster drive. Connect the nodes to the shared storage bus. Then, start the cluster drive and start the first node. After the Cluster service starts on the first node, start the additional nodes, and attempt to connect to the cluster drive.

**Cause:** If you are using a shared SCSI bus, the SCSI devices may not have unique IDs.

**Solution:** Verify that each SCSI device has a unique ID. SCSI controller IDs are preset to seven. Reset one SCSI controller ID to six.

**Cause:** The controllers on the shared storage bus may not be correctly configured.

**Solution:** Confirm that the controllers on the shared storage bus are correctly configured (with all cards configured to transfer data at the same rate).

**Cause:** The devices and controllers may not match.

**Solution:** Confirm that your devices and controllers match.

For example, do not use a wide connection controller on one node and a narrow connection controller on another node. It is also recommended that all fibre channel controllers be homogeneous, so do not use different brands of controllers together.

**The cluster quorum disk (containing the quorum resource) becomes disconnected from all nodes in a cluster and you are later unable to add the nodes back to the cluster.**
**Cause:** The cluster configuration on the nodes may not have been completely removed.

**Solution #1:** Use the cluster.exe node /force[cleanup] command to evict the nodes from the cluster. For more information, see Evict a node from the cluster.

**Solution #2:** Use the Cluster service fixquorum start up parameter to start the Cluster service. Only one node at a time can be started with this command. You cannot join any other nodes to the node started using this command. For more information, see Recover from a corrupted quorum log or quorum disk.

For information about how to obtain product support, see Technical support options.

# Client-to-cluster connectivity problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Client-to-cluster connectivity problems**
What problem are you having?

- Clients cannot connect to virtual servers.
- Clients cannot access resources.
- A node cannot communicate on a network.
- Clients cannot access a group that has failed over.
- Clients cannot attach to a cluster file share resource.
- Clients cannot access a cluster resource.
- Client can detect all nodes but cannot detect a virtual server.
- Clients cannot connect to a virtual server and the system event logs on the client computers contain Kerberos authentication errors.

**Clients cannot connect to virtual servers.**
**Cause:** The client might not be using the correct network name or IP address to access the cluster.

**Solution:** Make sure that the client is accessing the cluster using the correct network name or IP address.

**Cause:** The client might not have the TCP/IP protocol correctly installed and configured.

**Solution:** Make sure that the client has the TCP/IP protocol correctly installed and configured.

Depending on the application being accessed, the client can address the cluster by specifying either the resource network name or the IP address. In the case of the network name, you can verify proper name resolution by checking the NetBT cache (using the Nbtstat.exe utility) to determine whether the name had been previously resolved. Also, confirm proper WINS configuration, both at the client and through the WINS Administrator.

If the client is accessing the resource through a specific IP address, ping the IP address of the cluster resource and cluster nodes from a command prompt.

For more information on Nbtstat.exe, see Nbtstat.

For instructions on how to troubleshoot connectivity problems, see Troubleshoot client-to-virtual server connectivity.

**Cause:** The client may be attempting to connect to an incorrect node after a failover.

**Solution:** Make sure that the routers are configured correctly. For more information, see article Q244331, "MAC Address Changes for Virtual Server During a Failover with Clustering" in the Microsoft Knowledge Base.

**Clients cannot access resources.**
**Cause:** Both your private network and the primary network are down.

**Solution:** If your server cluster nodes are multihomed and use a private network to communicate, the primary network can be down and the Cluster service can still function normally.

If the private network is lost between nodes, resources that are configured to do so will fail over to the node that has ownership of the quorum resource. Each of the other nodes will stop its Cluster service.

**Cause:** A node might have lost connectivity with the network.

**Solution:** If you suspect a node has lost connectivity with the network:

- Confirm that the connection configuration settings are correct for each connection. To do this, open **Control Panel**, then double-click **Network Connections**. Right-click a connection and click **Properties**.
- Check WINS or DNS to make sure that they are properly configured.
- Confirm that the static IP addresses being used by the Cluster service are still in place and are not being used by other resources on the network.

**A node cannot communicate on a network.**
**Cause:** If a node cannot communicate on a network, it might lack a physical connection to the other nodes, or the other nodes might not be connected to one another.

If the cabling has failed, the Cluster service might not have received the heartbeat of the node and so failed the resources owned by that node over to other nodes in the cluster. The node can no longer communicate to clients on a network.

**Solution:** Check the hub and local cabling, both to the network and to the cluster disks.

**Clients cannot access a group that has failed over.**
**Cause:** There might not be a physical connection between the cluster nodes and the group that failed over has also failed to come online.

**Solution -- step 1:** Confirm that you have a physical connection between the cluster nodes.

- Make sure that the network cabling has not failed or been damaged.

  If the cabling has failed, the Cluster service might have failed over the resources to another node.
- Ensure that the storage device cabling has not failed.
- If the nodes are separated by one or more hubs, check the connectivity through all hubs.

**Solution -- step 2:** Bring the group back online.

**Clients cannot attach to a cluster file share resource.**
**Cause:** WINS or DNS might not be correctly configured.

**Solution:** Make sure that WINS or DNS are correctly configured.

If you are using WINS, run WINS Manager on the WINS server; then, on the **Mappings** menu, click **Show Database**. Make sure that each node and the cluster are registered in the WINS database and that the registrations are active.

For more information on WINS and WINS Manager, see the *Networking Guide* in the *Microsoft Windows Server 2003 Resource Kit*.

**Cause:** Your security policies might not allow the client to access the file share.

**Solution:** Make sure that your security policies allow the client to access the file share.

The client must have the right to log on to the file share, or the Guest account must be enabled for the client to have access.

**Clients cannot access a cluster resource.**
**Cause:** Either the IP Address resource or Network Name resource for the group in which the resource is contained is not online.

**Solution:** Check the group dependencies; the resource is supposed to be dependent on either the IP Address or the Network Name resource. Ensure that the IP Address and Network Name resources are online in the resource group. From the client computer, try to ping the IP addresses of the virtual server and individual nodes.

**Cause:** Either the client or the cluster computer is not configured for either WINS or DNS.

**Solution:** Make sure that the cluster nodes are configured properly for name resolution using either WINS or DNS, and make sure that clients are configured to use the same form of name resolution.

**Cause:** The client is attempting to access the cluster from a different subnet, and DNS is not correctly configured.

**Solution:** Configure the cluster nodes and client computer to use WINS or DNS. If you use DNS, add a DNS address record for the cluster in the DNS database.

**Client can detect all nodes but cannot detect a virtual server.**
**Cause:** The virtual server might not have its own IP Address and Network Name resources.

**Solution:** Make sure that the virtual server has its own IP Address and Network Name resources, and that both resources are online.

Your servers must have an address and a name on the network for any other server or client to properly recognize that the servers are on the network.

**Cause:** One or more nodes are not correctly configured to use WINS or DNS.

**Solution:** Make sure that all nodes are correctly configured to use WINS or DNS.

**Clients cannot connect to a virtual server and the system event logs on the client computers contain Kerberos authentication errors.**
**Cause:** The cluster might have used a previously-created computer object for the virtual server. When the virtual server's Network Name resource is brought online for the first time after Kerberos support has been enabled, the cluster changes the object's password. Active Directory then replicates this change to all domain controllers in the cluster. However, because of replication latencies, clients connecting to this virtual server might receive a Kerberos ticket encrypted with the old password. This can result in Kerberos authentication errors.

**Solution:** Wait until the new password has been replicated to all domain controllers, or force replication using the **repadmin** and **replmon** command-line tools, available in the \Support\Tools folder on your operating system installation CD.

For information on monitoring and troubleshooting replication issues, see Troubleshooting replication.

For information about how to obtain product support, see Technical support options.

# Group and resource failure problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Group and resource failure problems**
What problem are you having?

- A resource fails, but is not brought back online.
- You cannot bring a resource online.
- You cannot bring the default physical disk resource online in Cluster Administrator.
- In Disk Management, you do not see the disk for the group that is online on that node.
- You are unable to manually move a group, or it does not fail over to another node when it is supposed to.
- A group failed over but did not fail back.
- The entire group failed and has not restarted.
- All nodes are functioning, but resources fail back repeatedly.
- The Cluster service does not successfully fail over resources.
- You fail over a resource group from one node to another, but it automatically fails back.
- The Network Name resource fails when you change to a system locale that is different than the input language used by the Network Name resource.
- The Message Queuing resource fails to handle message activity correctly which may result in resource failures.
- A third-party resource fails to come online in a mixed-version cluster or while upgrading a cluster.

**A resource fails, but is not brought back online.**
**Cause:** A resource may depend on another resource that has failed.

**Solution:** In the resource **Properties** dialog box, make sure that the **Do not restart** check box is clear. If the resource needs another resource to function, and if the second resource fails, confirm that the dependencies are correctly configured.

**You cannot bring a resource online.**
**Cause:** The resource is not properly installed.

**Solution:** Make sure the application or service associated with the resource is properly installed.

**Cause:** The resource is not properly configured.

**Solution:** Make sure the properties are set correctly for the resource.

**Cause:** The resource is not compatible with server clusters.

**Solution:** Not all applications can be configured to fail over in a cluster. For more information, see Choosing applications to run on a server cluster.

**Cause:** The resource is generating a specific error.

**Solution:** Review the system Event Log (look for ClusSvc entries under the Source column) to see if that resource is generating a specific error message.

**You cannot bring the default physical disk resource online in Cluster Administrator.**
Most cluster configuration problems result from improper configuration of the shared storage bus or the restart of servers.

**Cause:** You may not have restarted the servers after installing the Cluster service.

**Solution:** Make sure that you restarted all servers after installing the Cluster service.

When the servers are restarted, the signature of each disk in the cluster storage is read, and the registries are updated with the signature information.

**Cause:** There may be hardware errors or transport problems.

**Solution:** Make sure that there are no hardware errors or transport problems.

Using Event Viewer (on the **Start** menu, under **Programs** and **Administrative Tools (Common)**), look in the event log for disk I/O error messages or indications of problems with the communications transport.

**Cause:** You may not have waited long enough for the registries to be updated.

**Solution:** Make sure that you waited long enough for the registries to be updated.

Cluster Administrator takes a backup of the registry when it starts up. However, it can take up to a minute after the second server restarts for the disk signatures to be written to the registries. Wait a minute, and then click **Refresh**.

**Cause:** One or more adapters on the shared storage bus are configured incorrectly.

**Solution:** Make sure that the adapters are configured correctly.

**Cause:** The shared storage bus exceeds the maximum cable length.

**Solution:** Make sure that the shared storage bus does not exceed the maximum cable length.

**Cause:** The disk is not supported.

**Solution:** Make sure that the disk hardware or firmware revision level is not outdated.

**Cause:** The bus adapter is not supported, or the adapter hardware or firmware revision level is outdated.

**Solution:** Make sure that the bus adapter is supported, and that the adapter hardware or firmware revision level is current.

**Cause:** If you move your storage bus adapter to another I/O slot, add or remove bus adapters, or install a new version of the bus adapter driver, the cluster software may not be able to access disks on your shared storage bus

**Solution:** To accommodate these changes, make sure that your shared storage bus adapter has been properly reconfigured.

**Cause:** The operating system is incorrectly configured to access the shared storage bus.

**Solution:** Verify that the operating system can detect the shared storage bus adapter.

**In Disk Management, you do not see the disk for the group that is online on that node.**
**Where?**

- Computer Management/Storage/Disk Management

**Cause:** You may not be looking at the right disks.

**Solution:** Make sure that you are looking at the right disks.

If you have not labeled your disks or assigned fixed drive letters to them, you may not recognize which disks are part of the cluster and which ones are not. Label your disks in a meaningful manner and assign fixed drive letters to all partitions.

**Cause:** There may have been hardware problems.

**Solution:** Make sure that there have not been any hardware problems.

Run Event Viewer and check for disk I/O error messages or indications of hardware problems.

**You are unable to manually move a group, or it does not fail over to another node when it is supposed to.**
**Cause:** The fail over node may not be designated as a possible owner for all resources in the group that you want to fail over.

**Solution:** Make sure that the fail over node is designated as a possible owner for all resources in the group you want to fail over.

Check the ownership configuration in the group resource **Properties** dialog box. If the node is not set as a possible owner for all resources in the group, the node cannot own the group, so failover will not occur. To fix this, make the node a possible owner for all resources in the group.

**Cause:** A resource in the group may be continually failing.

**Solution:** Determine if a resource in the group is continually failing.

If the node can, it will bring the resource back up without failing over the group. If the resource continually fails but does not fail over, make sure that the resource property **Restart and affect the group** is selected. Also, check the **Restart Threshold** and **Restart Period** settings, which are also in the resource **Properties** dialog box.

**A group failed over but did not fail back.**
**Cause:** The group will only fail back if the node the group was running on itself failed and then rejoined the cluster. If the group, but not the node, failed, then the group will fail over to another node, but will not fail back to the original node.

**Cause:** The failback policies of both the group and the resources may not be properly configured.

**Solution:** Make sure that the **Prevent failback** check box is clear in the group **Properties** dialog box. If the **Allow failback** check box is selected, be sure to wait long enough for the group to fail back. Check these settings for all affected resources within a group. Because groups fail over as a whole, one resource that is prevented from failing back affects the entire group.

**Cause:** The node to which you want the group to fail back is not configured as the preferred owner of the group.

**Solution:** Make sure that the node to which you want the group to fail back is configured as the preferred owner of the group. If not, the Cluster service leaves the group on the node to which they failed over.

**The entire group failed and has not restarted.**
**Cause:** A node is offline.

**Solution:** Make sure that the node is not offline.

If the node on which the group had been running is offline, check that another node is a possible owner of the group and of every resource in the group.

**Cause:** The group has failed repeatedly.

**Solution:** The group may have exceeded its failover threshold or its failover period. Try to bring the resources online individually (following the correct sequence of dependencies) to determine which resource is causing the problem. Or, create a temporary resource group (for testing purposes) and move the resources to it, one at a time.

**All nodes are functioning, but resources fail back repeatedly.**
**Cause:** Power may be intermittent or failing.

**Solution:** Ensure that your power is not intermittent or failing. You can correct this by using an uninterruptable power supply (UPS) or, if possible, by changing power companies.

**The Cluster service does not successfully fail over resources.**
**Cause:** Cluster storage device is not properly configured.

**Solution:** Verify that the cluster storage device is properly configured and that all cables are properly connected.

**You fail over a resource group from one node to another, but it automatically fails back.**
**Cause:** One or more resources fail to come online on the new node.

**Solution:** Use a process of elimination to determine which resource is failing to come online. For more information, see article Q303431, "Explanation of Why Server Clusters Do Not Verify that Resources will Work Properly on All Nodes" in the Microsoft Knowledge Base.

**The Network Name resource fails when you change to a system locale that is different than the input language used by the Network Name resource.**
**Cause:** The system locale must be the same on all nodes of a cluster and on the computer used to connect to the cluster.

**Solution:** Change the system locale. For more information, see Connect to a cluster with Cluster Administrator.

**The Message Queuing resource fails to handle message activity correctly which may result in resource failures.**

**Cause:** Each instance of Message Queuing on a server maps 4 MB of the system view space when handling message activity. This results in a default limit of three active, working instances of Message Queuing on a cluster node. In a server cluster with three Message Queuing resources, a node could have four concurrent Message Queuing services running (the service running on the local node plus the three services associated with the Message Queuing resources.) In this scenario, message activity could be limited, resulting in resource failures.

**Solution:** Increase the system view space memory pool on each node of a server cluster with three or more Message Queuing resources. (We also recommend that you increase the system view space memory pool even for nodes running fewer than three Message Queuing resources.)

- Open Registry Editor.
- Open the registry key **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management**.
- Create a new DWORD value called **SystemViewSize**.
- Calculate and enter the data for this DWORD value using the following formula: (16 + (the number of Message Queuing resources x 4)).

  For example, the calculation result for a cluster with three Message Queuing resources is 28.
- Reboot each node.

**A third-party resource fails to come online in a mixed-version cluster or while upgrading a cluster.**
**Cause:** If a resource uses a cryptographic provider not supplied by Microsoft to export (encrypt) and import (decrypt) resource data (cluster and cluster application cryptographic checkpoints), the default encryption key lengths may be different in the Windows 2000 and the Windows Server 2003 family operating systems. The result is that the resource might fail to come online and the cluster and event logs might contain cryptographic checkpoint synchronization errors for that resource.

**Solution:** Use the cluster.exe "CSP" private property to set the key length and effective key length for the third-party cryptographic provider that encrypts and decrypts data for the failing resource type.

- Open Command Prompt.
- Type **cluster***ClusterName***"***CSP***"**=*key_length,effective_key_length***:MULTISTR**

  *ClusterName* is the name of the cluster, *CSP* is the name of the cryptographic provider, and *key_length* and *effective_key_length* are the key and effective key lengths for the RC2 encryption algorithm, in bits. For more information on using cluster.exe, see Cluster.
- Depending on the resource, either bring the resource online or recreate the resource to add the new cryptographic checkpoint.

**Note**

- Review the documentation for your cryptographic provider to obtain valid values for the following RC2 encryption algorithm parameters: *key_length* and *effective_key_length*. Also review the cryptographic provider documentation for the correct procedure for adding the cryptographic checkpoint.

For information about how to obtain product support, see Technical support options.

# File and print server cluster problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**File and print server cluster problems**
What problem are you having?

- Clients cannot attach to a cluster file share resource.
- Clients cannot attach to a cluster printer share resource.
- After a resource failure, the clustered print server does not come back online.

**Clients cannot attach to a cluster file share resource.**
**Cause:** WINS or DNS might not be correctly configured.

**Solution:** Make sure that WINS or DNS are correctly configured.

If you are using WINS, run WINS Manager on the WINS server; then, on the **Mappings** menu, click **Show Database**. Make sure that each node and the cluster are registered in the WINS database and that the registrations are active.

For more information on WINS and WINS Manager, see the *Networking Guide* in the *Microsoft Windows Server 2003 Resource Kit*.

**Cause:** Your security policies might not allow the client to access the file share.

**Solution:** Make sure that your security policies allow the client to access the file share.

The client must have the right to log on to the file share, or the Guest account must be enabled for the client to have access.

**Clients cannot attach to a cluster printer share resource.**
**Cause:** Not all printer ports may be used in a server cluster.

**Solution:** Use cluster-aware ports, for example LPR or Standard TCP/IP ports.

The LPR and Standard TCP/IP Port, both provided with Windows Server 2003 family operating systems, can be used in a server cluster. Check your printer documentation to verify that your printer can use one of these two ports.

For more information, see Create a cluster-managed printer.

**After a resource failure, the clustered print server does not come back online.**
**Cause:** The share name for the printer may also used by another printer in the cluster.

**Solution:** Choose a unique share name for the printer.

We recommend that you do not use the same share name for different printers, even if they are in a different resource group and associated with a different Print Spooler resource. In the event of a failure, the same node in the cluster may own both resource groups. If this occurs, printers that share a common name will not be available.

For information about how to obtain product support, see Technical support options.

# General administrative problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**General administrative problems**
**What problem are you having?**

The Cluster service fails and the node cannot detect the network.

An IP address added to a group in the cluster fails.

An IP address resource is unresponsive when taken offline, for example you are unable to query its properties.

You receive the error: "RPC server is unavailable."

Cluster Administrator cannot open a connection to a node.

An application starts but cannot be closed.

A resource group has failed over but will not fail back.

All nodes appear to be functioning correctly, but you cannot access all of the drives from one node.

Cluster Administrator update delays.

Cluster Administrator stops responding when a node fails.

Cannot connect to cluster from recent file list.

Node performance is sluggish and node fails.

The cluster log contains numerous resource informational messages (for example, Entered LooksAlive, Entered Open, Entered Offline).

The Cluster service fails to start and returns an error code of ERROR_SHARING_VIOLATION (32) with event ID 1144 (NM_EVENT_REGISTER_NETWORK_FAILED).

You cannot manually restore the cluster database on a local node by copying the systemroot\cluster\CLUSDB file from another node.

**The Cluster service fails and the node cannot detect the network.**

In this case, you probably have a configuration problem. Check the following:

- **Cause:** Have you made any configuration changes recently?

  **Solution:** If the node was recently configured, or if you have installed some resource that required you to restart the computer, make sure that the node is still properly configured for the network.

- **Cause:** Is the node properly configured?

  **Solution:** Check that the server is properly configured for TCP/IP. Also check that the appropriate services are running. If the node recently failed, there is an instance of failover; but, if the other nodes are misconfigured as well, the failover will be inadequate and client access will fail.

**An IP address added to a group in the cluster fails.**

- **Cause:** The Internet protocol (IP) address is not unique.

  **Solution:** The IP address must be different from every other group IP address and every other IP address on the network.

- **Cause:** The IP address is not a static IP address.

**Solution:** The IP addresses must be statically assigned outside of a DHCP scope, or they must be reserved by the network administrator.

**An IP address resource is unresponsive when taken offline, for example you are unable to query its properties.**

- **Cause:** You may not have waited long enough for the resource to go offline.

  **Solution:** If an IP Address resource is unresponsive when taken offline, make sure that you wait long enough for the resource to go offline.

  Certain resources take time to go offline. For example, it can take up to three minutes for the IP Address resource to go fully offline.

**You receive the error: "RPC server is unavailable."**

- **Cause:** The server may not be operational, or the Cluster service and the RPC services may not be running.

  **Solution:** If you receive the error "RPC Server is unavailable," make sure the server is operational and that both the Cluster service and the RPC services are running. Also, check the name resolution of the cluster; it is possible that you are using the wrong name or that the name is not being properly resolved by WINS or DNS.

**Cluster Administrator cannot open a connection to a node.**

- **Cause:** The node may not be running.

  **Solution:** If Cluster Administrator cannot open a connection to a node, make sure that the node is running. If it is, confirm that both the Cluster service and the RPC services are running.

**An application starts but cannot be closed.**

- **Cause:** You may not have taken a resource offline using Cluster Administrator.

  **Solution:** When you bring resources online using Cluster Administrator, you must also take those resources offline using Cluster Administrator; do not attempt to close or exit the application from the application interface.

**A resource group has failed over but will not fail back.**

- **Cause:** The hardware and network configurations may not be valid.

  **Solution:** Make sure that the hardware and network configurations are valid.

  If any interconnect fails, failover can occur because the Cluster service does not detect a heartbeat, or it may not even register that the node was ever online. In this case, the Cluster service fails over the resources to the other nodes in the server cluster, but it cannot fail back because that node is still down.

- **Cause:** The resource group may not have been configured to fail back immediately, or you are not troubleshooting the problem within the allowable failback hours for the resource.

  **Solution:** Make sure that the resource group is configured to fail back immediately, or that you are troubleshooting the problem within the allowable failback hours for the resource group.

  A group can be configured to fail back only during specified hours. Often, administrators prevent failback during peak business hours. To check this, use Cluster Administrator to view the resource failback policy.

- **Cause:** You restarted the node to test the failover policy for the group instead of pressing the reset button.

**Solution:** Make sure that you press the reset button on the node. The resource group will not failback to the preferred node if you shutdown, then restart the node. For more information on testing failback policies, see Test node failure.

**All nodes appear to be functioning correctly, but you cannot access all of the drives from one node.**

- **Cause:** The shared drive may not be functioning.

  **Solution:** Confirm that the shared drive is still functioning.

  Try to access the drive from another node. If you can do that, check the cable from the device to the node that you cannot perform the access. If the cable is not the problem, restart the computer and then try again to access the device. If you cannot access the drive, check your configuration.

- **Cause:** The drive has completely failed.

  **Solution:** Determine (from another node) whether the drive is functioning at all. You may have to restart the drive (by restarting the computer) or replace the drive.

  The hard disk with the resource or a dependency for the resource may have failed. You may have to replace a hard disk. You may also have to reinstall the cluster.

**Cluster Administrator update delays.**

- **Cause:** If you run Cluster Administrator from a remote computer, it may not display the correct (updated) cluster state when the cluster network name fails over from one node to another node. This can result in Cluster Administrator displaying a node as being online, when it is actually offline.

  **Solution:** To work around this problem, restart Cluster Administrator.

  You can avoid this problem by connecting to clusters through node names. However, if the node you are connected to fails, Cluster Administrator stops responding until the RPC connection times out.

**Cluster Administrator stops responding when a node fails.**

- **Cause:** The Cluster Administrator may be slow in doing dynamic updates.

  **Solution:** If Cluster Administrator stops responding when a node fails, make sure that Cluster Administrator is not just slow in doing dynamic updates. If the Cluster service is running on a remaining node, Cluster Administrator is either not responding or is updating very slowly. There are two ways to see if the Cluster service is running on a remaining node:

- Use the TCP/IP Ping utility to ping the cluster name on a remaining node.

- In **Control Panel**, double-click **Services**, and check whether the Cluster service is running.

**Cannot connect to cluster from recent file list.**

- **Cause:** Files listed in the Cluster Administrator recent file list (both on the **File** menu and in the **Open Connection to Cluster** dialog box) have the cluster name appended to the path. For example, instead of Webclust1, the recent file list may list C:\Windows\Cluster\Webclust1. This problem occurs when Microsoft Visual C++ version 5.0 is installed.

  **Solution:** To work around this problem, manually type the cluster name when you open the connection.

**Node performance is sluggish and node fails.**

- **Cause:** CPU may be overloaded.

  **Solution:** Check that your node is not processor-bound. That is, that the CPU is not running at 100-percent utilization. If

you try to run too many resources for the node capacity, you can overload the CPU.

Also, review the size of your paging file. If the paging file is too small, the Cluster service can detect this as a node failure and fail over the groups.

**The cluster log contains numerous resource informational messages (for example, Entered LooksAlive, Entered Open, Entered Offline).**

- **Cause:** One or more of your Generic Script resources fills the cluster log with multiple copies of Entered LooksAlive, Entered Open, Entered Offline messages.

  **Solution:** When creating a script for a Generic Script resource, do not use the LogInformation method when calling the LooksAlive function. For more information, see the Microsoft Platform Software Development Kit (SDK).

**The Cluster service fails to start and returns an error code of ERROR_SHARING_VIOLATION (32) with event ID 1144 (NM_EVENT_REGISTER_NETWORK_FAILED).**

- **Cause:** The Internet Assigned Numbers Authority (IANA)-assigned port (3343) used by the cluster network driver (ClusNet) is bound to another process, preventing the Cluster service from starting.

  **Solution:** Use port scanning and process termination utilities to identify and end the process that is bound to port 3343.

To do this:

1. Open Command Prompt.

2. Navigate to the %systemroot%\system32 directory.

3. Type **netstat -a -o**.

   This will display all listening and connected ports and the process ID of each process bound to that port. Port 3343 will appear for each cluster network on the node.

   **Notes**

   - The **-a** option indicates that all connections and listening ports are supposed to be displayed. Server clusters uses UDP so the ports are normally in listening mode rather than in connections.

   - The **-o** option indicates that the owning process ID is supposed to be displayed.

4. Type **tasklist**.

   This will display the IDs for all the processes running on the node, including the process ID that matches the Cluster service (ClusSvc.exe).

5. Type **taskkill /pid** ID to terminate the process(es) bound to port 3343 that do not match the ID for the Cluster service.

**You cannot manually restore the cluster database on a local node by copying the systemroot\cluster\CLUSDB file from another node.**

- **Cause:** If the cluster registry hive is already locked and loaded by the Cluster service, the operating system will prevent you from copying a local CLUSDB file or overwriting an existing CLUSDB file on another node.

  **Solution:** Stop the Cluster service. Then unload the **HKEY_LOCAL_MACHINE\Cluster** hive before restoring the cluster database file.

To do this:

1. Open **Command Prompt**.

2. Type **net stop clussvc** to stop the Cluster service.

3. Use the Registry Editor to unload the hive under **HKEY_LOCAL_MACHINE\Cluster**. For more information, see Unload a hive from the registry.

   The operating system will now allow you to copy the CLUSDB file from a node and manually restore it to another node.

   For information about how to obtain product support, see Technical support options.

# Enterprise Memory Architecture

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Enterprise Memory Architecture**
Enterprise Memory Architecture (EMA) increases the amount of physical memory available to applications. EMA supports two types of memory enhancement: application memory tuning--also known as 4-gigabyte tuning (4GT)--and Physical Address Extension (PAE) X86. Neither is enabled by default. Both application memory tuning and PAE must be manually enabled by editing the Boot.ini file.

- Before enabling application memory tuning, see Checklist: Enabling application memory tuning.
- Before enabling PAE, see Checklist: Enabling Physical Address Extension (PAE).
- For help with specific tasks, see Enterprise Memory Architecture How To....
- For general background information, see Enterprise Memory Architecture Concepts.
- For problem-solving instructions, see Enterprise Memory Architecture Troubleshooting.

### Notes

- This feature is not required on Microsoft® Windows® XP 64-bit Edition (Itanium) or the 64-bit versions of the Microsoft® Windows Server 2003 family.
- This topic does not apply to Windows Server 2003, Web Edition.

# Checklist: Enabling application memory tuning

Updated: January 21, 2005

# Enterprise Memory Architecture How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

- Enable application memory tuning
- Enable Physical Address Extension (PAE)
- Configure the memory dump settings for PAE

**Notes**

- This feature is not needed on Windows XP 64-bit Edition (Itanium) and the 64-bit versions of the Windows Server 2003 family.
- This topic does not apply to Windows Server 2003, Web Edition.

# Enable application memory tuning

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To enable application memory tuning

1. Open Windows Explorer.
2. On the **Tools** menu, click **Folder Options**.
3. On the **View** tab, click **Show hidden files and folders**, clear the **Hide protected operating system files** check box, and then click **OK**. If you are presented with a warning dialog box, click **Yes** to continue.
4. In the root folder (for example, C:), locate the Boot.ini file and remove its read-only attribute.
5. Open the Boot.ini file, and then add the **3GB** parameter to the ARC path, as shown in the following example for Windows Server 2003, Datacenter Edition:

   ```
   multi(0)disk(0)rdisk(0)partition(2)\%systemroot%="Windows Server 2003, Datacenter Edition" /3GB
   ```

6. On the **File** menu, click **Save**.
7. Restore the read-only attribute to the Boot.ini file.
8. For the change to take effect, restart the computer.

### Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Windows Explorer, click **Start**, point to **All programs**, point to **Accessories**, and then click **Windows Explorer**.
- This topic does not apply to Windows Server 2003, Web Edition.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable Physical Address Extension (PAE)

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Physical Address Extension (PAE) X86**

1. Open Windows Explorer.
2. On the **Tools** menu, click **Folder Options**.
3. On the **View** tab, click **Show hidden files and folders**, clear the **Hide protected operating system files** check box, and then click **OK**. If you are presented with a warning dialog box, click **Yes** to continue.
4. In the root folder (for example, C:), locate the Boot.ini file and remove its read-only attribute.
5. Open the Boot.ini file, and then add the **/PAE** parameter to the ARC path, as shown in the following example for Windows Server 2003, Datacenter Edition:

   ```
   multi(0)disk(0)rdisk(0)partition(2)\%systemroot%="Windows Server 2003, Datacenter Edition" /PAE
   ```

6. On the **File** menu, click **Save**.
7. Restore the read-only attribute to the Boot.ini file.
8. For the change to take effect, restart the computer.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open Windows Explorer, click **Start**, point to **All programs**, point to **Accessories**, and then click **Windows Explorer**.
- This topic does not apply to Windows Server 2003, Web Edition.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure the memory dump settings for PAE

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the memory dump settings for PAE**

1. Open System Properties.
2. On the **Advanced** tab, click **Settings** in the **Startup and Recovery** box.
3. Under **Write debugging information**, select **Kernel memory dump**.
4. Under **Dump File**, you can accept the default, **%systemroot%\MEMORY.DMP**, or type the path and name of a memory dump file of your own choosing.

## Notes

- To perform this procedure, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure. As a security best practice, consider using Run as to perform this procedure.
- To open System properties, click **Start**, click **Control Panel**, and then double-click **System**.
- This topic does not apply to Windows Server 2003, Web Edition.
- The drive specified in step 4 needs to have at least 2,060 megabytes (MB) of free disk space if your system contains 4 gigabytes (GB) or more of physical memory and you specify **Kernel memory dump** under **Write debugging information**.
- Make sure the paging file size is at least 2,060 MB if your system contains 4 GB or more of physical memory and you specify **Kernel memory dump** under **Write debugging information**. For instructions on changing your paging file size, see Related Topics.
- For more information about memory dump file creation, see "Resources" in Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Physical Address Extension (PAE) and application memory tuning

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Physical Address Extension (PAE) X86 and application memory tuning**
Physical Address Extension (PAE) X86 and application memory tuning, also known as 4-gigabyte tuning (4GT), are complementary technologies for computers that use Intel processors.

Application memory tuning provides more of the computer's virtual memory to applications by providing less virtual memory to the operating system. PAE X86 allows software using the Address Windowing Extensions (AWE) API set running on a computer with an Intel Pentium Pro processor or later and either Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition, to map more physical memory into the application's virtual address space.

For example, if you have a computer with a Pentium Pro processor or later and 16 gigabytes (GB) of physical memory (the maximum amount supported by application memory tuning), you can use application memory tuning to allocate 3 GB of virtual memory to applications (leaving 1 GB for the operating system). A given application can then lock the physical memory. Using the AWE API set and the PAE X86 kernel, the remaining 12 GB of physical memory is available to the application for caching purposes. Consequently, the application can access up to 15 GB of physical memory.

For more information, see:

- Application memory tuning
- Physical Address Extension (PAE) overview

**Important**

- On computers with more than 16 GB of physical memory using application memory tuning, physical memory above the 16 GB address is ignored by the operating system. For more information, see Enable application memory tuning.

**Note**

- This topic does not apply to Windows Server 2003, Web Edition.

# Application memory tuning

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Application memory tuning**
With application memory tuning, also known as 4-gigabyte tuning (4GT), memory-intensive applications running on Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition, can use up to 50 percent more virtual memory. This capability is intended for applications that run on powerful computers with 2 to 4 gigabytes (GB) of physical RAM and that can take advantage of a larger virtual address space. The application must also be configured to use application memory tuning.

Application memory tuning makes more of the computer's virtual memory available to applications by making less virtual memory available to the operating system. Applications can use this feature to address 3 GB of virtual memory instead of the 2 GB normally allocated to each application process.

For more information, see Enabling application memory tuning support in your applications.

**Note**

- This topic does not apply to Windows Server 2003, Web Edition.

# Physical Address Extension (PAE) overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Physical Address Extension (PAE) X86 overview**

Physical Address Extension (PAE) X86 allows software using the Address Windowing Extensions (AWE) API set and running on a computer with an Intel Pentium Pro processor or later, and more than 4 gigabytes (GB) of physical memory to map more physical memory into the application's virtual address space.

Applications not using the AWE API set can also benefit from PAE X86 because the operating system uses the larger physical memory to reduce paging and thus increase performance. This can also benefit consolidation servers hosting multiple applications.

Applications that manipulate large amounts of data achieve better performance by keeping data in memory instead of on disk. For example, PAE X86 can significantly improve the performance of the following types of applications:

- Databases, such as Microsoft SQL/E 7.0 or later.
- Scientific and engineering applications, such as computational fluid dynamics.
- Statistical analysis applications that do extensive data mining.

**Updates to PAE X86**

The following updates have been made to support the addition of Data Execution Prevention (DEP), which is also known as no-execute page protection:

- PAE is automatically enabled on computers running Windows Server 2003 with Service Pack 1 (SP1) and Windows XP with Service Pack 2 (SP2) when DEP is enabled on a computer with a processor that supports the no-execute page protection feature.
- When PAE mode is enabled on Windows Server 2003, Standard Edition with SP1 and Windows XP with SP2, physical address space is limited to 4 GB. Limiting physical address space to 4 GB helps prevent driver compatibility issues with PAE mode.

Only specific hardware will support PAE X86, therefore, this feature is not enabled upon initial installation of the operating system. For more information on what hardware supports PAE X86, refer to the hardware compatibility information for products in the Windows Server 2003 family, which you can find by clicking the appropriate link in Support resources. For more information about how to enable PAE X86, see Enable Physical Address Extension (PAE).

**Note**

- This topic does not apply to Windows Server 2003, Web Edition.

# Using Enterprise Memory Architecture

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Enterprise Memory Architecture**
This section covers:

- Enterprise Memory Architecture hardware and software requirements
- Enabling application memory tuning support in your applications
- Changing the default paging file size on large-memory computers

**Note**

- This topic does not apply to Windows Server 2003, Web Edition.

# Enterprise Memory Architecture hardware and software requirements

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Enterprise Memory Architecture hardware and software requirements**

The table below shows the hardware and software requirements for the two types of memory enhancement that EMA supports: application memory tuning and Physical Address Extension (PAE) X86.

| Technology | Hardware and software requirements |
|---|---|
| Application memory tuning, also known as 4-gigabyte tuning (4GT) | • X86-based processor<br>• 2 gigabytes (GB) or more of random access memory (RAM) |
| Physical Address Extension (PAE) X86 | • Pentium Pro processor or later<br>• More than 4 GB of RAM<br>• 450 NX or compatible chip set and support, or later<br>• The Hardware Abstraction Layer (HAL) must support PAE mode and the proper access to RAM.<br>• Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition |

Contact your hardware vendor for additional information.

**Note**

- This topic does not apply to Windows Server 2003, Web Edition.

# Enabling application memory tuning support in your applications

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Enabling application memory tuning support in your applications**
The changes to support application memory tuning, also known as 4-gigabyte tuning (4GT), are done at both the system and application levels. For background information, see Application memory tuning.

**System changes**
After you have installed Windows Server 2003, Datacenter Edition, you must modify the Boot.ini file to enable application memory tuning. To do this, add the **/3GB** parameter to the ARC path, as shown in the following example for Windows Server 2003, Datacenter Edition:

```
multi(0)disk(0)rdisk(0)partition(2)\%systemroot%="Windows Server 2003, Datacenter Edition" /3GB
```

For more information, see Enable application memory tuning.

**Application changes**
No new application programming interfaces (APIs) are required for application memory tuning support. However, it would be ineffective to automatically provide every application with a 3-gigabyte (GB) address space, therefore this feature is not enabled upon initial installation of the operating system.

Executable files that can use the 3-GB address space are required to have the bit IMAGE_FILE_LARGE_ADDRESS_AWARE set in their image header. Some manufacturers preconfigure their applications to use application memory tuning, making it unnecessary for you to make any changes. For more information, see your application documentation and contact your application vendor to determine if they support Large Address Awareness (which allows them to address 3 GB of virtual memory instead of the 2 GB normally allocated to each application process), or whether you can enable Large Address Awareness in their application.

### Notes

- When modifying executable files to make use of application memory tuning, be aware that it is not necessary to modify the associated DLLs.
- This topic does not apply to Windows Server 2003, Web Edition.

# Changing the default paging file size on large-memory computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Changing the default paging file size on large-memory computers**

If you have 4 gigabytes (GB) or more of memory on your server, you may want to change the default size of your paging file. On x86-based computers with 4 GB or more of physical memory there should be a paging file sufficiently large to capture a kernel memory dump. This is true even if there is little use of the paging file due to the majority of the memory being used by an Address Windowing Extensions (AWE) application.

When setting up the paging file on a large memory system, make the minimum and maximum page file sizes the same (for example, set **Initial size (MB)** to 2,050 MB and set **Maximum size (MB)** to 2,050 MB). This prevents the page file from getting fragmented on the hard drive, which might cause problems when writing a kernel memory dump to disk. A paging file size of at least 2,050 MB is the minimum size necessary for computers with 4 GB or more of physical memory to capture a complete kernel memory dump. The paging file can be much larger (up to three times the physical RAM is typical) if the system is being used for application consolidation. For instructions on changing the paging file size, see Change the size of the virtual memory paging file.

In computers with eight or more processors that have the maximum amount of RAM installed, you might be able to gain some incremental performance improvement by splitting the paging file into multiple paging files. Each paging file must be on a separate physical disk and for reliability, each disk should be part of a hardware RAID-5 volume.

For more information about dividing the paging file into multiple paging files, see "Troubleshooting Performance" at the Microsoft Windows Resource Kits Web site.

**Note**

- This topic does not apply to Windows Server 2003, Web Edition.

# Enterprise Memory Architecture Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resources**

Microsoft Product Support Services provides a searchable database of technical support information for Microsoft products. You can search here for general information about Enterprise Memory Architecture or for information related to other Microsoft products. You can get to the Microsoft Product Support Services Web site by clicking the appropriate link in Support resources.

### Note

- This topic does not apply to Windows Server 2003, Web Edition.

# Enterprise Memory Architecture Troubleshooting

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting**
What problem are you having?

- The computer will not start after PAE is enabled.
- After PAE is enabled, the computer runs for a time and then displays a Stop error.
- System Properties, Microsoft System Diagnostics (WinMSD) or other system utilities report 256MB less than the total physical memory installed to the system.
- The writing of memory dumps stops or stalls when the Physical Addressing Extension (PAE) option is enabled, or a written memory dump is corrupt or incomplete.
- You cannot enable application memory tuning (4-gigabyte tuning) and Physical Address Extension (PAE) X86 on 64-bit versions of the Windows Server 2003 operating systems running on Itanium architecture-based or x64-based computers.

**The computer will not start after PAE is enabled.**
**Cause:** Your hardware may not support PAE.

**Solution:** When starting, run in Safe Mode, which disables PAE, and then remove the **/PAE** parameter from the Boot.ini file.

Also, determine whether your hardware supports PAE by consulting the hardware compatibility information for products in the Windows Server 2003 family, which you can find by clicking the appropriate link in Support resources. Contact your vendor for additional compatibility information.

You are also advised to contact your hardware vendor.

For more information, see Checklist: Enabling Physical Address Extension (PAE), and Enterprise Memory Architecture hardware and software requirements.

**After PAE is enabled, the computer runs for a time and then displays a Stop error.**
**Cause:** Your hardware may not support PAE.

**Solution:** Determine whether your hardware supports PAE by consulting the hardware compatibility information for products in the Windows Server 2003 family, which you can find by clicking the appropriate link in Support resources. Also contact your vendor for additional compatibility information.

If your hardware does not support PAE, or if the problem persists and you continue to believe that PAE might be the cause, remove the **/PAE** parameter from the Boot.ini file. To remove the **/PAE** parameter, restart your computer in Safe Mode, which disables PAE, and then remove the parameter from the Boot.ini file. You start your computer in Safe Mode by pressing F8, when indicated, during startup.

It is also recommended that you contact your hardware vendor.

For more information, see Checklist: Enabling Physical Address Extension (PAE), and Enterprise Memory Architecture hardware and software requirements.

**System Properties, Microsoft System Diagnostics (WinMSD) or other system utilities report 256MB less than the total physical memory installed to the system.**
**Cause:** 256MB of physical memory will appear to be missing on servers using certain hardware. The system ROM may reserve the upper 256MB memory region for memory mapped I/O devices. The amount of reserved physical memory may increase to 512MB depending on the number of I/O devices installed to the system. For example, a system with 4GB of actual physical memory may appear to have 3.84 GB total physical memory.

**Solution:** No correction is necessary. However, to see all memory, add a **/PAE** switch to the system's **boot.ini** file. For more information, see Enable Physical Address Extension (PAE).

**The writing of memory dumps stops or stalls when the Physical Addressing Extension (PAE) option is enabled, or a written memory dump is corrupt or incomplete.**
**Cause:** You might have misconfigured your recovery settings, your paging file might not be large enough for the memory dump, or you might lack available disk space.

**Solution:** Ensure that you are writing kernel-only debug information. Also, make sure the paging file size is at least 2,060 MB if your system contains 4 GB or more of physical memory and you have clicked **Kernel memory dump** under **Write debugging information**. For more information, see Configure the memory dump settings for PAE.

**See Also:** Article Q299515, "Crashdump Does Not Work on a Computer with More Than 4 Gigabytes of Memory," in the Microsoft Knowledge Base.

**You cannot enable application memory tuning (4-gigabyte tuning) and Physical Address Extension (PAE) X86 on 64-bit versions of the Windows Server 2003 operating systems running on Itanium architecture-based or x64-based computers.**
**Cause:** Not applicable - these features are not available on 64-bit versions of the Windows Server 2003 operating systems running on Itanium architecture-based or x64-based computers.

**Solution:** Not applicable - these features are not available on 64-bit versions of the Windows Server 2003 operating systems running on Itanium architecture-based or x64-based computers.

For more information about how to obtain product support, see Support resources.

### Note

- This topic does not apply to Windows Server 2003, Web Edition.

# Technologies for Application and Development Support

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Application and development support**
This section covers:

- The .NET Framework
- Message Queuing
- UDDI Services overview
- Using Component Services
- Using Data Sources (ODBC)
- Windows Management Instrumentation Control
- Using MSDN

# The .NET Framework

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**The .NET Framework**
The .NET Framework is a new computing platform designed to simplify application development in the highly distributed environment of the Internet. The .NET Framework has several main components: the common language runtime, the .NET Framework class library, and the runtime hosts. The common language runtime is the foundation of the .NET Framework. It manages code execution and provides core services such as memory management, thread management, and remote execution. The .NET Framework class library is a comprehensive, object-oriented collection of reusable classes that you can use to develop a wide range of applications, including ASP.NET applications and XML Web services. The .NET Framework also provides several runtime hosts, including Windows Forms and ASP.NET, which work directly with the runtime to provide a scalable, server-side environment for managed code. The .NET Framework is installed by default with Windows Server 2003 operating systems.

For more information about the .NET Framework, see .NET Framework at the Microsoft Web site.

### Notes

- This feature is not available on the Itanium-based versions of the Windows operating systems.

- For more information about using the .NET Framework, open a command prompt, and then type:

  **start %systemroot%\Microsoft.NET\Framework\<*LCID*>\Admin.chm**

  where <*LCID*> is the locale identifier. For example, if you are using an English language installation of the .NET Framework, type:

  **start %systemroot%\Microsoft.NET\Framework\1033\Admin.chm**

- To open a command prompt, click **Start**, point to **All programs**, point to **Accessories**, and then click **Command prompt**.

# Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing**
Message Queuing (also known as MSMQ) is a messaging infrastructure and a development tool for creating distributed messaging applications for Microsoft® Windows® operating systems.

Message Queuing is of interest to both system administrators (for installing and managing the infrastructure) and software developers (for creating messaging applications). This documentation is written for system administrators and discusses management of the infrastructure provided by Message Queuing. This documentation does not discuss application development.

For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed on it. The term *Message Queuing client* can refer to either an *independent client* or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed. Such computers are referred to as having independent client functionality or dependent client functionality. The following links provide detailed information:

- Before installing or upgrading Message Queuing, see Checklists.
- To find features that have been moved in Windows Server 2003 family operating systems, see New ways to do familiar Message Queuing tasks.
- For instructions on specific administration tasks, see Message Queuing How To....
- To learn more about Message Queuing features, planning, installing, and upgrading Message Queuing, and background information to help you understand Message Queuing, see Message Queuing Concepts.
- For troubleshooting help and links to other Message Queuing resources, see Troubleshooting and Additional Resources.

# Using Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Using Message Queuing**

Message Queuing (also known as MSMQ) is a messaging infrastructure and environment for building and running distributed, loosely coupled, messaging applications. As part of the application server role, Message Queuing provides features for developing and managing Web-based applications. Message Queuing applications running on source computers send messages to queues, and applications running on target computers retrieve messages from queues. Such applications communicate across the Internet and other heterogeneous networks, and with computers that might be temporarily offline.

Message Queuing can be installed in various configurations. Computers configured as Message Queuing independent clients run the Message Queuing service, host queues, send and receive messages, and do not require synchronous access to a Message Queuing server. Message Queuing servers provide additional functionality, including:

- Directory access for client computers running earlier versions of Message Queuing on Windows NT 4.0, Windows 98, or Windows 95 computers.
- Support for dependent clients, which are a limited Message Queuing client configuration that requires synchronous access to a server for all messaging functions.
- Routing capabilities that enable you to route messages within a site or between different sites when there is no direct connectivity between client computers.

When you install Message Queuing you choose the subcomponents for your required configuration. The Message Queuing component is not installed by default during Windows Setup. For more information about Message Queuing, see Message Queuing Help.

**To install Message Queuing with independent client functionality**

1. Open the Windows Components Wizard.
2. In the Windows Components Wizard, select the **Application Server** check box, and then click **Details**.
3. Select the **Message Queuing** check box.
4. If you want to change the default set of optional subcomponents that will be installed, click **Details**, and then:
    - If the computer belongs to a domain and you want it to operate in workgroup mode, clear the **Active Directory Integration** check box.

**Notes**

- To open the Windows Components Wizard, click **Start**, click **Control Panel**, double-click **Add or Remove programs**, and then click **Add/Remove Windows Components**.
- Use the following administrative tools to manage Message Queuing:
    - Computer Management, which provides access to local queue and message information. To open Computer Management, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Computer Management**.
    - Active Directory Users and Computers, and Active Directory Sites and Services, which provide access to information in Active Directory for routing configurations, computers, public queues, and other Message Queuing objects. To open Active Directory Users and Computers, click **Start**, click **Control Panel**, double-click

**Administrative Tools**, and then double-click **Active Directory Users and Computers**. To open Active Directory Sites and Services, click **Start**, click **Control Panel**, double-click **Administrative Tools**, and then double-click **Active Directory Sites and Services**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Checklists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklists**

This section provides checklists for installing Message Queuing client and server software on new computers. For details, see the following links:

- Checklist: Installation for Message Queuing clients
- Checklist: Installation for Message Queuing servers

# Checklist: Installation for Message Queuing clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installation for Message Queuing clients**
Use this checklist when installing Message Queuing clients on Windows Server 2003 family computers that do not have previous versions of Message Queuing installed. Message Queuing is not installed by default during Windows Server 2003 family operating system setup.

| Step | Reference |
|---|---|
| Review key concepts and determine the client functionality needed. | Message Queuing features |
| Review the installation requirements. | Installation overview |
| Review the problems that may arise during installation and their solutions. | Troubleshooting installation problems |
| Log on with local administrative permissions (as a member of the local Administrators group). For best security practice, log off as administrator after installation is complete. | Installation permissions |
| For a dependent client, verify that a Message Queuing computer with at least independent client functionality is available, preferably in the same site in which you are installing. Any such computer operating in domain mode can serve as a supporting server. Following installation, Message Queuing computers are not configured to support dependent clients, and this feature must be enabled. Note that a computer in workgroup mode cannot act as a supporting server for a dependent client. | Enable a supporting server; Installing dependent clients |
| Run the Windows Components Wizard and select the subcomponents that provide the applicable client functionality. | Install independent clients; Install dependent clients |
| Verify that the Message Queuing service has started. | Start or stop services for Message Queuing |
| Send a test message. Note that this feature must be enabled following Message Queuing installation. | Enable route tracking and test messages; Send test messages |

**Notes**

- New Message Queuing 3.0 features, such as HTTP transport, Message Queuing Triggers, and sending messages to multiple destinations, are not available to dependent clients. Thus, distribution lists, multiple-element format names, and multicast messaging are not supported for dependent clients.

- Dependent clients will no longer be supported in future versions of Message Queuing.

# Checklist: Installation for Message Queuing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Checklist: Installation for Message Queuing servers**

Use this checklist when installing Message Queuing servers on computers running on Windows Server 2003 family computers that do not have previous versions of Message Queuing installed. Message Queuing is not installed by default during Windows Server 2003 family operating system setup.

| Step | Reference |
|---|---|
| Review key concepts and determine the server functionality needed. | Message Queuing features |
| Review installation requirements. | Installation overview |
| Review the problems that may arise during installation and their solutions. | Troubleshooting installation problems |
| Log on with the appropriate administrative permissions. | Installation permissions |
| Before installing a Message Queuing server on a computer in a particular site, verify that there is at least one available domain controller in that site or in a nearby site. | Installation overview |
| For each Windows Server 2003 or Windows 2000 domain controller, verify that the computer is trusted for delegation. | Make a domain controller trusted for delegation |
| To reduce replication traffic, consider configuring at least one computer from the Windows Server 2003 or Windows 2000 domain controller in each site as a global catalog server. | Configure a domain controller as a global catalog server |
| If this server will be installed in domain mode and act as a supporting server for dependent clients, enable this feature. | Enable a supporting server |
| If this server will support Windows 2000 Message Queuing clients in the same site, verify that there is a domain controller running the Message Queuing directory service (Downlevel Client Support) or Message Queuing 2.0 in the site, or promote this computer to a domain controller and select the **Downlevel Client Support** subcomponent during installation. | Installing Message Queuing servers |
| If this server will support MSMQ 1.0 clients in the same site, verify that there is a domain controller running the Message Queuing directory service (Downlevel Client Support) or Message Queuing 2.0 and configured as a global catalog server from the domain of each such client in the site. Or, if applicable, promote this computer to a domain controller, configure it as a global catalog server, and select the **Downlevel Client Support** subcomponent during installation. | Installing Message Queuing servers |
| Run the Windows Components Wizard and select the subcomponents that provide the services needed. | Install Message Queuing servers |

| | |
|---|---|
| When prompted during the first or a subsequent installation of a Message Queuing server with **Downlevel Client Support** on a domain controller in your organization, weaken security if you want to support MSMQ 1.0 clients or clients logged on with local user accounts. For best security practice, only weaken security if necessary. | Enabling weakened security |
| If this server will be deployed for Internet messaging, configure HTTPS authentication. | HTTPS authentication |
| Verify that the Message Queuing service has started. | Start or stop services for Message Queuing |
| If this server has been enabled for routing, create a routing link for this computer to serve as a site gate to route messages to another site. | Create routing links |
| Send a test message. Note that this feature must be enabled following Message Queuing installation. | Enable route tracking and test messages; Send test messages |

# New ways to do familiar Message Queuing tasks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**New ways to do familiar tasks**

These tables compare different user interfaces used for common tasks in Message Queuing in:

- Windows Server 2003 family operating systems and Windows NT 4.0.
- Windows Server 2003 family operating systems and Windows 2000.

For a table that lists terminology and architectural differences between previous versions and the current version of Message Queuing, see Upgrade overview.

**Windows Server 2003 family operating systems and Windows NT 4.0**

| If you want to | In Windows NT 4.0 use | In Windows Server 2003 family |
|---|---|---|
| Set access control, set access auditing, or change ownership for Message Queuing | MSMQ Explorer | Open Active Directory Users and Computers. For more information, see Message Queuing security overview. |
| Change the Message Queuing service account | **Services** in Control Panel | Open Computer Management. For more information, see Change the Message Queuing service account. |
| Configure routing links | MSMQ Explorer | Open Active Directory Sites and Services. For more information, see Routing links. |
| For cross-platform messaging, create foreign sites or add foreign computers | MSMQ Explorer | Open Active Directory Sites and Services. For more information, see Foreign computers and sites. |
| Configure Message Queuing computers and properties, or set computer quotas or properties | MSMQ Explorer | Open Active Directory Users and Computers. For more information, see Administration overview. |
| Set DNS properties for Message Queuing computers | **Network** in Control Panel | Open Network Connections in Control Panel. For more information, see Set DNS properties for Message Queuing. |
| Create, delete, or configure queues, or set queue quotas or properties | MSMQ Explorer | Open Computer Management or open Active Directory Users and Computers. For more information, see Administering Queues. |
| View or delete messages, or view message properties | MSMQ Explorer | Open Computer Management or open Active Directory Users and Computers. For more information, see Managing messages. |

**Windows Server 2003 family operating systems and Windows 2000**

| If you want to | In Windows 2000 use | In Windows Server 2003 family |
|---|---|---|
| Specify a new site for mobile computers. | **Message Queuing** in Control Panel | Open Computer Management. For more information, see Specify a new site for mobile computers. |

| | | |
|---|---|---|
| Change the supporting server for a dependent client. Note that Message Queuing computers are not enabled by default to support dependent clients. | **Message Queuing** in Control Panel | Open Computer Management. For more information, see Enable a supporting server and Change the supporting server for a dependent client. |
| Specify the drives and folders for storing message files, message logs, and transaction logs. | **Message Queuing** in Control Panel | Open Computer Management. For more information, see Store messages on multiple disk drives. |
| Change, register, view, and remove certificates. | **Message Queuing** in Control Panel | Open Computer Management. For more information, see Authentication for Message Queuing. |
| To renew cryptographic keys for Message Queuing. | **Message Queuing** in Control Panel | Open Computer Management. For more information, see Renew cryptographic keys for Message Queuing. |

**Notes**

- Message Queuing 3.0 does not support a mixed-mode domain environment. That is, an environment where MSMQ 1.0 controller servers running on a Windows NT 4.0 computer exist in a Windows Server 2003 domain, together with Windows Server 2003 domain controllers. After you upgrade Windows NT 4.0 controller servers to the Windows Server 2003 family operating system, and follow the Message Queuing upgrade procedures, the result is a Windows Server 2003 domain environment, with no MQIS servers remaining, and no replication service.

- Until this process is completed, and as long as the domain environment is in mixed-mode, Message Queuing directory service functionality (Downlevel Client Support component) cannot be added to Windows Server 2003 domain controllers. In Message Queuing 3.0, directory service functionality is only required to provide directory services for Message Queuing objects to Message Queuing client computers running MSMQ 1.0 and 2.0. Message Queuing 3.0 servers and independent clients running on Windows Server 2003 family computers can access Active Directory directly.

- The Message Queuing directory service is not installed by default. To install it, you must select the **Downlevel Client Support** check box during Message Queuing 3.0 installation. You cannot add this functionality in a mixed-mode environment.

- A mixed-mode Windows 2000 domain environment comprised of MSMQ 1.0 controller servers and Windows 2000 domain controllers can still exist. In such an environment, Windows Server 2003 domain controllers can exist, but the Downlevel Client Support component cannot be installed on them.

- MSMQ Explorer does not run on Windows Server 2003 family or Windows 2000 computers.

- There are no tools that allow you to manage an MSMQ 1.0 enterprise from a Windows Server 2003 family or Windows 2000 computer.

# Message Queuing How To...

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How to...**

This section provides instructions on completing Message Queuing administration tasks:

- For information on how to install and uninstall Message Queuing, configure independent and dependent clients, and configure Message Queuing in clusters, see Install Message Queuing.
- For instructions on managing routing links, and site gates, see Administer a Message Queuing Network.
- For information on Message Queuing in Active Directory, see Administer Message Queuing in Active Directory.
- For information on administering tasks on Message Queuing computers, see Administer Message Queuing Computers.
- To learn about security tasks, including managing Message Queuing object security, authentication, and encryption, see Administer Security for Message Queuing.
- For instructions on managing and configuring queues and queue aliases, see Administer Queues for Message Queuing.
- For information on distribution list tasks, see Administer Distribution Lists for Message Queuing.
- To learn about message properties, including setting default message lifetime, and purging messages, see Administer Messages for Message Queuing.
- For information on creating and managing triggers and rules, modifying default trigger values, and configuring Message Queuing trigger resources for clusters, see Administer Triggers for Message Queuing.
- For instructions on viewing Message Queuing events, external transactions, and performance counters, and to learn to enable message route tracking and test messages, see Monitor and Test Message Queuing.

# Install Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Install Message Queuing**

This section shows you how to:

- Configure a domain controller as a global catalog server
- Make a domain controller trusted for delegation
- Set installation permissions to enable upgrade from MSMQ 1.0
- Install Message Queuing servers
- Install independent clients
- Enable network DTC access
- Enable a supporting server
- Install dependent clients
- Configure Message Queuing resources for server clusters
- Configure Message Queuing with HTTP for server clusters
- Uninstall Message Queuing

# Configure a domain controller as a global catalog server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure a domain controller as a global catalog server**

1. Open Active Directory Sites and Services.
2. In the console tree, right-click **NTDS Settings**.

   **Where?**

   - Active Directory Sites and Services/Sites/*YourApplicableSite*/Servers/*YourApplicableServer*/NTDS Settings

3. Click **Properties**.
4. On the **General** page, select the **global catalog** check box.

**Notes**

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- Each Windows Server 2003 family site or Windows 2000 site containing MSMQ 1.0 clients running on Windows NT 4.0, Windows 98, or Windows 95 computers must contain at least one Windows Server 2003 domain controller that is running the Message Queuing directory service (Downlevel Client Support) and is configured as a global catalog server or at least one Windows 2000 domain controller that is running a Message Queuing server and is configured as a global catalog server from the domain of each such client. This is required to enable such clients to send queries programmatically to Message Queuing servers.
- When a Windows NT 4.0 primary enterprise controller (PEC) is migrated, it is automatically promoted to a domain controller configured as a global catalog server.
- The first domain controller in a Windows Server 2003 family forest is automatically configured as a global catalog server.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

**Concepts**
Installing on a domain controller
Working with MMC console files

# Make a domain controller trusted for delegation

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To make a domain controller trusted for delegation**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click the applicable domain controller.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/Domain Controllers/*YourDomainController*

4. Click **Properties**.
5. On the **General** page, select the **Trust computer for delegation** check box (if needed).

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- If this property is disabled for a domain controller, the Message Queuing service cannot run.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set installation permissions to enable upgrade from MSMQ 1.0

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set installation permissions to enable upgrade from MSMQ 1.0**

1. Open Active Directory Users and Computers.
2. In the console tree, right-click **Computers** (or applicable organizational unit).

   **Where?**

   - Active Directory Users and Computers/*YourDomain/Computers* (or applicable organizational unit)

3. Click **Delegate control** to start the Delegation of Control Wizard, and then click **Next**.
4. On the **Users or Groups** page, click **Add**.
5. In the **Select Users, Computers, or Groups** dialog box, ensure that **Users, Groups, or Build-in Security Principals** appears in **Select this object type**. If it does not, click **Object Types**, and select these objects, clearing any other check boxes that are selected. Then click **OK**.
6. In **Enter the object name to select**, do the following:

   - To allow authenticated users permission to install Message Queuing, under **Name**, type **Authenticated Users**, and then click **OK**.
   - To allow everyone permission to install Message Queuing, under **Name**, type **Everyone**, and then click **OK**.

7. On the **Users or Groups** page, click **Next**.
8. Select **Create a custom task to delegate**, and then click **Next**.
9. On the **Active Directory Object Type** page, click **Only the following objects in the folder**, select the **Computer objects** check box, and then click **Next**.
10. On the **Permissions** page, under **Show these permissions**, clear the **General** check box, and then select the **Creation/deletion of specific child objects** check box.
11. Under **Permissions**, ensure that the **Create MSMQ Configuration objects** check box and the **Delete MSMQ Configuration objects** check box are selected, and that the other check boxes are cleared. Click **Next**, and then click **Finish**.

**Notes**

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- Use the Delegation of Control Wizard to grant the proper permissions to users that want to install MSMQ 1.0 on a computer that is part of a domain that runs Windows Server 2003 family or Windows 2000.
- On the **Security** page of the **Properties** dialog box, the check boxes for permissions granted using the Delegation of

Control Wizard or using inherited permissions are dimmed.

- The Delete MSMQ Configuration Objects permission is required to uninstall Message Queuing.

- When Message Queuing is installed on computers running Windows 95, Windows 98, and some versions of Windows NT 4.0 (without a hotfix) or Windows 2000 (prior to Service Pack 4), or when these computers join a Windows Server 2003 domain, they require a given GUID when creating MSMQ configuration objects. By default a Windows Server 2003 forest does not support the addition of objects with a given GUID. To overcome this problem, it is recommended that you upgrade the client computer to an operating system that does not require creating an object with a given GUID. These include Windows NT 4.0 (with a hotfix), and Windows 2000 (with Service Pack 4).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Install Message Queuing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install Message Queuing servers**

1. Open Add or Remove Programs in Control Panel.
2. Click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Application Server** check box, click **Details**, select the **Message Queuing** check box, and then click **Details**.
4. On the **Message Queuing** page, you can select the following subcomponents for your Message Queuing server:
   - To provide message routing services, select the **Routing Support** check box.
   - To install the Message Queuing directory service, which provides access to Message Queuing objects in Active Directory for MSMQ 1.0 clients running on Windows 98, Windows 95, Windows Millennium Edition and Windows NT 4.0 computers, and for MSMQ 2.0 clients running on Windows 2000 computers, select the **Downlevel Client Support** check box.
   - If the computer belongs to a domain and you want it to operate in workgroup mode, clear the **Active Directory Integration** check box. In this case, you cannot install Routing Support.
   - If you want to install Message Queuing Triggers, select the **Triggers** check box.
   - If you intend to send messages by HTTP transport, select the **MSMQ HTTP Support** check box.
5. Click **OK**, and then click **Next**.
6. If prompted, type the DNS or NetBIOS name of an MSMQ 1.0 PEC or PSC (in a Windows NT 4.0 enterprise) in the local site, and then click **Next**.
7. Follow the remaining instructions in the wizard.

**Notes**

- To open Add or Remove Programs, click **Start**, point to **Settings**, click **Control Panel**, and then double-click **Add or Remove Programs**.
- Message Queuing 3.0 servers can be installed only on computers running on platforms from the Windows Server 2003 family.
- Only Message Queuing 3.0 clients, not servers, can be installed in a Windows NT 4.0 enterprise.
- During setup, an attempt is made to automatically detect the nearest Windows Server 2003 or Windows 2000 domain controller in the local site or in a nearby site. If a suitable domain controller cannot be found, Setup assumes that you are installing a Message Queuing client in a Windows NT 4.0 environment and prompts you for the name of a controller server (PEC or PSC) before Setup can continue.
- The following subcomponents are selected by default for 32-bit servers: Active Directory Integration and Common (consisting of Core functionality and Local Storage).

- In a Windows Server 2003 site, to provide access to Message Queuing objects in Active Directory for Message Queuing 1.0 clients on Windows 95, Windows 98, Windows Millennium Edition, Windows NT 4.0 computers, or Message Queuing 2.0 clients running on Windows 2000 computers, you must install a Message Queuing server with the **Downlevel Client Support** check box selected on a Windows Server 2003 domain controller in that site, or you must install a Message Queuing server on a Windows 2000 domain controller in that site. For MSMQ 1.0 clients, you must also configure the applicable domain controller as a global catalog server, and each MSMQ 1.0 client must have such a domain controller from its own domain in the site.

- Although the **Downlevel Client Support** component can be installed on all Message Queuing servers, it is relevant only for domain controllers. If it is installed on a computer that is not a domain controller, it only becomes active if the server is converted to a domain controller.

- You can install a Message Queuing server without Routing Support in workgroup mode if the computer is part of a Windows Server 2003 family workgroup. In this case, only private queues can be accessed and direct connectivity is required to send messages. For more information, see Related Topics.

- If you are installing a Message Queuing server with Downlevel Client Support on a domain controller and security has not been weakened in your organization to support MSMQ 1.0 clients or clients logged on with local user accounts, you will be prompted during installation about whether or not to weaken security. Weaken security only if you want to support such clients.

- Do not attempt to use Message Queuing 3.0 files to create a Message Queuing server on a computer that does not belong to the Windows Server 2003 family.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Choosing installation subcomponents

# Install independent clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install independent clients**

1. Open Add or Remove Programs in Control Panel.
2. Click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Application Server** check box, click **Details**, select the **Message Queuing** check box, and then click **Details**.
4. On the **Message Queuing** page, you can select the following subcomponents for the independent client computer:
   - If the computer belongs to a domain and you want it to operate in workgroup mode, clear the **Active Directory Integration** check box. In this case, you cannot install Routing Support.
   - If you want to install Message Queuing Triggers, select the **Triggers** check box.
   - If you intend to send messages by HTTP transport, select the **MSMQ HTTP Support** check box.
5. Click **Next**.
6. Follow the remaining instructions in the wizard.
7. If prompted to restart your computer, click **Yes** to allow Setup to complete.

**Notes**

- To open Add or Remove Programs, click **Start**, point to **Settings**, click **Control Panel**, and then double-click **Add or Remove Programs**.
- The following subcomponents are selected by default for 32-bit servers: Active Directory Integration and Common (consisting of Core functionality and Local Storage).
- If a domain controller cannot be found automatically in the local site or in a nearby site, the installation will continue, and Message Queuing will be installed in workgroup mode. In the context of Message Queuing, any mode of operation that does not allow access to a directory service is called workgroup mode, even if the applicable computer belongs to a domain.
- You can also install an independent client in workgroup mode if the computer is part of a Windows Server 2003 family workgroup. In this case, direct connectivity is required to send messages. For more information, see Related Topics.
- Do not attempt to use Message Queuing 3.0 files to create an independent client on a computer that does not belong to the Windows Server 2003 family.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable network DTC access

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable network DTC access**

1. Open Add or Remove Programs in Control Panel.
2. Click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Application Server** check box, and then click **Details**.
4. Select **Enable network DTC access**, and then click **OK**.

### Note

- To open Add or Remove Programs, click **Start**, point to **Settings**, click **Control Panel**, and then double-click **Add or Remove Programs**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Installing dependent clients

# Enable a supporting server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable a supporting server**

1. Open Computer Management.
2. In the console tree, click **Services and Applications**.

   **Where?**

   - Computer Management/Services and Applications

3. In the details pane, right-click **Message Queuing**, and then click **Properties**.
4. On the **Server Security** tab, clear the selection **Disable dependent client support to prevent this computer acting as a supporting server for dependent clients**, and then click **OK**.

**Important**

- Before enabling a supporting server, you must enable network access for Microsoft Distributed Transaction Coordinator (DTC). For instructions, see Enable network DTC access

**Notes**

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- For best security practice, only turn on this feature if it is required.
- Following installation, dependent client support is disabled by default for Message Queuing computers.
- To reset server security settings on this tab to the default settings following installation, click **Restore Defaults**.
- Dependent clients cannot be installed on computers in workgroup mode or on 64-bit computers.
- New Windows Server 2003 family Message Queuing features, such as HTTP transport, Message Queuing Triggers, and sending messages to multiple destinations, are not available to dependent clients. Thus, distribution lists, multiple-element format names, and multicast messaging are not supported for dependent clients.
- Dependent clients will no longer be supported in future versions of Message Queuing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Install dependent clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To install dependent clients**

1. Open Add or Remove Programs in Control Panel.
2. Click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Application Server** check box, click **Details**, select the **Message Queuing** check box, and then click **Details**.
4. On the **Message Queuing** page, clear the **Active Directory Integration**, **Triggers**, and **MSMQ HTTP Support** check boxes, select the **Common** check box, and then click **Details**.
5. Clear the **Local Storage** check box, click **OK**, click **OK**, and then click **Next**.
6. If prompted, type the DNS or NetBIOS name of a supporting server in the local site. If the specified supporting server cannot be found:
   - Click **Yes** to complete setup. Note that the dependent client cannot send or receive messages until a connection with a Message Queuing server is established.
   - Click **No** to specify a different Message Queuing server.

**Notes**

- To open Add or Remove Programs, click **Start**, point to **Settings**, click **Control Panel**, and then double-click **Add or Remove Programs**.
- The following subcomponents are selected by default for 32-bit servers: Active Directory Integration and Common (consisting of Core functionality and Local Storage).
- By default, following installation, Message Queuing servers are not enabled to support dependent clients. For instructions on enabling a Message Queuing computer to act as a supporting server, see Enable a supporting server.
- Any Message Queuing server operating in domain mode with at least independent client functionality can serve as the supporting server for a dependent client. Setup automatically attempts to locate such a Message Queuing server in the same site or in a nearby site. If one cannot be located, Setup prompts you for the name of such a server. If the server specified is not available, Setup displays a message stating that the server is not reachable. You can choose to complete setup without a specified server, allowing you to install a dependent client before you install its supporting Message Queuing server. For best security practice, do not configure servers as supporting servers unless this functionality is required.
- Dependent clients cannot be installed on computers in workgroup mode or on 64-bit computers.
- New Windows Server 2003 family Message Queuing features, such as HTTP transport, Message Queuing Triggers, and sending messages to multiple destinations, are not available to dependent clients. Thus, distribution lists, multiple-element format names, and multicast messaging are not supported for dependent clients.
- Dependent clients will no longer be supported in future versions of Message Queuing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Message Queuing resources for server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure Message Queuing resources for server clusters**

1. Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Cluster Administrator**.

2. To create a Message Queuing resource:

   - When the **Open Connection to Cluster** dialog box appears, in the **Cluster or server name** list box, select the applicable cluster or server. If you select a server, the name of the cluster to which it belongs will appear in the console tree (console tree location is: ClusterName/Groups/YourGroup).

   - In the console tree, right-click the cluster group to which you want the Message Queuing resource to belong.

   - On the **File** menu, point to **New**, and then click **Resource**.

   - In the New Resource Wizard, type the applicable information in **Name** and **Description**, select **Message Queuing** in the **Resource type** list box, and then click **Next**.

   - On the **Possible Owners** page, if you want to add nodes to the automatically chosen list under **Possible owners**, select them from the list under **Available nodes**, and then click **Add**. If you want to remove nodes from the automatically chosen list under **Possible owners**, select them in this list, click **Remove**, and then click **Next**.

   - On the **Dependencies** page, under **Available resources**, select the name of the Network Name resource in the group and click **Add**, and then select the name of the Physical Disk resource in the group and click **Add**. Then click **Finish**.

3. If Message Queuing has the Active Directory Integration component installed, enable Kerberos authentication for the Network Name resource on which the Message Queuing resources depends. This is not enabled by default. To enable, do the following:

   - To bring the Network Name resource offline, in the console tree for the cluster group, right-click the Network Name resource selected as a dependency in the details pane, and then click **Take Offline**.

   - Right-click the Network Name resource again, and then click **Properties**.

   - On the **Parameters** tab, select the **Enable Kerberos Authentication** check box, to enable authentication.

   - To bring the Network Name resource online, in the console tree for the cluster group, right-click the Network Name resources in the details pane, and then click **Bring Online**.

   **Caution**

   - Other resources in the group may also depend on the Network Name resource. These will be taken offline automatically when the Network Name resource goes offline. When you bring the Network Name resource online, bring these other resources online too.

4. To bring the Message Queuing resource online, in the console tree, click the **Resources** folder. In the details pane, click the Message Queuing resource. On the **File** menu, click **Bring Online**.

5. To manage the Message Queuing resource from Computer Management, create a Generic Application resource in the same cluster group and configure it to launch the Computer Management MMC snap-in:

    - In the Cluster Administrator console tree, click the cluster group to which the Message Queuing resource belongs.
    - On the **File** menu, point to **New**, and then click **Resource**. The New Resource Wizard launches.
    - In the New Resource Wizard, type **Computer Management** in the **Name** text box and select **Generic Application** in the **Resource type** list box. Then click **Next**.
    - On the **Possible Owners** page, select possible owners to match those selected for the Message Queuing resource. Then click **Next**.
    - On the **Dependencies** page, under **Available resources**, select the name of the Network Name resource in the group and click **Add**, and then select the Message Queuing resource previously created and click **Add**. Then click **Next**.
    - On the **Generic Application Parameters** page, in **Command line**, type **mmc compmgmt.msc**.
    - In **Current directory**, type **%windir%/system32**.
    - Select the **Allow application to interact with desktop** check box, select the **Use Network Name for computer name** check box, click **Next**, and then click **Finish**.
    - Bring the resource online using the procedure above. The Computer Management snap-in will appear on the desktop of the computer node that owns the resource.

**Notes**

- This task is performed on a computer that is running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition as part of a server cluster, and has the Message Queuing service already installed.
- If you want to use triggers, HTTP messaging, or external transactions in your cluster, before creating a Message Queuing resource in any cluster group hosted on a node of a server cluster, you must configure a Microsoft Distributed Transaction Coordinator (DTC) resource in the cluster. For instructions on creating a cluster, see Create a cluster, in Server Clusters Help.
- Errors occurring during the performance of this task are recorded in a Windows event log. For example, a "device not ready" error indicates that Message Queuing was not installed on the node.
- All Message Queuing applications that run in the context of a cluster group (whether cluster-aware or not) must depend on the Message Queuing resource in that group, and use the Network Name resource in that group. Repeat the steps stated above for the Computer Management MMC snap-in to properly configure Generic Application resources for "cluster-unaware" applications.
- Once created, do not rename resources for Message Queuing.
- If the virtual Message Queuing service managed by the Network Name resource will access Active Directory, you must enable Kerberos authentication on the Network Name resource on which the Message Queuing resource depends. Note that this feature is not enabled by default.
- You can also enable Kerberos authentication from the command line by typing the following command *cluster res "Network_Name_resource_name" /priv RequireKerberos=1:DWORD*
- When you select the Physical Disk resource in the group, Message Queuing allocates its storage in the *MSMQ\STORAGE*

folder on the shared disk. After storage has been allocated, you cannot modify the folder location.

- To uninstall Message Queuing on a computer that is part of a server cluster, the Message Queuing virtual server must be deleted from the node before uninstalling Message Queuing on the physical node. For example, if Message Queuing is installed on NodeA of a server cluster, you need to identify all Message Queuing resources on this cluster, ensure that NodeA does not own any cluster groups containing Message Queuing resources, and remove NodeA from the list of possible owners of each Message Queuing resource. Then you uninstall Message Queuing from NodeA.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure Message Queuing with HTTP for server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure Message Queuing with HTTP for server clusters**

1. Open Computer Management.

2. In the console tree, click to expand **Services and Applications**.

   **Where?**

   - Computer Management/Services and Applications

3. Click **Internet Information Services (IIS) Manager**, click to expand **Web Sites**, right-click **Default Web Site**, and then click **Properties**.

4. To assign to the site all IP addresses that are not assigned to other sites, on the **Web Site** tab, in **Web site identification**, select **Default Web Site**, and in IP Address select **All Unassigned**.

5. To assign the explicit IP address of the virtual server as the default Web site, on the **Web Site** tab, in **Web Site Identification**, click **Advanced**, and then in **Advanced Multiple Web Site Configuration**, click **Add** to add the IP address of the virtual server.

### Note

- This task is performed on a computer that is running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition as part of a server cluster, and has the Message Queuing service already installed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Uninstall Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To uninstall Message Queuing**

1. Open Add or Remove Programs in Control Panel.
2. Click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Application Server** check box, click **Details**, clear the **Message Queuing** check box, and then click **Next**.
4. When asked if you want to permanently delete the queues and messages created by Message Queuing, click **Yes**.

## Notes

- To open Add or Remove Programs, click **Start**, point to **Settings**, click **Control Panel**, and then double-click **Add or Remove Programs**.
- When uninstalling Message Queuing in a multi-domain environment, wait for Active Directory replication to occur and check that the msmq object for the applicable computer was removed before attempting to reinstall Message Queuing on the same computer.
- Uninstalling Message Queuing does not remove Message Queuing files from the \Windows\System32 and \Windows\System32\Drivers folders.
- To uninstall Message Queuing on a computer that is part of a server cluster, the Message Queuing virtual server must be deleted from the node before uninstalling Message Queuing on the physical node.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer a Message Queuing Network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer a Message Queuing Network**
This section shows you how to:

- Create routing links
- Change the cost for a routing link
- Change the site gates for a routing link
- Administer Cross-Platform Messaging

# Create routing links

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create routing links**

1. Open Active Directory Sites and Services.
2. On the **View** menu, click **Show Services Node**.
3. In the console tree, right-click **MsmqServices**.

   **Where?**

   - Active Directory Sites and Services/Services/MsmqServices

4. Point to **New**, and then click **MSMQ Routing Link**.
5. On the **New Object - Routing Link** dialog box, in **Site 1** and in **Site 2**, click the arrows that open the lists and select the two sites between which you want to route messages.
6. In **Routing Link Cost**, enter a cost.

## Notes

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- A routing link defines the route for connectivity between two sites. For more information on routing links, how they are used to route messages, and routing-link costs, see Related Topics.
- Costs can range from 1 to 999999.
- By default, users in the Enterprise Admins group and Domain Admins group can create or modify routing links. For information on how to set permissions for routing links, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the cost for a routing link

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the cost for a routing link**

1. Open Active Directory Sites and Services.
2. On the **View** menu, click **Show Services Node**.
3. In the console tree, click **MsmqServices**.

   **Where?**

   - Active Directory Sites and Services/Services/MsmqServices

4. In the details pane, right-click the applicable routing link, and then click **Properties**.
5. On the **General** page, in **Routing Link Cost**, specify a new cost.

## Notes

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- A routing link defines the route for connectivity between two sites. For more information on routing links, how they are used to route messages, and routing-link costs, see Related Topics.
- All routing links are assigned a default cost of 1. Change routing-link costs only in the case where alternative routes are possible and you want to enforce one route over another route using link costs. In that case, you can assign costs that reflect the differences in the communications costs.
- Costs can range from 1 to 999999.
- By default, only users in the Enterprise Admins group can create or modify routing links if there are multiple domains in your organization. For users in the Domain Admins group to be able to create or modify routing links, they will need to be granted the Create All Child Objects permission for the MsmqServices object. For information on how to set permissions for routing links, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the site gates for a routing link

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the site gates for a routing link**

1. Open Active Directory Sites and Services.
2. On the **View** menu, click **Show Services Node**.
3. In the console tree, click **MsmqServices**.

   **Where?**

   - Active Directory Sites and Services/Services/MsmqServices

4. In the details pane, right-click the applicable routing link, and then click **Properties**.
5. On the **Site Gates** page, do one of the following:

   - To add a Message Queuing routing server as a site gate to the routing link, in **Available servers**, select a server from the list, and then click **Add**.
   - To remove a Message Queuing routing server from the routing link, in **Site gates**, select the applicable server from the list, and then click **Remove**.

6. Repeat step 5 as needed.

## Notes

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- A routing link defines the route for connectivity between two sites, and a site gate is a Message Queuing routing server or one of several such servers through which the message traffic between two sites is configured to pass. For more information on routing links, site gates, and how they are used to route messages, see Related Topics.
- A site gate can belong to either or both of the sites connected by a routing link. A routing link can have any number of site gates or no site gate.
- By default, only users in the Enterprise Admins group can create or modify routing links if there are multiple domains in your organization. For users in the Domain Admins group to be able to create or modify routing links, they will need to be granted the Create All Child Objects permission for the MsmqServices object. For information on how to set permissions for routing links, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Cross-Platform Messaging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Cross-Platform Messaging**
This section shows you how to:

- Create foreign sites
- Add foreign computers to a site

# Create foreign sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create foreign sites**

1. Open Active Directory Sites and Services.
2. On the **View** menu, click **Show Services Node**.
3. In the console tree, right-click **MsmqServices**.

   **Where?**

   - Active Directory Sites and Services/Services/MsmqServices.

4. Click **New Foreign Site**.
5. In the **New Object – Foreign Site** dialog box, type a name for the new site under **Foreign site name**.

**Notes**

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- A routing link defines the route for connectivity between any two sites, including a foreign site and a non-foreign site. A site gate is a Message Queuing routing server or one of several such servers through which the message traffic between two sites is configured to pass. For more information, see Related Topics. To provide connectivity to a foreign site, you must perform the following task:
- Create a routing link between the foreign site and a Windows Server 2003 family or Windows 2000 Message Queuing (non-foreign) site that contains a Message Queuing server running a connector application. For more information, see Related Topics.

  1. Define this Message Queuing server as a site gate for the routing link. For more information, see Related Topics.
  2. Open Active Directory Users and Computers.
  3. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
  4. In the console tree, right-click the **msmq** object of the computer running the connector application.
  5. Click **Properties**.
  6. On the **Sites** page, select the foreign site under **All sites**, and then click **Add** to add this site to the list of sites where this server resides and to add it to the foreign site.

- To delete a foreign site, in the Active Directory Sites and Services console tree, right-click the name of the foreign site under **Sites**, and then click **Delete**. Before deleting a foreign site, you may need to refresh the list of sites. To do this, right-click **Sites**, and then click **Refresh**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add foreign computers to a site

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add foreign computers to a site**

1. Open Active Directory Sites and Services.
2. On the **View** menu, click **Show Services Node**.
3. In the console tree, right-click **MsmqServices**.
4. Click **New Foreign Computer** to open the **New Object – Foreign Computer** dialog box.
5. In the **Computer name** text box, type the name of the foreign computer.
6. In the **Foreign site** list box, select the name of the foreign site to which the computer will be added from the list of available foreign sites.

**Notes**

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- This procedure creates two objects in Active Directory for the foreign computer. One is a computer object in the Computers container. This object is similar to an ordinary computer object. The other is an msmq (MSMQ Configuration) object, which is created under the computer object and contains a pointer to the foreign site in the **MSMQ-Sites** attribute.
- You must create a foreign site before you can add a foreign computer to the site. For information on how to create a foreign site, see Related Topics.
- Typing the name of a foreign computer in the **New Foreign Computer** dialog box does not guarantee that messages can be sent to it.
- A routing link defines the route for connectivity between two sites. A site gate is a Message Queuing routing server or one of several such servers through which the message traffic between two sites is configured to pass. For more information on routing links, site gates, and how they are used to route messages, see Related Topics.
- A Message Queuing routing server that is running a connector application and has been configured as a site gate for a routing link between its site and the foreign site must also be added to the foreign site. To do this, perform the following task:

    1. Open Active Directory Users and Computers.
    2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
    3. In the console tree, right-click **msmq** (console tree location is: Active Directory Users and Computers/*YourDomain*/Domain Controllers/*ApplicableServer*/msmq).
    4. Click **Properties**.
    5. On the **Sites** page, select the foreign site under **All sites**, and then click **Add** to add this site to the list of sites where this server resides and to add it to the foreign site.

- For Windows 2000 computers running a connector application, after adding the foreign site to the list of sites, the foreign site will not appear in the list until you restart the Message Queuing service on the domain controller of the domain to which the Message Queuing server running the connector application belongs.

- Messages cannot be sent over HTTP transport to foreign computers.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Message Queuing in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Message Queuing in Active Directory**

This section shows you how to:

- Remove Message Queuing objects from Active Directory

# Remove Message Queuing objects from Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove Message Queuing objects from Active Directory**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer*/**msmq**

4. Click **Delete**. When prompted, click **Yes**.
5. Open Active Directory Sites and Services.
6. In the details pane, right-click **Msmq Settings**.

   **Where?**

   - Active Directory Sites and Services/**Sites**/*YourSite*/**Servers**/ *YourServer*/**MSMQ Settings**

7. Click **Delete**. When prompted, click **Yes**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- It is best to remove Message Queuing objects from Active Directory by uninstalling Message Queuing software from the actual computer. It is recommended that you perform the procedure above only if you cannot uninstall Message Queuing software from a computer, such as during a hardware malfunction, if you no longer have physical access to the computer, or if Message Queuing Setup has failed. For information on how to uninstall Message Queuing software from a computer, see Related Topics.
- When you remove Message Queuing objects from Active Directory, all queues and messages are also removed. However, actual Message Queuing software, including registry values and storage files, remains on the computer.
- If you remove objects for an in-routing or out-routing server, the server is also removed from the routing lists of all clients using that server.
- If you remove objects for a site gate, the server is also removed from the associated routing link.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Message Queuing Computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Message Queuing Computers**
This section shows you how to:

- Join a domain from a workgroup
- Add sites to a Message Queuing server's list of sites
- Remove sites from a Message Queuing server's list of sites
- Specify a new site for mobile computers
- Change in-routing or out-routing servers
- Change the supporting server for a dependent client
- View the dependent client list for a server
- Set the message storage size for computers
- Set the journal storage size for computers
- Store messages on multiple disk drives
- Set DNS properties for Message Queuing
- Start or stop services for Message Queuing

# Join a domain from a workgroup

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To join a domain from a workgroup**

1. Open System in Control Panel.
2. On the **Computer Name** page, click **Change**.
3. Under **Member of**, click **Domain**, type the domain name, and then click **OK**.
4. When prompted, provide a valid user name and password.
5. When prompted, restart your computer to apply the changes.

### Caution

- When you join a Message Queuing computer in workgroup mode to a domain, or move a Message Queuing computer to a different forest, all messages in outgoing transactional queues on the computer will be discarded, or placed in the dead-letter queue if negative source journaling is enabled.

### Notes

- To open System, click **Start**, point to **Settings**, and then click **Control Panel**.
- Use this procedure if you are running Message Queuing in a workgroup environment and want to join (or rejoin) a domain. When you join a domain, the computer can access public queues listed in Active Directory.
- For more information on this procedure, see Join a domain in the System online Help file.
- To perform this procedure, the Active Directory Integration subcomponent must be selected during setup. If the Active Directory Integration subcomponent is not installed, Message Queuing can run only in workgroup mode.
- You can use this procedure to join a workgroup from a domain. In that case, click **Workgroup** under **Member of** and type the name of the workgroup. You will be disjoined from the domain.
- You can use this procedure to move a computer from one domain to another domain within your forest. In this case, if you leave the msmq (MSMQ Configuration) object in the old domain, the computer will continue to use the old object. Otherwise, it will create a new msmq object in the new domain.
- After joining a domain from a workgroup or another domain, some time (as much as 20-30 minutes) is required for replication of the changes in Active Directory.
- When a computer running Message Queuing in workgroup mode joins a Windows NT 4.0 domain, the installation subcomponent for Active Directory Integration is removed. After the computer has been joined to the domain and rebooted, open **Add or Remove Programs** in Control Panel, and add the Active Directory Integration subcomponent.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add sites to a Message Queuing server's list of sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add sites to a Message Queuing server's list of sites**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer*/**msmq**

4. Click **Properties**.
5. Click the **Sites** tab, and in **All Sites**, select a site to add to the list of sites where the server resides, and then click **Add**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- In most cases, Message Queuing automatically determines the sites in which servers reside. This procedure is needed to add sites manually to the list of sites where a server resides. The applicable servers are Message Queuing servers with routing enabled, which are also called routing servers. Any routing server that resides in a specific site can be configured as an in-routing or out-routing server for computers that reside in that site. Such routing servers can be configured as site gates in routing links to that site. A routing server can reside in multiple sites, and it can be configured as an in-routing server, an out-routing server, or a site gate, independently in each site in which it resides.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove sites from a Message Queuing server's list of sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To remove sites from a Message Queuing server's list of sites**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq

4. Click **Properties**.
5. Click the **Sites** tab, and in ***ComputerName* Sites**, select a site to remove from the list of sites where the server resides, and then click **Remove**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- In most cases, Message Queuing automatically determines the sites in which servers reside. This procedure is needed to remove sites manually from the list of sites where a server resides. The applicable servers are Message Queuing servers with routing enabled, which are also called routing servers. Any routing server that resides in a specific site can be configured as an in-routing or out-routing server for computers that reside in that site. Such routing servers can be also configured as site gates in routing links to that site. A routing server can reside in multiple sites, and it can be configured as an in-routing server, an out-routing server, or a site gate, independently in each site in which it resides.

**Information about functional differences**

# Specify a new site for mobile computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify a new site for mobile computers**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. In the **Message Queuing Properties** dialog box, click the **Mobile** tab, and in **New site**, click the arrow that opens the list and select the site to which the mobile computer will move.
5. When prompted to restart Windows, click **Restart Now**.

**Note**

- To open Computer Management, right-click **My Computer**, and then click **Manage**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change in-routing or out-routing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change in-routing or out-routing servers**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq

4. Click **Properties**.
5. Click the **Routing** tab.
6. To change an in-routing server used, under **In-routing servers**, click the arrow that opens the list. Select a new Message Queuing server or select **none** to remove a particular Message Queuing server used as an in-routing server.
7. To change an out-routing server used, under **Out-routing servers**, click the arrow that opens the list. Select a new Message Queuing server or select **none** to remove the Message Queuing server used as an out-routing server.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- This task is applicable only to independent clients and Message Queuing servers without routing enabled that are installed on a nondomain controller, but can be performed from any computer with suitable permissions.
- You can install a Message Queuing server with routing enabled on a domain controller, but it may impair performance.
- When a client is moved to another site, these routing settings are disabled until the client returns to its original site.
- Message Queuing servers used as in-routing or out-routing servers must be in the same site as the client. The same computer can be used as both the in-routing server and the out-routing server for a client.
- If used, it is recommended that you assign more than one in-routing or out-routing server per client. This provides load balancing and failure recovery.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Assigning in-routing and out-routing servers

# Change the supporting server for a dependent client

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the supporting server for a dependent client**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. On the **Message Queuing Client** page in the **Message Queuing Properties** dialog box, type the name of the supporting Message Queuing server.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- This task is performed from the dependent client.
- Message Queuing 3.0 dependent clients cannot be installed with a Windows NT Server 4.0 computer as a supporting server.
- Any Message Queuing server operating in domain mode with at least independent client functionality, preferably in the local site, but also in a nearby site, can serve as the supporting server for a dependent client.
- By default, following installation, Message Queuing servers are not enabled to support dependent clients. For instructions on enabling a Message Queuing server to act as a supporting server, see Enable a supporting server.
- To enable a Message Queuing server to act as a supporting server for a dependent client, you must change the security configuration of the Microsoft Distributed Transaction Coordinator (DTC) to support network transactions. For details, see Enable network DTC access.
- If you have the early version of a dependent client running on Windows NT 4.0 and you want to change its supporting server to a Message Queuing server running on Windows 2000, the dependent client must first have Windows NT 4.0 Service Pack 4 or higher installed or transactional messaging will not function.
- New Message Queuing 3.0 features, such as HTTP transport, Message Queuing Triggers, and sending messages to multiple destinations, are not available to dependent clients. Thus, distribution lists, multiple-element format names, and multicast messaging are not supported for dependent clients.
- Dependent clients will no longer be supported in future versions of Message Queuing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Working with MMC console files

# View the dependent client list for a server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view the dependent client list for a server**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer*/msmq

4. Click **Properties**.
5. Click the **Dependent Clients** tab, and then click **Refresh** to ensure that the list is current.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- You can only view those dependent clients that are currently active (such as currently sending messages), which may not be the total number of dependent clients in your organization.
- By default, following installation, Message Queuing servers are not enabled to support dependent clients. For instructions on enabling a Message Queuing server to act as a supporting server, see Enable a supporting server.
- For information on how to change the supporting Message Queuing server for a dependent client, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the message storage size for computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the message storage size for computers**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer*/msmq

4. Click **Properties**.
5. On the **General** tab, in **Storage limits**, select the **Limit message storage to (KB)** check box, and then type a maximum total size (in kilobytes) for messages stored in all queues on the selected computer.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- This procedure is not applicable to computers operating in workgroup mode or virtual servers in clusters. You can set the computer quota of a workgroup computer using the **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\MachineCache\MachineQuota** registry key. To change the quota for a virtual server, you need to change the analogous registry key for clustered servers. After setting the registry, restart the Message Queuing service for the changes to take effect.

  **Caution**

  - Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

- Following a new installation of Message Queuing, or an upgrade from Windows 2000, the default limit for these storage sizes is 8 gigabytes (GB).
- When the computer quota is reached, no messages can be delivered to any queue or journal on the computer. No negative acknowledgment message is generated, and an error is returned for messages sent locally, while a remote computer tries to resend until the cumulative size of all messages in the queues drops below the specified limit.
- For information on how to set the journal storage size limit (or quota) for a computer, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Working with MMC console files

# Set the journal storage size for computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the journal storage size for computers**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer*/msmq

4. Click **Properties**.
5. On the **General** page, in **Storage Limits**, select the **Limit journal storage to (KB)** check box, and then type the total size (in kilobytes) of all journal messages that can be stored in the computer journal on the selected computer.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- This procedure is not applicable to computers operating in workgroup mode or virtual servers in clusters. You can set the computer quota of a workgroup computer using the **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\MachineCache\MachineJournalQuota** registry key. To change the quota for a virtual server, you need to change the analogous registry key for clustered servers. After setting the registry, restart the Message Queuing service for the changes to take effect.

  **Caution**

  - Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

- Following a new installation of Message Queuing, or an upgrade from Windows 2000, the default limit for these storage sizes is 8 gigabytes (GB).
- Automatically created folders used to store copies of messages are called *journals*. Messages stored in journals are called *journal messages*. When the journal storage limit (or quota) is reached, additional messages cannot be placed in the computer journal on the computer until the cumulative size of the journal messages in all journals on that computer drops below the specified limit.
- When you set the journal storage size limit for a computer, you automatically set equal quotas for the computer journal (the Journal messages queue), the dead-letter queue, and the transactional dead-letter queue.
- The journal messages stored in source or computer journals can include any outgoing nontransactional message. The journal messages stored in target or queue journals can include any incoming message, including transactional messages.
- For information on how to set the message storage limit (or quota) for a computer, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Store messages on multiple disk drives

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To store messages on multiple disk drives**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. On the **Storage** page, type a different drive letter and path as applicable in **Message files folder**, **Message logger folder**, or **Transaction logger folder**.
5. If prompted to stop the Message Queuing service, click **Yes**.
6. If prompted to restart Windows, click **Restart Now**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- By default, Message Queuing stores all message files, log files, and transaction log files in the \Windows\System32\Msmq\Storage folder on the drive on which Message Queuing is installed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set DNS properties for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set DNS properties for Message Queuing**

1. Open Network Connections in Control Panel.
2. Right-click **Local Area Connection**, and then click **Properties**.
3. In the **Local Area Connection Properties** dialog box, in the components list, click **Internet Protocol (TCP/IP)**.
4. Click **Properties**.
5. On the **General** page, do any of the following:

   - To specify that the DNS server will be located automatically, on the **General** page, select **Obtain DNS server address automatically**.
   - To specify one or two DNS servers, on the **General** page, select **Use the following DNS server addresses**. Then, in **Preferred DNS server**, type the IP address of the preferred DNS server, and in **Alternate DNS server**, type the IP address of an optional alternate DNS server.
   - To specify more than two DNS servers, on the **General** page, click **Advanced**. On the **Advanced TCP/IP Settings** page, click the **DNS** tab. Under **DNS server addresses, in order of use**, click **Add**; in **DNS server**, type the address of a DNS server and click **Add**. Repeat this step for each DNS server that you want to specify. You can use the **Up** and **Down** buttons to change the order of the DNS servers in the list. You can also click **Edit** to change the address of the selected DNS server in the list, or you can click **Remove** to delete it from the list.

## Notes

- To open Network Connections, click **Start**, point to **Settings**, click **Control Panel**, and then double-click **Network Connections**.
- This task is performed only if you are operating in a DNS-only environment (an environment that has no WINS server). Message Queuing requires DNS to be configured to correctly resolve computer names.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Start or stop services for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To start or stop services for Message Queuing**

1. Open Computer Management.
2. In the console tree, click **Services**.

   **Where?**

   - Computer Management/Services and Applications/Services

3. In the details pane, right-click the applicable service, and then do one of the following, if applicable (options that are not applicable are dimmed):

   - To start a service, click **Start**.
   - To stop a service, click **Stop**.
   - To pause a service, click **Pause**.
   - To resume a service that has been paused, click **Resume**.
   - To restart a service, click **Restart**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- You can view the status of a service by looking in the **Status** column in the details pane.
- This procedure is applicable to the Message Queuing service, and the Message Queuing Triggers service.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Security for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Security for Message Queuing**
This section shows you how to:

- Set permissions for computer and queue objects
- Set permissions for routing link objects
- Set permissions for MSMQ Settings objects
- Set permissions for Message Queuing files
- Set permissions for distribution lists
- Change ownership of computer and queue objects
- Change the Message Queuing service account
- Audit access to computer and queue objects
- Enable Message Queuing to access SACL information
- Audit access to routing link objects
- Enable hardened MSMQ mode
- Enable secured remote read
- Weaken security using ADSI Edit
- Change the security settings for Internet Information Services
- Administer Authentication and Encryption for Message Queuing

# Set permissions for computer and queue objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set permissions for computer and queue objects**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. Do one of the following:
   - To grant Message Queuing-specific permissions for a computer (an msmq object), in the console tree, right-click **msmq** (console tree location is: Active Directory Users and Computers/*YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq).
   - To grant Message Queuing-specific permissions for a queue, right-click the applicable queue. (console tree location is: Active Directory Users and Computers\ *YourDomain*\ *YourOrganizationalUnit* (such as Computers or Domain Controllers)\ *YourComputer*\ msmq\ *YourQueueFolder* (Private Queues for a private queue)\ *YourQueue*).
4. Click **Properties**.
5. On the **Security** page, set permissions for the object specified in Step 3, as needed:
   - To grant permissions for this object to a group or user appearing under **Group or user names**, select the applicable group or user, and then in **Permissions for *GroupOrUser***, select the check boxes in the **Allow** column following the names of the applicable permissions.
   - To deny a group or user permissions for this object, select the applicable group or user in **Group or user names**, and then in **Permissions for *GroupOrUser***, select the check boxes in the **Deny** column following the names of the applicable permissions.
   - To add a new group or user for access, click **Add**. In the **Select Users, Computers, or Groups** dialog box, click **Object Types**, select the **Group** and/or **Users** check box as appropriate, clear the remaining check boxes, and click **OK**. In **Enter the object name to select**, type the name of a group or user or the names of several groups or users separated by semicolons, and click **OK**. Or, click **Advanced** to search for groups or users, enter the applicable parameters, click **Find Now**, select the group or user, click **OK**, and then click **OK** again. Then, select the group or user you just added and select the applicable check boxes as needed.

**Notes**

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- The queue objects for the queues residing on a particular computer are child objects of the msmq object of the applicable computer. For example, to create a queue, a user must have the Create All Child Objects permission for the msmq object under which the queue will be created.
- You can grant or deny permissions for an object even to the Administrators group.
- This procedure cannot be used to set permissions for a private queue on a remote computer.

**Important**

- The default permission is that everyone can send messages to a queue. For tighter security, you can change the default security permissions for the queue. You can also specify properties for greater security when you create a queue, for example, to accept authenticated messages only. For instructions, see Allow only authenticated messages on queues.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set permissions for routing link objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set permissions for routing link objects**

1. Open Active Directory Sites and Services MsmqServices node.

   **Where?**

   - Click **Start**, click **Programs**, click **Administrative Tools**, and click **Active Directory Sites and Services** to launch the **Active Directory Sites and Services** dialog box.
   - Click **Active Directory Sites and Services** in the console tree.
   - Click the **View** menu of the **Active Directory Sites and Services** dialog box and select the option to **Show Services Node** if this option is not already enabled.
   - Click to expand the **Services** node in the console tree.
   - Right-click **MsmqServices**, and then click **Properties**.

2. On the **Security** page of the MsmqServices node, set permissions as needed:

   - To grant permissions for this object to a group or user appearing under **Group or user names**, select the applicable group or user, and then in **Permissions for *GroupOrUser***, select the check boxes in the **Allow** column.
   - To deny a group or user permissions for this object to a group or user appearing under **Group or user names**, select the applicable group or user appearing under **Group or user names**, select the applicable group or user, and then in **Permissions for *GroupOrUser***, select the check boxes in the **Deny** column.
   - To add a new group or user for access, click **Add** and in the **Select Users, Computers, or Groups** dialog box, click **Object Types**, select the appropriate Object type, clear the remaining check boxes, and click **OK**. In **Enter the object name to select**, type the name of a group or user or the names of one or more groups or users separated by semicolons, and then click **OK**. Or, click **Advanced** to search for groups or users, enter the applicable parameters, click **Find Now**, select the group or user, click **OK**, and then click **OK** again. Then select the group or user you just added and select the applicable check boxes in **Permissions for *GroupOrUser*** as needed.

| **Note** |
| --- |
| Each routing link object is a child object of the MsmqServices object. Thus, the **Create all child objects** and **Delete all child objects** permissions for the MsmqServices object are needed to create, modify, and delete routing links. By default, only the Enterprise Admins group is granted both of these permissions. |

**Information about functional differences**

# Set permissions for MSMQ Settings objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set permissions for MSMQ Settings objects**

1. Open Active Directory Sites and Services.

2. In the console tree, select the applicable server object.

   **Where?**

   - Active Directory Sites and Services/Sites/*YourSiteObject*/Servers/*YourServerObject*

3. Right-click the **MSMQ Settings** object in the details pane, and then click **Properties**.

4. On the **Security** page, set permissions as needed:

   - To grant permissions for this object to a group or user appearing under **Group or user names**, select the applicable group or user, and then in **Permissions for *GroupOrUser***, select the check boxes in the **Allow** column following **Create All Child Objects** and **Delete All Child Objects**.

   - To deny a group or user permissions for this object, select the applicable group or user in **Group or user names**, and then select the check boxes in the **Deny** column following **Create All Child Objects** and **Delete All Child Objects**.

   - To add a new group or user for access, click **Add**. In the **Select Users, Computers, or Groups** dialog box, click **Object Types**, select the **Group** and/or **Users** check box as appropriate, clear the remaining check boxes, and click **OK**. In **Enter the object names to select**, type the name of a group or user or the names of several groups or users separated by semicolons, and then click **OK**. Or, click **Advanced** to search for groups or users, enter the applicable parameters, click **Find Now**, select the group or user, click **OK**, and then click **OK** again. Then select the group or user that you just added and select the applicable check boxes as needed.

**Note**

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set permissions for Message Queuing files

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set permissions for Message Queuing files**

1. On the desktop, right-click **My Computer**, and then click **Explore**.
2. Locate and right-click the folder used to store the message files, log files, and transaction log files (usually **Storage** under \Windows\System32\Msmq), and then click **Properties**.
3. On the **Security** page, in **Group or user names**, click **Administrators**.
4. In **Permissions for Administrators**, under **Allow**, select the **Full Control** check box.
5. In **Group or user names**, select any group or user, including the Administrators group, that you do not want to access the Message Queuing storage files directly, and click **Remove**. Repeat this step as needed.

### Note

- You can set both file-level and folder-level permissions only on NTFS-formatted drives. You cannot set folder-level permissions on FAT-formatted drives. (The **Security** tab is not available for folders on FAT-formatted drives.)

### Important

- By default, only members of the Administrators group of the local computer have permissions for the folder used to store message files, log files, and transaction log files. For best security practice, it is not recommended that you widen these default permissions, or you may open Message Queuing for access by unauthorized persons.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set permissions for distribution lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set permissions for distribution lists**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. To grant permissions for a distribution list, in the console tree, right-click the applicable distribution list (group).

   **Where?**

   - Active Directory Users and Computers/*YourDomain/*Users/*YourDistributionList(Group)*

4. On the **Security** page, set permissions for the object specified in Step 3, as needed:

   - To grant permissions for this object to a group or user appearing under **Group or user names**, select the applicable group or user, and then in **Permissions for *GroupOrUser***, select the check boxes in the **Allow** column following the names of the applicable permissions.
   - To deny a group or user permissions for this object, select the applicable group or user in **Group or user names**, and then select the check boxes in the **Deny** column following the names of the applicable permissions.
   - To add a new group or user for access, click **Add**. In the **Select Users, Computers, or Groups** dialog box, click **Object Types**, select the **Group** and/or **Users** check box as appropriate, clear the remaining check boxes, and click **OK**. In **Enter the object name to select**, type the name of a group or user or the names of several groups or users separated by semicolons, and then click **OK**. Or, click **Advanced** to search for groups or users, enter the applicable parameters, click **Find Now**, select the group or user, click **OK**, and then click **OK** again. Then, select the group or user you just added and select the applicable check boxes as needed.

### Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- Message Queuing distribution lists are distribution group objects in Active Directory.

### Important

- Distribution lists are not created or managed with Message Queuing tools or APIs. For best security practice, consider carefully the permissions granted to distribution list objects.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change ownership of computer and queue objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change ownership of computer and queue objects**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. To change the ownership of a computer (an msmq object), in the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq

   Or, to change the ownership of a queue, right-click the applicable queue.

   **Where?**

   - Active Directory Users and Computers\ *YourDomain*\ *YourOrganizationalUnit* (such as Computers or Domain Controllers)\ *YourComputer*\ msmq\ *YourQueueFolder* (Private Queues for a private queue)\ *YourQueue*

4. Click **Properties**.
5. On the **Security** page, click **Advanced**.
6. On the **Owner** page, in **Change Owner to**, click a new user or group, and then click **OK**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- By default, the computer account is the owner of the msmq object, unless routing or the Downlevel Client Support component is enabled on the server. In that case, the creator is the owner. For the queue object, the creator is the owner by default.
- When a local user (a user not logged on to a Windows Server 2003 family domain) creates an object, the Everyone group is granted **Full Control** permissions for the object.
- There can be only one owner per Message Queuing computer or queue.
- This procedure cannot be used to change the ownership of a private queue on a remote computer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the Message Queuing service account

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the Message Queuing service account**

1. Open Computer Management.
2. In the console tree, click **Services**.

   **Where?**

   - Computer Management/Services and Applications/Services

3. In the details pane, double-click **Message Queuing**.
4. On the **Log On** page, click **This account**, and then click **Browse**. In **Name**, type the name of the user account, and then click **OK**.
5. In **Password**, type the account password.
6. In **Confirm Password**, type the account password again.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- This procedure is also applicable to the Message Queuing Triggers service. In this case, in Step 3, double-click **Message Queuing Triggers** in the details pane.
- Running the Message Queuing service under user accounts is not supported on domain controllers. Thus, the Message Queuing Downlevel Client Support service, which enables pre-Windows Server 2003 family clients to access objects in Active Directory, must run under the Local System account on domain controllers.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Audit access to computer and queue objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To audit access to computer and queue objects**

1. Open Active Directory Users and Computers.

2. Highlight **Active Directory Users and Computers**, and on the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.

3. To audit access to a computer (an msmq object), in the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq

   Or, to audit access to a queue, right-click the applicable queue.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq/*YourQueueFolder* (Private Queues for a private queue)/*YourQueue*

4. Click **Properties**.

5. On the **Security** page, click **Advanced**.

6. On the **Auditing** page of the **Advanced Security Settings** dialog box, click **Add**.

7. In the **Select Users, Computers, or Groups** dialog box, click **Object Types**, select the **Group** and/or **Users** check box as appropriate, clear the remaining check boxes, and click **OK**. In **Enter the object name to select**, type the name of a group or user whose access you want to audit or the names of several such groups or users separated by semicolons and click **OK**. Or, click **Advanced** to search for groups or users, enter the applicable parameters, click **Find Now**, select the group or user, click **OK**, and then click **OK** again.

8. In the **Auditing Entry** dialog box, in **Apply onto**, select the applicable objects for which user access will be audited. Then, under **Access**, select the appropriate check boxes next to the applicable entries and click **OK**. Or, to clear all audit entries, click **Clear All**, and then click **OK**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.

- This procedure cannot be used to audit access to a private queue on a remote computer.

- In addition to auditing access to computer and queue objects, you must also establish an audit policy for the local computer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable Message Queuing to access SACL information

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable Message Queuing to access SACL information**

1. Open Active Directory Users and Computers.
2. In the console tree, right-click **Domain Controllers**.

   **Where?**

   - Active Directory Users and Computers/Domain Controllers

3. Click **Properties**.
4. Click the **Group Policy** tab.
5. Click the default Group Policy, and then click **Edit**.
6. In the Group Policy object snap-in, open **Computer Configuration**, open **Windows Settings**, open **Security Settings**, open **Local Policies**, right-click **User Rights Assignment**, and then click **Open**.
7. Double-click **Manage Auditing and Security Log**, and then click **Add User or Group**.
8. Add the computer account name of the computer running the Message Queuing service, and then click **OK**.
9. Wait for about 5 minutes to allow changes to take effect in Active Directory, and then restart the computer.

### Note

- After the Message Queuing service is enabled to access SACL information, you need to establish an auditing policy. For information, see Define or modify auditing policy settings for an event category.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Audit access to routing link objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To audit access to routing link objects**

1. Open Active Directory Sites and Services.
2. Highlight **Active Directory Sites and Services**, and on the **View** menu, click **Show Services Node**.
3. In the console tree, click **MsmqServices**.

   **Where?**

   - Active Directory Sites and Services/Services/MsmqServices

4. In the details pane, right-click the applicable routing link, and then click **Properties**.
5. On the **Security** page, click **Advanced**.
6. On the **Auditing** page of the **Advanced Security Settings** dialog box, click **Add**.
7. In the **Select Users, Computers, or Groups** dialog box, click **Object Types**, select the **Group** and/or **Users** check box as appropriate, clear the remaining check boxes, and click **OK**. In **Enter the object name to select**, type the name of a group or user whose access you want to audit or the names of several such groups or users separated by semicolons and click **OK**. Or, click **Advanced** to search for groups or users, enter the applicable parameters, click **Find Now**, select the group or user, click **OK**, and click **OK** again.
8. In the **Auditing Entry** dialog box, in **Apply onto**, select the applicable objects for which user access will be audited. Then, under **Access**, select the appropriate check boxes next to the applicable entries and click **OK**. Or, to clear all audit entries, click **Clear All**, and then click **OK**.

## Notes

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- The information generated by an audit is stored in the security log. For information on how to use Event Viewer to view information in the security log, see Related Topics.
- This procedure can be used to audit access to any Message Queuing object under, and including, the MsmqServices object.
- In addition to auditing access to computer and queue objects, you must also establish an audit policy for the local computer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable hardened MSMQ mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable hardened MSMQ mode**

1. Open Computer Management.
2. In the console tree, click **Services and Applications**.

   **Where?**

   - Computer Management/Services and Applications

3. In the details pane, right-click **Message Queuing**, and then click **Properties**.
4. On the **Server Security** tab, select **Enable Hardened MSMQ mode to secure this computer on the Internet**, and then click **OK**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- Following installation, hardened MSMQ mode is not enabled by default.
- To reset server security settings on this tab to the default settings following installation, click **Restore Defaults**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Enable secured remote read

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable secured remote read**

1. Open Computer Management.
2. In the console tree, click **Services and Applications**.

   **Where?**

   - Computer Management/Services and Applications

3. In the details pane, right-click **Message Queuing**, and then click **Properties**.
4. On the **Server Security** tab, select **Enable secured remote receiving. In this mode, only servers running Windows Server 2003 can receive messages remotely from queues on this computer**, and then click **OK**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- To reset server security settings on this tab to the default settings following installation, click **Restore Defaults**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Weaken security using ADSI Edit

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To weaken security using ADSI Edit**

1. Click **Start**, click **Run**, type **adsiedit.msc**, and then press **Enter**.
2. In the console tree, right-click **CN=MsmqServices**.

   **Where?**

   - Configuration Container/CN=Configuration,.../CN=Services/CN=MsmqServices

3. Click **Properties**.
4. On the **Attribute Editor** page, in **Attributes**, select *mSMQNameStyle*, and then click **Edit**.
5. In **Boolean Attribute Editor**, select **True** to weaken security, or **False** to tighten security.
6. Click **OK**.

## Notes

- Windows Server 2003 family Support Tools, which is provided on the Windows Server 2003 family compact disc, must be installed before you can use ADSI Edit. To install these tools, perform the following steps:

  1. Insert the Windows Server 2003 family CD in your CD-ROM drive.
  2. Open the Support folder, and then open the Tools folder.
  3. Double-click **Suptools** to start the install program.
  4. Follow the instructions in the Windows Support Tools Setup Wizard, and select **Complete** on the **Select An Installation Type** page.

- This procedure is used to weaken Active Directory security to support MSMQ 1.0 users, Message Queuing 2.0 clients logged on with local user accounts, and certain operating configurations.
- Only users with the Write permission for the MsmqServices object can perform this procedure. By default, only members of the Domain Admins or Enterprise Admins groups of the root domain and members of the SYSTEM group (local system services running on a domain controller) have the Write permissions for this object.
- Dependent clients cannot run under a local user account. Also, any computer that sends queries about Message Queuing objects to Active Directory on a domain controller directly, rather than through the Message Queuing directory service, will not be able to access Active Directory when it logs on using a local user account even if weakened security for Active Directory is enabled.
- After performing this procedure, for the change to take effect, you must restart all instances of the Message Queuing Downlevel Client Support service running on Windows Server 2003 domain controllers and Message Queuing servers running on Windows 2000 domain controllers.

- For best security practice, it is recommended that Active Directory security not be weakened unless necessary.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the security settings for Internet Information Services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the security settings for Internet Information Services**

1. Click **Start**, click **Run**, type **mmc**, and then click **OK**.

2. On the **File** menu, click **Add/Remove Snap-in**.

3. In the **Add/Remove Snap-in** dialog box, click **Add**, select **Internet Information Services**, click **Add**, click **Close**, and then click **OK**.

4. In the console tree, right-click **MSMQ** virtual directory.

   **Where?**

   - Console Root/Internet Information Services/*YourInternet Information ServicesComputer/*Web Sites/Default Web Site/MSMQ

5. Click **Properties**, and then click the **Directory Security** tab.

6. Under **Authentication and access control**, click **Edit**.

7. To use a domain user account instead of the Internet Information Services local user for Anonymous Access, do the following:

   - In the **User Name** edit box, type the name of a domain user with the required permissions for the Message Queuing operation.

   - Type the user password, and then click **OK**.

   - Retype the password in the **Confirm Password** dialog, and then click **OK**.

8. To disable anonymous access and trust the Internet Information Services computer for delegation, do the following:

   - In the **Enable Anonymous Access** group, clear the **Enable anonymous access** check box, and click **OK**.

   - Open Active Directory Users and Computers.

   - On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.

   - In the console tree, right-click the name of your Internet Information Services computer.

     **Where?**

     Active Directory Users and Computers\ *YourDomain*\ Computers\ *YourInternet Information ServicesComputer*

   - Click **Properties**.

   - On the **General** page, select the **Trust computer for delegation** check box, and then click **OK**

9. In the **Internet Information Services** snap-in, right-click *YourInternet Information ServicesComputer*.

   **Where?**

   Console Root\ Internet Information Services\ *YourInternet Information ServicesComputer*

10. Restart Internet Information Services by selecting **All Tasks \ Restart Internet Information Services...**, and then click **OK**.

## Notes

- By default, Internet Information Services (IIS) impersonates a special Internet Information Services *local* user account. This account is local to the IIS computer (unless it is a domain controller). It cannot be authenticated by other computers in the network, and is treated as an anonymous user. Active Server Page (ASP) applications and scripts run under IIS and, by default, impersonate the IIS local user for any Message Queuing operations, including queries to Active Directory. Since anonymous users no longer belong to the Everyone group in Windows Server 2003 family operating systems, these queries fail. ASP applications and scripts cannot locate, create, and delete queues by default. In addition anonymous users cannot open a queue for remote read, and you cannot read messages from queues not belonging to the IIS computer using ASP by default.

- For the changes to take effect, you must stop and start the World Wide Web Publishing service.

- Trusting the computer for delegation allows multiple hops to communicate with a domain controller, assuming that the user account is trusted for delegation.

### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Authentication and Encryption for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Authentication and Encryption for Message Queuing**
This section shows you how to:

- Obtain client certificates
- Enable client certificates
- Register certificates for Message Queuing
- Remove certificates for Message Queuing
- View certificates for Message Queuing
- Renew certificates for Message Queuing
- Renew cryptographic keys for Message Queuing
- Obtain server certificates for HTTPS messaging
- Administer Server Authentication

# Obtain client certificates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To obtain client certificates**

1. In your Web browser, open the form at http://*servername*/certsrv for requesting a certificate from your CA, where *servername* is the name of the Web server where the CA that you want to access is located.

2. Click **Request a certificate**, click **Advanced certificate requests**, and then click **Create and submit a request to this CA**.

3. Type the information requested and any other options required, including:

   - Select **Mark keys as exportable**.

   - Select **Store certificate in the local computer certificate store**.

4. Click **Submit**, and then do one of the following:

   - If you see the **Certificate Pending** Web page, check on the pending certificate request.

   - If you see the **Certificate Issued** Web page, click **Install this certificate**.

5. If you are finished using the Certificate Services Web pages, close Internet Explorer.

Once you have obtained the client certificate, verify that it is in your Personal store and is valid. To do this:

1. Open the Certificates MMC snap-in.

2. Locate the installed client certificate in the **Personal** store under **Certificates (Local Computer)**, and then double-click the certificate to verify it.

Once you have ensured that the client certificate is valid, copy it to the MSMQ certificates store, as follows:

1. Open the Certificates MMC snap-in.

2. Locate the installed client certificate in the **Personal** store under **Certificates (Local Computer)**.

   **Where?**

   - Console Root/Certificates (Local Computer)/Personal/Certificates

3. Drag the certificate with your mouse to move it to the **MSMQ\Personal** store under **Certificates - Service (Message Queuing) on Local Computer** in the Certificates snap-in.

   **Where?**

   - Console Root/Certificates - Service (Message Queuing) on Local Computer/MSMQ\Personal/Certificates

**Notes**

- To open the Certificates snap-in, click **Start**, click **Run**, type **mmc**, and then click **OK**. On the **File** menu, click **Add/Remove Snap-in**, and then click **Add**. Select **Certificates**, and then click **Add**. Select **Service account**, click **Next**, select **Local Computer (the computer this console is running on)**, and then click **Next**. In **Service Account**, select **Message Queuing**, and then click **Finish**. When you finish working in the MMC console, you can save the settings so that the custom MMC is available next time you open the console.

- To check on a pending certificate request, in the CA Web page, click **View the status of a pending certificate request**. If you see pending certificates, select the certificate request you want to check, and then click **Next**. If the status is **Still pending**, you must wait for the administrator of the CA to issue the certificate. If the status is **Issued**, to install the certificate, click **Install this certificate**. If the status is **Denied**, contact the CA administrator for more information.

- Note that before requesting a client certificate, you might need to make the CA Web page a trusted site for Internet Explorer. To do this, on the **Tools** menu in Internet Explorer, click **Internet Options**. On the **Security** tab, click **Trusted Sites**, and then click **Sites**. Uncheck **Require server verification (https:) for all sites in the zone**. Type **http://*servername***, and then click **Add**.

- It is not necessary to have the client certificate locally on the receiving computer, but the receiving computer must be able to access the client certificate.

- This task can be performed only from a Message Queuing server installed on a Windows Server 2003 family domain controller.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Working with MMC console files

# Enable client certificates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To enable client certificates

1. On the receiving computer, open the Internet Information Services snap-in as follows: click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Internet Information Services (IIS)**.

2. In the console tree, right-click **MSMQ**.

   **Where?**

   - Console Root/Internet Information Services/*YourComputer*/Web Sites/Default Web Site/MSMQ

3. Click **Properties**.

4. Select the **Directory Security** tab, and then under **Secure Communications**, click **Edit**.

5. To require that a secure link be used for a site resource, click **Require secure channel (SSL)**.

6. Under **Client certificates**, select one of the following to enable client certificate authentication:

   - To enable clients to access a resource with a client certificate, click **Accept client certificates**. Note that a client certificate is not required.

   - To ensure that users without a valid client certificate will be denied access to the site resource, click **Require client certificates**.

   - To grant access to users with or without a client certificate, click **Ignore client certificates**.

7. To enable client certificate mapping, in the **Secure Communications dialog box,** select **Enable client certificate mapping** if not already selected, and then click **Edit**. For instructions on creating a mapping, see the IIS online Help file.

### Notes

- By default, anonymous access is enabled for the **MSMQ** virtual directory using the account IUSR_computername. To prevent both authenticated and unauthenticated HTTP messages from being sent, disable anonymous access. For instructions, see Change the security settings for Internet Information Services.

- By default, IUSR_computername user has write permission for the physical MSMQ directory (default is %SystemDrive%\Inetpub\wwwroot\msmq), and **Ignore client certificates** is selected, thus allowing everyone to send HTTPS messages. You can control access to **MSMQ** virtual directory by configuring security settings for the physical Message Queuing directory.

- Requiring a secure channel means that a user cannot connect to a site resource without using a secure link (that is, the link's URL must begin with https://).

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Register certificates for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To register certificates for Message Queuing**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. In the **Message Queuing Properties** dialog box, click the **User Certificate** tab, and then under **User certificates**, click **Register**.
5. In the **Personal Certificates** dialog box, click a certificate, and then click **Register**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- Your computer must have access to Active Directory to perform this task.
- During setup, an internal user certificate is automatically created for you on the local computer and is registered in Active Directory the first time you log on to the local computer in a domain provided your computer can communicate with a domain controller when you log on.
- If no internal certificate exists, such as when the internal certificate is removed, this procedure creates a new internal certificate, which you can register. You can also use this procedure to register an external certificate after you import it.
- If a certificate registered on the local computer is removed from a remote computer, the record of the certificate is removed from Active Directory, but the certificate will still exist on the local computer.
- By default, users have permission to register certificates for Message Queuing. However, if default user permissions are changed, this might affect your ability to register certificates. For registering certificates, the user object requires the Write Personal Information permission in the Active Directory.
- Active Directory sets a multi-valued attribute limit of approximately 800 user certificates for a specific user account. This limit is usually exceeded when obsolete user certificates have not been deleted from Active Directory. If multiple certificates exist for a user account, only the latest is used, and obsolete certificates can be deleted. For instructions, see Remove certificates for Message Queuing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Remove certificates for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

#### To remove certificates for Message Queuing

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. In the **Message Queuing Properties** dialog box, click the **User Certificate** tab, and then under **User certificates**, click **Remove**.
5. In the **Personal Certificates** dialog box, click the applicable user certificate, and then click **Remove**.

### Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- A list of all certificates registered for the user in Active Directory is displayed in the **Personal Certificates** dialog box. There might be a certificate for the same user on more than one computer, including the computer from which you are currently running the MMC snap-in. The list will take the form of **domain\user, computer name**.
- You can remove any user certificate that is listed. However, if a registered certificate for a computer is removed using another computer, the certificate is removed from Active Directory, but will still exist on the local computer.
- Active Directory sets a multi-valued attribute limit of approximately 800 user certificates for a specific user account. This limit is usually exceeded when obsolete user certificates have not been deleted from Active Directory. If multiple certificates exist for a user account (*user account, computer_name*), indicating obsolete entries, then only the latest certificate is used, and the others can be deleted. For example:
  - DOMAINA\user1, computer3
  - DOMAINA\user1, computer3
  - DOMAINA\user1, computer3
- You can check which is the latest entry for **DOMAINA\user1, computer3**, and delete the other **computer3** entries. To check the latest entry, click the required certificate, and then click **View Certificate**. On the **Details** tab, look at the **Valid from** field. Note that only the certificate with the most recent **Valid from** date is in use. The others are obsolete.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View certificates for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view certificates for Message Queuing**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. In the **Message Queuing Properties** dialog box, click the **User Certificate** tab, and then under **User certificates**, click **View**.
5. In the **Personal Certificates** dialog box, click a certificate, and then click **View Certificate**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- A list of all certificates registered for the user in Active Directory is displayed in the **Personal Certificates** dialog box. There might be a certificate for the same user on more than one computer (including the computer from which you are currently running the MMC snap-in. The list will take the form of **domain\user, computer name**.

# Renew certificates for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To renew certificates for Message Queuing**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. In the **Message Queuing Properties** dialog box, click the **User Certificate** tab, and then under **Internal certificate**, click **Renew**.

   A warning appears stating that authenticated messages that you have already sent using the current internal certificate may be rejected as not authenticated.

5. If rejecting those messages is acceptable, click **Yes**. Or, if it is not acceptable, click **No** and renew your internal certificate some other time.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- When the certificate is successfully renewed, a message appears stating that the internal certificate was successfully renewed and registered in Active Directory.
- This task is not relevant for Message Queuing computers installed in workgroup mode.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Renew cryptographic keys for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To renew cryptographic keys for Message Queuing**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. In the **Message Queuing Properties** dialog box, click the **Service Security** tab, and under **Cryptographic keys**, click **Renew**.

   A warning appears stating that received messages may be encrypted with a cryptographic key different from the one that your computer currently has. You will not be able to read those messages. You will be asked whether you want to continue.

5. If not being able to read those messages is acceptable, click **Yes**. Or, if it is not acceptable, click **No** and renew your cryptographic key at some other time.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- Only the user who installed Message Queuing has the permissions needed to renew the cryptographic keys. If Message Queuing is installed in workgroup mode, and then the computer joins a domain, only domain administrators are allowed to renew the cryptographic keys.
- This task does not apply to dependent clients and Message Queuing computers installed in workgroup mode.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Obtain server certificates for HTTPS messaging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To obtain server certificates for HTTPS messaging**

1. On the server requiring a certificate, to request a certificate, open Internet Explorer.
2. In Internet Explorer, connect to http://*servername*/certsrv, where *servername* is the name of the server where the certification authority (CA) you want to access is located.
3. Click **Request a certificate**, and then click **Advanced certificate request**.
4. To submit a request using a form, click **Create and submit a certificate request to this CA**, and then click **Next**.
5. Fill in any identifying information requested and any other options you require, including:
   - In **Name**, enter the name of the computer that requires the certificate.
   - In **Type of Certificate Needed**, choose **Server Authentication Certificate**.
   - In **Key Options**, select **Use the local machine store**.
   - In **Key Options**, select **Marks keys as exportable** if you want to export the private key at a later time.
   - Leave other options at default values.
6. Click **Submit**.
7. When you see the Certificate Service Web Page, click **Install this certificate** to add the certificate to your certificate store.
8. If you are finished using the Certificate Services Web pages, close Internet Explorer.
9. After you have the certificate, open Computer Management.
10. In the console tree, click **Default Web Site**.

    **Where?**

    - Computer Management/Services and Applications/Internet Information Services (IIS)/Web Sites
11. Right-click **Default Web Site**, and then click **Properties**.
12. On the **Directory Security** tab, click **Server Certificate**.
13. In the Web Server Certificate Wizard, do the following:
    - On the **Server Certificate** page, select **Assign an existing certificate**.
    - In **Available Certificates**, select the required certificate, and then click **Next**.

- In the **SSL Port** page, click **Next**.
- In **Certificate Summary**, click **Next**, and then click **Finish**.

### Note

- After this procedure is complete, you can view the certificate. To do this, right-click **Default Web Site**, and then click **Properties**. On the **Directory Security** tab, click **View Certificate**.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Server Authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Server Authentication**
This section shows you how to:

- Export key certificates from Windows NT 4.0
- Create server certificates for Message Queuing
- Import server certificates for Message Queuing
- Change server certificates for Message Queuing
- Import a CA certificate from Microsoft Certificate Services

# Export key certificates from Windows NT 4.0

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To export key certificates from Windows NT 4.0**

1. On your MSMQ 1.0 controller server with Windows NT 4.0 Option Pack installed, click **Start**, point to **Programs**, point to **Windows NT 4.0 Option Pack**, point to **Microsoft Information Server**, and then click **Internet Services Manager**.

2. In the console tree, right-click **Default Web Site**.

   **Where?**

   - Console Root/Internet Information Services/*YourComputer*/Default Web Site

3. Click **Properties**.

4. Click the **Directory Security** tab, and then under **Secure Communications**, click **Key Manager**.

5. In the Key Manager console, click **Certificate**.

   **Where?**

   - Local Computer/MSMQ/Certificate

6. On the **Key** menu, point to **Export Key** and click **Backup File**.

7. Follow the instructions in the wizard and type a name for the backup file.

## Notes

- For more information about using Internet Services Manager, click the **Action** menu after the console appears, and then click **Help**.

- This task applies only if you are upgrading an MSMQ 1.0 controller server to a Message Queuing server.

- You must export the key certificate before you upgrade the MSMQ 1.0 controller server. Then you can import the certificate to the upgraded server. You need to import a server (key) certificate only for each Message Queuing server that will reply to Active Directory queries from MSMQ clients running on Windows NT 4.0, Windows 98, or Windows 95.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create server certificates for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create server certificates for Message Queuing**

1. Click **Start**, click **Run**, type **mmc**, and then click **OK**.
2. On the **File** menu, click **Add/Remove Snap-in**.
3. In the **Add/Remove Snap-in** dialog box, click **Add**, select **Certificates**, and then click **Add**.
4. In the **Certificates snap-in** dialog box, click **Computer account**, click **Next**, click **Finish**, click **Close**, and then click **OK**.
5. In the console tree, double-click **Certificates**, right-click **Personal**, point to **All Tasks**, and then click **Request New Certificate**.
6. Follow the instructions that appear in the Certificate Request Wizard. When prompted to type a friendly name for the certificate, type the name of the local Message Queuing server.
7. After you have obtained the certificate, open Computer Management.
8. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

9. Click **Properties**.
10. In the **Message Queuing Properties** dialog box, click the **Service Security** tab, and then in the **Server certificates** group box, click **Select a Certificate**.
11. Under **Issued to**, select the certificate with the name of the applicable Message Queuing server, and then click **OK**.
12. When prompted to restart Windows, click **Restart Now**.

**Notes**

- You can open the Certificates snap-in after you have added it to a console and saved the console settings in an .msc file as follows: click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click the name of the saved .msc file.
- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- This task can be performed only from a Message Queuing server installed on a Windows Server 2003 family domain controller.
- You need to create a server certificate only for each Message Queuing server that replies to Active Directory queries from MSMQ clients running on Windows NT 4.0, Windows 95, or Windows 98.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Import server certificates for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To import server certificates for Message Queuing**

1. Click **Start**, click **Run**, type **mmc**, and then click **OK**.
2. On the **File** menu, click **Add/Remove Snap-in**.
3. In the **Add/Remove Snap-in** dialog box, click **Add**, select **Internet Information Services**, click **Add**, click **Close**, and then click **OK**.
4. In the console tree, right-click **MSMQ**.

   **Where?**

   - Console Root/Internet Information Services/*YourComputer*/Web Sites/Default Web Site/MSMQ

5. Click **Properties**.
6. Click the **Directory Security** tab, and then click **Server Certificate**. In the Web Server Certificate Wizard, click **Next**.
7. Click **Import a certificate from a Key Manager backup file**, and then click **Next**.
8. Enter the path and file name for the backup file you previously created when you exported the certificate from Windows NT 4.0, and then click **Next**.
9. Type the proper password, click **Next**, and then click **Finish**.
10. After you have obtained the certificate, open Computer Management.
11. In the console tree, right-click **Message Queuing**.

    **Where?**

    - Computer Management/Services and Applications/Message Queuing

12. Click **Properties**.
13. In the **Message Queuing Properties** dialog box, click the **Service Security** tab, and then in the **Server certificates** group box, click **Select a Certificate**.
14. Under **Issued to**, select the certificate with the name of the Message Queuing server to which you imported the certificate, and then click **OK**.

**Notes**

- You can also open the Internet Information Services snap-in as follows: click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Internet Services Manager**. Or, you can open this snap-in after you have added it to a console and saved the console settings in an .msc file as follows: click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click the name of the saved .msc file.

- To open Computer Management, right-click **My Computer**, and then click **Manage**.

- This task applies only if you are upgrading an MSMQ 1.0 controller server to a Message Queuing server installed on a Windows Server 2003 family domain controller.

- You must first export the key certificate before you upgrade the computer to Windows Server 2003 family. Then you can import the server certificate. You need to import a server (key) certificate only for each Message Queuing server that will reply to Active Directory queries from MSMQ clients running on Windows NT 4.0, Windows 98, or Windows 95.

# Change server certificates for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change server certificates for Message Queuing**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Click **Properties**.
4. In the **Message Queuing Properties** dialog box, click the **Service Security** tab, and then in the **Server certificate** group box, click **Select a Certificate**.
5. In the **Choose MSMQ Server Certificate** dialog box, select the applicable certificate, and then click **OK**.
6. When prompted to restart Windows, click **Restart Now**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- This task can be performed only from a Message Queuing server installed on a Windows Server 2003 family domain controller.

**Information about functional differences**

# Import a CA certificate from Microsoft Certificate Services

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To import a CA certificate from Microsoft Certificate Services**

1. On the sender computer requiring a CA certificate, open Internet Explorer.
2. In Internet Explorer, connect to http://*servername*/certsrv, where *servername* is the name of the server where the certification authority (CA) you want to access is located.
3. Click **Download a CA certificate, certificate chain, or CRL**.
4. Do one of the following:
   - If you want to trust all the certificates issued by this certification authority (CA), click **Install this CA certificate chain**.
   - If the certification authority has been renewed, you will have the choice of which version of the CA certificate you want to download:
   - Select the encoding method you want for the CRL: **DER** or **Base 64**.
   - Under **CA Certificate**, click the CA certificate you want to download, and then click **Download CA certificate** or click **Download CA certificate chain**.
   - In **File Download**, click **Open this file from its current location**, and then click **OK**.
   - When the Certificate dialog box appears, click **Install this certificate**.
   - In the Certificate Import wizard, click **Automatically select the certificate store based on the type of certificate**. This places the CA certificate in your Trusted Root store.
5. If you are finished using the Certificate Services Web pages, close Internet Explorer.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Queues for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Queues for Message Queuing**

This section shows you how to:

- Create queues
- Allow only authenticated messages on queues
- Change the privacy level for queues
- Find queues
- Delete queues
- Purge all messages in a queue
- Take outgoing queues offline
- Pause or resume an outgoing queue
- Change queue labels
- Change queue type IDs
- Change the base priority of queues
- Specify or view queue multicast addresses and ports
- Set the message storage size for queues
- Manage queues on other computers
- Manage queues using Active Directory Users and Computers
- Administer Journals for Message Queuing
- Administer Queue Aliases for Message Queuing

# Create queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create queues**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue folder.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)

3. Point to **New**, and then click **Public Queue** (or **Private Queue**) to open the **New Object – Public Queue** dialog box (or the **New Private Queue** dialog box).
4. Under **Queue name**, type a name for the new queue. Or, if you want to create a queue to accept transactional messages, type a name and select the **Transactional** check box.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.
- You cannot create queues in the Outgoing Queues or System Queues folder. These queues are created automatically.
- The queue objects for the queues residing on a particular computer are child objects of the msmq object of the applicable computer. Thus, to create a queue, a user must have the Create All Child Objects permission for the msmq object under which the queue will be created.
- You can create public queues on remote computers using the Active Directory Users and Computers snap-in provided you have domain administrative permissions and are logged on using a domain user account.
- When you create a queue, you are prompted to specify the minimal information needed. Each queue has many more properties (attributes) that can be set. After a queue is created, the values of many additional attributes can be viewed and modified. For information on how to do this, see Related Topics.
- When you create a queue, the default permission is that everyone can send to this queue. For tighter security, you can change the default security permissions for the queue. You can also specify properties for the queue when you create it. For example, you can specify to accept authenticated messages only. For instructions, see Allow only authenticated messages on queues.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Allow only authenticated messages on queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To allow only authenticated messages on queues**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**.
4. On the **General** page, select the **Authenticated** check box. Or, to accept any messages on the queue, clear the **Authenticated** check box.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- If you select the **Authenticated** check box, the queue accepts only authenticated messages.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the privacy level for queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the privacy level for queues**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**.
4. On the **General** page, in **Privacy Level**, do one of the following:

   - To have the queue accept both encrypted and unencrypted messages, click **Optional** (the default).
   - To have the queue accept only encrypted messages, click **Body**.
   - To have the queue accept only unencrypted messages, click **None**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.
- Privacy levels are used to specify whether a queue accepts encrypted messages, unencrypted messages, or both by selecting the privacy level for the queue. If the queue privacy level is set to None, the queue accepts only unencrypted messages. If the queue privacy level is set to Body, the queue accepts only encrypted messages. If the queue privacy level is set to Optional, the queue accepts both unencrypted and encrypted messages. You can check whether a message sent to the queue was encrypted or unencrypted by using Active Directory Users and Computers (or programmatically by checking the PROPID_M_PRIV_LEVEL message property).

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Find queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To find queues**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click any folder or object shown.
4. Click **Find**.
5. In **Find**, click the arrow that opens the list, and then click **Message Queuing Queue**.
6. On the **Find Message Queuing Queue** page, in **Label** or **Type ID**, type the appropriate queue information, and then click **Find Now**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- If you leave **Label** and **Type ID** empty, a list of all queues will be displayed. If you enter information in both **Label** and **Type ID**, only those queues that satisfy both criteria will be displayed.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete queues**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)/*YourQueue*

3. Click **Delete**.
4. When prompted, click **Yes** to delete the queue.

### Important

- When you delete a queue, all messages within the queue are also deleted.

### Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- You cannot delete queues in the Outgoing Queues or System Queues folder.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.
- When you delete a queue, the triggers associated with that queue are not deleted. If you later re-create a queue of the same name, any existing triggers will be used by this queue. However, this re-created queue will not be monitored by the Message Queuing Triggers service until the computer is restarted, or the associated triggers disabled, and then enabled again. For instructions on setting the enabled or disabled property for a trigger, see View or change properties of triggers and rules for triggers.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Purge all messages in a queue

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To purge all messages in a queue**

1. Open Computer Management.
2. In the console tree, right-click **Queue messages** (or **Journal messages**).

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)/*YourQueue/*Queue messages/Journal messages

3. Point to **All Tasks**, and then click **Purge**.
4. When prompted, click **Yes**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- You cannot purge individual messages from a queue.
- To increase performance, messages in journals and dead-letter queues must be purged on a regular basis.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Take outgoing queues offline

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To take outgoing queues offline**

1. Open Computer Management.
2. In the console tree, right-click **Message Queuing**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing

3. Point to **All Tasks**, and do one of the following:

   - To take Message Queuing offline from the network, click **Take Message Queuing Offline**.
   - To bring Message Queuing back online, click **Bring Message Queuing Online**.

4. When prompted, click **Yes**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- When you take Message Queuing offline from the network, you pause the operation of all outgoing queues on the local computer. This is useful when you communicate over a slow, expensive connection and want to defer sending messages in all outgoing queues on the computer to a later time.
- You can also pause the operation of a single outgoing queue. For more information, see Related Topics.
- This task can be performed only by using the Computer Management snap-in.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Pause or resume an outgoing queue

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To pause or resume an outgoing queue**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/Outgoing Queues/*YourOutgoingQueue*

3. Point to **All Tasks**.
4. Click **Pause**. Or, to resume the operation of the queue, click **Resume**.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- When you pause the operation of an outgoing queue, you postpone the sending of messages from that queue to the corresponding destination queue. This way, you can send all pending messages to a destination queue at a later time.
- You can also pause the operation of all outgoing queues by taking Message Queuing offline from the network. For more information, see Related Topics.
- The icons of outgoing queues that are offline are marked by an X on a circular red background in the Computer Management console tree.
- This task can be performed only by using the Computer Management snap-in.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change queue labels

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change queue labels**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**.
4. On the **General** page, in **Label**, type the new label for the queue.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- A queue label is a string with a maximum length of 124 Unicode characters that can be used to identify the queue. For example, queues that accept messages sent by a specific application may all have the label "Messages from my application."
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change queue type IDs

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change queue type IDs**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**.
4. On the **General** page, in **Type ID**, type the new queue type ID.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- The queue type ID specifies the function or type of service provided by the queue. The queue type ID must be a valid GUID in the form {*dddddddd-dddd-dddd-dddd-dddddddddddd*}, where *d* is a hexadecimal text digit. The use of the queue type ID is optional and depends on the requirements of the Message Queuing application.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change the base priority of queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change the base priority of queues**

1. Open Computer Management.
2. In the console tree, right-click the applicable public queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/Public Queues/ *YourQueue*

3. Click **Properties**.
4. On the **General** page, in **Base Priority**, type a new value or use the UP ARROW or DOWN ARROW keys to enter a new value.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- The base priority can be set from -32768 to 32767. The default priority setting is 0.
- The base priority (also known as queue priority) can be set only for public queues. Private queues do not support base priority.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Specify or view queue multicast addresses and ports

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To specify or view queue multicast addresses and ports**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**, and then click **Multicast**.
4. Under **Multicast address**, type the multicast address and port number in the *IP_Address*:*PortNumber* syntax.

**Notes**

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- A multicast address and a port number can be associated with any public or private queue. However, in workgroup mode, multicast addresses can be associated only with private queues, and in domain mode, a Windows Server 2003 family domain controller must be available to associate multicast addresses with public queues.
- No spaces or leading zeros are allowed in the multicast address that you type.
- IP multicast addresses must consist of four bytes and must lie in the class D range from 224.0.0.0 to 239.255.255.255. However, only certain ranges of addresses in this range are available for sending multicast messages. For more information, see Related Topics.
- You can also specify or view the multicast addresses and port numbers of queues using the Active Directory Users and Computers snap-in. For more information, see Related Topics.
- After setting the multicast properties of a remote queue, it may take up to 15 minutes for the change to take effect.
- On a computer with multiple NICs, a problem will arise when the computer tries to send multicast messages by means of these multiple NICs. In effect, Message Queuing will randomly choose a NIC for sending multicast messages. If the private NIC is chosen, multicast recipients will not receive the message. To work around this issue, you can specify the source IP address to be used for sending multicast messages. To do this, create the string value **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\MulticastBindIP**, in the usual IP address format. After setting the registry, restart the Message Queuing service for the changes to take effect. For more information, see IP multicasting.

  **Caution**

  - Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

- Be aware of the security implications of multicasting. Messages cannot be encrypted, and messages could be read or used by unauthorized persons. Ensure that the address specified is used only for Message Queuing multicasting.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the message storage size for queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the message storage size for queues**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**.
4. Select the **Limit message storage to (KB)** check box, and then type the total size, in kilobytes, of all queue messages that can be stored in the queue.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- Any changes made will not take effect until the Message Queuing service is stopped and restarted.
- The message storage size limit, or quota, for a queue specifies the maximum cumulative size of all messages contained in the applicable queue. This quota can be any integer between 0 and 4,294,967,294.
- When the message storage size limit for a destination queue is reached, new incoming messages are discarded, and a negative acknowledgment message indicating that the destination queue is full is generated. Messages can be placed in the queue only after one or more messages are removed from the queue.
- If you clear the **Limit message storage to (KB)** check box, the message size will be limited only by the available disk space on the local computer.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage queues on other computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manage queues on other computers**

1. Open Computer Management.
2. Right-click **Computer Management**, and then click **Connect to another computer**.
3. In the **Select Computer** dialog box, select the computer on which you want to manage queues, and then click **OK**.
4. Perform the desired task as you would for the local computer.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- To manage public queues, you must have access to Active Directory.
- You cannot manage private queues located in a remote computer.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage queues using Active Directory Users and Computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manage queues using Active Directory Users and Computers**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click the applicable queue.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq/*YourQueueFolder* (such as Private Queues for a private queue)/*YourQueue/YourMessage*

4. Complete the desired task as you would using Computer Management.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- This method can be used only if the local computer belongs to a Windows Server 2003 family or Windows 2000 domain and can contact a domain controller.
- You can create, delete, and change the properties of public queues on remote computers using the Active Directory Users and Computers snap-in only if you have domain administrative permissions and are logged on using a domain user account.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Journals for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Journals for Message Queuing**

This section shows you how to:

- Enable or disable target journaling
- Set the journal storage size for queues

# Enable or disable target journaling

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable or disable target journaling**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**.
4. On the **General** page, in **Journal**, select the **Enabled** check box. Or, to disable target journaling for the queue, clear the **Enabled** check box.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- Target journaling is enabled or disabled on a queue basis.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Set the journal storage size for queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the journal storage size for queues**

1. Open Computer Management.
2. In the console tree, right-click the applicable queue.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (Public Queues or Private Queues)/*YourQueue*

3. Click **Properties**.
4. On the **General** page, in **Journal**, select the **Limit journal storage to (KB)** check box, and then type the total size (in kilobytes) of all journal messages that can be stored in the queue journal.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- The journal storage size limit, or quota, for a queue specifies the maximum cumulative size of all journal messages contained in the applicable queue journal. This quota can be any integer between 0 and 4,294,967,294.
- The journal storage size limit is applicable only when target journaling is enabled.
- When the journal storage size limit is reached, additional messages can no longer be placed in the queue journal until the cumulative size of the journal messages in the queue journal drops below the specified limit.
- If you clear the **Limit journal storage to (KB)** check box, the journal size will be limited by the computer quota of the local computer.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

# Administer Queue Aliases for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Queue Aliases for Message Queuing**

This section shows you how to:

- Create queue aliases
- Add descriptions to queue aliases
- View or change properties of queue aliases
- Delete queue aliases

# Create queue aliases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create queue aliases**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then on the **View** menu, click **Advanced Features**.
3. In the console tree, right-click the applicable container.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourContainer* (such as Computers or Domain Controllers)
4. Point to **New**, and then click **Message Queuing Queue Alias** to open the **New Object - Message Queuing Queue Alias** dialog box.
5. Under **Queue alias name**, type the alias.
6. Under **Format name**, type the applicable format name.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- The format name typed can be any public, private, or direct single-element format name. The validity of the format name typed and the existence of the queues to which the queue alias points are not tested during this procedure. For examples of valid format names, see **Queue Names** in Related Topics.
- Multiple aliases can be created for the same physical queue.
- When you create a queue alias in Active Directory, you are prompted to specify the minimal information needed to establish the object in Active Directory. Each queue alias has many more properties (attributes) that can be set. After a queue alias is created, the values of many additional attributes can be viewed and modified. For information on how to do this, see Related Topics.
- A queue alias can be used to point to a private queue and publish a private queue. For best security practice, create a queue alias with the narrowest security permissions possible.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Add descriptions to queue aliases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To add descriptions to queue aliases**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then on the **View** menu, click **Advanced Features**.
3. In the console tree, click the applicable container.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourContainer* (such as Computers or Domain Controllers)
4. In the details pane, double-click the applicable queue alias or right-click the queue alias, and then click **Properties**.
5. Under **Description**, type a description for the alias queue.

## Notes

- To see the new queue alias description, press F5 to refresh the pane.
- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View or change properties of queue aliases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view or change properties of queue aliases**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then on the **View** menu, click **Advanced Features**.
3. In the console tree, click the applicable container.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourContainer* (such as Computers or Domain Controllers)
4. In the details pane, double-click the applicable queue alias or right-click the queue alias, and then click **Properties**.
5. View or change the queue alias properties as needed.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- The format name typed can be any public, private, or direct single-element format name. The validity of the format name typed and the existence of the queues to which the queue alias points are not tested during this procedure.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete queue aliases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete queue aliases**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then on the **View** menu, click **Advanced Features**.
3. In the console tree, click the applicable container.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourContainer* (such as Computers or Domain Controllers)
4. In the details pane, click the applicable queue alias, and then press the DELETE key.

**Note**

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Distribution Lists for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Distribution Lists for Message Queuing**

This section shows you how to:

- Create distribution lists
- View, add, or delete elements in a distribution list
- View or change properties of distribution lists
- Get a list of distribution lists containing a given element
- Delete distribution lists

# Create distribution lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create distribution lists**

1. Open Active Directory Users and Computers.
2. In the console tree, double-click the domain node.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*

3. Right-click the folder in which you want to add the group, point to **New**, and then click **Group**.
4. In the **New Object – Group** dialog box, type the name of the distribution list under **Group Name**, select the group scope that you want to use, and then select the group type **Distribution**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- You can choose to give your distribution list universal, global, or domain local scope, as follows:
  - **Universal**. Members of universal groups can include other groups and accounts from any domain in the domain tree or forest and can be granted permissions in any domain in the domain tree or forest.
  - **Global**. Members of global groups can include other groups and accounts only from the domain in which the group is defined and can be granted permissions in any domain in the forest.
  - **Domain local**. Members of domain local groups can include other groups and accounts from Windows Server 2003, Windows 2000, or Windows NT domains and can be granted permissions only within a domain.
- Message Queuing distribution lists are distribution group objects in Active Directory.
- When you create a distribution list (group) in Active Directory, you are prompted to specify the minimal information needed to establish the object in Active Directory. Each distribution list (group) has many more properties (attributes) that can be set. After a distribution list (group) is created, the values of many additional attributes can be viewed and modified. For information on how to do this, see Related Topics.
- For information on how to add and remove members from distribution lists (groups), see Related Topics.
- With distribution lists, a single operation sends the same message to multiple destinations, and does so by duplicating packets from senders to receivers. For best security practice, consider security permissions for the distribution list object in Active Directory — who is authorized to manage it and use it.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Working with MMC console files

# View, add, or delete elements in a distribution list

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view, add, or delete elements in a distribution list**

1. Open Active Directory Users and Computers.

2. In the console tree, double-click the domain node.

3. Click the folder that contains the distribution group.

4. In the console tree, right-click the applicable distribution list (group).

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/Folder/*YourDistributionList(Group)*

5. Click **Properties**.

6. On the **Members** page, you can view the list of members in the distribution list (group) selected. The explicit members of a distribution list can be public queues, queue aliases, and other distribution lists. You can also delete elements (members) from the distribution list (group) as follows: click the applicable element (member), click **Remove**, and then click **OK**.

7. To add a public queue to a distribution list (group), do the following:

   In the console tree, right-click the applicable queue (console tree location is: Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer*/msmq/*YourPublicQueue*).

   - Click **Properties**.

   - On the **Member of** page, click **Add**.

   - On the **Select Groups** dialog box, in **Name**, type the name of a distribution list (group) or the names of several distribution lists (groups) separated by semicolons, click **OK**, and then click **OK** again. Or click **Advanced** to search for distribution lists (groups), enter the applicable parameters, click **Find Now**, select the applicable distribution lists (groups), click **OK**, click **OK** again, and then click **OK** a third time.

8. To add private queues or URL-named queues to a distribution list (group), do the following:

   - Create an alias for each private queue or URL-named queue that you want to add to the distribution list (group). For information on how to create an alias for a private queue or a URL-named queue, see Related Topics.

   - In the console tree, right-click the distribution list (group) to which you want to add a queue alias or queue aliases (console tree location is: Active Directory Users and Computers/*YourDomain*/Users/*YourDistributionList(Group)*).

   - Click **Properties**.

   - On the **Members** page, click **Add**. In the **Select Groups** dialog box, click **Look For**, select the **Other objects** check box, clear the remaining check boxes, and click **OK**. In **Name**, type the name of a queue alias or the names of

several queue aliases separated by semicolons, click **OK**, and then click **OK** again. Or click **Advanced** to search for queue aliases, enter the applicable parameters, click **Find Now**, select the queue alias, click **OK**, click **OK** again, and then click **OK** a third time.

9. To add a queue alias to one or several distribution lists (groups), do the following:

   - In the console tree, right-click the applicable queue alias (console tree location is: Active Directory Users and Computers/*YourDomain*/*YourContainer* (such as Computers or Domain Controllers)/*YourAlias*).
   - Click **Properties**.
   - On the **Member of** page, click **Add**.
   - On the **Select Groups** dialog box, in **Name**, type the name of a distribution list (group) or the names of several distribution lists (groups) separated by semicolons, click **OK**, and then click **OK** again. Or click **Advanced** to search for distribution lists (groups), enter the applicable parameters, click **Find Now**, select the applicable distribution lists (groups), click **OK**, click **OK** again, and then click **OK** a third time.

10. To add a distribution list (group) as a member of another distribution list (group), do the following:

    - In the console tree, right-click the distribution list (group) that you want to be a new member of another distribution list (group) (console tree location is: Active Directory Users and Computers/*YourDomain*/Users/*YourDistributionList(Group)*).
    - Click **Properties**.
    - On the **Member of** page, click **Add**.
    - On the **Select Groups** dialog box, in **Name**, type the name of a distribution list (group) or the names of several distribution lists (groups) separated by semicolons, click **OK**, and then click **OK** again. Or click **Advanced** to search for distribution lists (groups), enter the applicable parameters, click **Find Now**, select the applicable distribution lists (groups), click **OK**, click **OK** again, and then click **OK** a third time.

### Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- Message Queuing distribution lists are distribution group objects in Active Directory.
- The explicit members of distribution lists can be public queues, queue aliases, and other distribution lists, but not private queues or URL-named queues. Private queues and URL-named queues can be included in a distribution list by using queue aliases. For information on how to create an alias for a private queue or a URL-named queue, see Related Topics.

Working with MMC console files

# Get a list of distribution lists containing a given element

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To get a list of distribution lists containing a given element**

1. Open Active Directory Users and Computers.
2. In the console tree, double-click the domain node.
3. Click the folder that contains the distribution group.
4. In the console tree, do one of the following:
   - Right-click the applicable distribution list (group)

     Console tree location is: Active Directory Users and Computers/*YourDomain*/Folder/*YourDistributionList(Group)*)
   - Right-click the applicable public queue

     Console tree location is: Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer*/msmq/*YourPublicQueue*)
   - Right-click the applicable queue alias

     Console tree location is: Active Directory Users and Computers/*YourDomain*/*ContainerForAliases*/*YourAlias*)
5. Click **Properties**.
6. On the **Member of** page, you can view the list of distribution lists (groups) of which the applicable object is a member. For information on how to add the object selected to another distribution list (group), see Related Topics. You can remove the applicable object from a distribution list (group) of which it is a member as follows: click the name of the host distribution list (group), and then click **Remove**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- Message Queuing distribution lists are distribution group objects in Active Directory.
- The explicit members of distribution lists can be public queues, queue aliases, and other distribution lists, but not private queues or URL-named queues. Private queues and URL-named queues can be included in a distribution list by using queue aliases.

# Administer Messages for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Messages for Message Queuing**

This section shows you how to:

- View message properties
- Set the default lifetime for messages
- Manage messages on other computers
- Manage messages using Active Directory Users and Computers

# View message properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view message properties**

1. Open Computer Management.
2. In the console tree, right-click **Queue messages** (or **Journal messages**).

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/*YourQueueFolder* (such as Public Queues or Private Queues)/*YourQueue/*Queue messages/Journal messages

3. In the details pane, right-click a message, and then click **Properties**.
4. Click each tab to view the various message properties and other relevant information.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- You can also perform this task using the Active Directory Users and Computers snap-in. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Working with MMC console files

# Set the default lifetime for messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To set the default lifetime for messages**

1. Open Active Directory Sites and Services.
2. On the **View** menu, click **Show Services Node**.
3. In the console tree, right-click **MsmqServices**.

   **Where?**

   - Active Directory Sites and Services/Services/MsmqServices

4. Click **Properties**.
5. On the **General** page, type a new value and select new units as needed.

### Notes

- To open Active Directory Sites and Services, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
- Note that the default lifetime for transactional messages is 4 days.
- The default lifetime of a message is also known as the time-to-reach-queue (TTRQ).

### Important

- For best security practice, it is recommended that messages not be set with an infinite lifetime to ensure tighter control over messages that are traveling through the network. Also, MSMQ can request that a negative acknowledgment message is returned if a timer expires, and Message Queuing sends the appropriate negative acknowledgment message to the administration queue specified by the message.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Manage messages using Active Directory Users and Computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To manage messages using Active Directory Users and Computers**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click the applicable message.

   **Where?**

   - Active Directory Users and Computers/*YourDomain/YourDomain/YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq/*YourQueueFolder* (such as Private Queues for a private queue)/*YourQueue/YourMessage*

4. Complete the desired task as you would using Computer Management.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- This method can be used only if the local computer belongs a Windows Server 2003 family or Windows 2000 domain and can contact a domain controller.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Administer Triggers for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administer Triggers for Message Queuing**

This section provides instructions for creating and managing triggers:

- Create triggers
- Create and attach rules to triggers
- View or change properties of triggers and rules for triggers
- Delete triggers and rules for triggers
- Change default configuration values for triggers
- Configure trigger resources for server clusters

# Create triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create triggers**

1. Open Computer Management.
2. In the console tree, right-click **Triggers**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/Triggers/Triggers

3. Point to **New**, and then click **Trigger**.
4. In **Trigger name** on the first page of the **New Trigger** dialog box, type a name for the new trigger.
5. If you want to specify a user-defined queue as the *monitored queue*, in **Queue path name**, type the path name of the queue with which the trigger will be associated in the *ComputerName**QueueName* syntax, or the .*QueueName* syntax for the local computer. (Do not use format names.) Otherwise, click the name of an automatically created queue on your computer.
6. Click **Peeking**, **Retrieval**, or **Transactional retrieval** to specify the type of message processing.
7. Click the applicable check box to configure the trigger as enabled or disabled.
8. Click the applicable check box to configure the trigger as serialized or not serialized, and then click **Next**.
9. On the second page of the **New Trigger** dialog box, to attach an existing rule to the trigger, select a rule in the **Rules** list, and then click **Attach**
10. To remove a rule from a trigger, select a rule in the **Attached Rules** list, and then click **Detach**.
11. To change the order in which rules are tested for the triggers, click the **Up** and **Down** buttons.
12. When you have the list of attached rules that you want, click **Finish**.

**Notes**

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- Triggers are not installed by default during Message Queuing installation. For information on installing triggers, see Installing Message Queuing triggers.
- This procedure can also be performed by opening the **New Trigger** dialog box from the Triggers folder under any monitored queue in the console tree as follows: right-click **Triggers**, point to **New**, and then click **Trigger**. In this case, the queue automatically becomes the monitored queue.
- Regardless of where the creation of a trigger is initiated, all the triggers created on the local computer, which is called the *trigger set*, are listed in the details pane of the Computer Management snap-in when **Triggers** is selected in the console tree under the Triggers folder. By default, for each trigger, the following is displayed in the details pane:

    - Trigger name
    - Name of the monitored queue
    - Number of rules attached to the trigger
    - Whether the trigger is enabled
    - Whether the trigger is serialized
    - Message processing type

- Before creating a trigger, verify that the account under which the Message Queuing Triggers service is running has been granted the Peek Message permission and the Receive Message permission for all existing queues that will be associated with triggers having the retrieval or transactional-retrieval processing type. For more information, see Related Topics.

- After you type the name of a user queue to which the trigger will be associated in **Queue path name**, the existence of the queue is verified. If a queue with the name typed cannot be found, an error message appears.

- Triggers can be serialized or nonserialized. A serialized trigger tests the conditions of all the rules associated with it on each message and performs all the applicable actions before moving on to the next message in the order in which the messages arrive. However, the throughput is lower than for nonserialized triggers because the messages are processed one at a time. Nonserialized triggers permit higher throughput but may fail to perform a given operation on the messages in the order in which they arrive. This occurs, for example, when multiple messages are processed simultaneously. If you create multiple triggers for a particular queue and at least one of them is serialized, all the triggers will behave as serialized triggers, even if they are not defined as serialized. Triggers with the transactional-retrieval processing type can only be serialized. If message processing order is significant, it is recommended that you use only a single trigger per queue and enable the serialized option, because the order of trigger firing is random with respect to their GUIDs.

- By default, the Message Queuing Triggers service runs under the Network Service account. Note that when the Triggers service is running under the Network Service account, it does not interact with the desktop. If this functionality is required, you can configure the Triggers service to run under the Local System account and enable interaction with the desktop in Computer Management. For best security practice, do not change the default account to a less secure account unless absolutely necessary. The Triggers service must run under an account with administrator permissions.

- Executable files that are invoked by triggers are invoked with the same security privileges as those assigned to the Triggers service.

- After a trigger has been created, rules can be attached to it. For more information, see Related Topics.

- When you delete a queue, the triggers associated with that queue are not deleted. If you later re-create a queue of the same name, any existing triggers will be used by this queue. However, this re-created queue will not be monitored by the Message Queuing Triggers service until the computer is restarted, or the associated triggers disabled, and then enabled again. For instructions on setting the enabled or disabled property for a trigger, see View or change properties of triggers and rules for triggers.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Create and attach rules to triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To create and attach rules to triggers**

1. Open Computer Management.
2. In the console tree, right-click **Rules**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/Triggers/Rules

3. Point to **New**, and then click **Rule**.
4. On the first page of the **New Rule** dialog box, in **Rule name**, type a name for the new rule, and in **Rule description**, type an optional description.
5. Click **Next**.
6. In **New condition**, enter a condition by selecting the initial string in the list box, typing the applicable final string in the **Filter value/string** text box below, and clicking **Add**. The complete condition then appears in **Condition list**. You can create additional conditions by repeating this operation.
7. When you finish creating the conditions that you want to create, click **Next**.
8. To specify whether the trigger will invoke a stand-alone executable or a COM component (the default), click the applicable button.
9. To specify that the trigger invoke a COM component, in **COM component invocation**, select **Invoke COM component**. In **Component ProgID**, type the ID of the COM component, and in **Method name**, type the name of the method.
10. To specify that the trigger invoke a stand-alone executable, in **Standalone executable invocation**, select **Invoke standalone executable(EXE)**. In **Executable path**, type the full path of the executable file.
11. To add parameters for either a COM component or a stand-alone executable, click **Parameters**. Select a parameter in the **Parameter** list box. If the parameter is a numeric literal or a string literal, type its value in **Literal value**. Click **Add** to add the parameter to the **Invocation parameters** list. Repeat this operation for each parameter that you want to add, and use the **Up** and **Down** buttons to change the order in which the parameters are transferred to the program. Click **OK**, and then click **Finish**.
12. To attach existing rules to a trigger, do the following:

    - In the console tree, click **Triggers**.

      Console tree location is: Computer Management/Services and Applications/Message Queuing/Triggers

      Or, click **Triggers** under the applicable monitored queue.

      Console tree location is: Computer Management/Services and Applications/Message Queuing/ *YourQueueFolder* (Public Queues, Private Queues, or System Queues)/ *YourMonitoredQueue*/Triggers

- In the details pane, right-click the applicable trigger, click **Properties**, and then click the **Attached Rules** tab. Select the rule you want to attach to the trigger from the **Rules** list, and then click **Attach** to move it to the **Attached Rules** list. Then click **OK**.

### Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.

- All the rules created on the local computer, which is called the *rule set*, are listed in the details pane of the Computer Management snap-in when **Rules** is selected in the console tree.

- A rule is composed of one or more conditions and an action that is executed when the conditions are true. Each condition is applied to a message when it arrives at the monitored queue, and the result is either true or false. After being created, the conditions applied to a particular rule are listed in **Condition list** on the second page of the **New Rule** dialog box as well as on the **Conditions** page of the **Properties** dialog box for that rule. A condition can be eliminated from this list by selecting it and clicking **Remove**. Multiple conditions must all be true for an action to be executed. If no condition is specified, a true value will always be returned. This is useful when you want a trigger to fire unconditionally every time a message arrives at the monitored queue.

- The actions performed when a condition is true are expressed either in the form of an executable file and parameters (arguments) or in the form of a COM component, a method, and parameters. You can also invoke other types of files by making them parameters of an .exe file. For example, you can invoke an .msc file by specifying mmc.exe as the executable file and including the full path of the .msc file as an invocation parameter of the string literal type. You can specify one or more parameters to be passed per action. The supported parameters are listed in the list box on the **Invocation Parameters** dialog box.

- If your trigger invokes an executable file with command-line arguments, these arguments can be included as parameters of the string literal type. However, you must add a separate parameter for each command-line argument.

- You can attach multiple rules to a trigger. In this case, the rules are executed in the order in which they are displayed on the **Attached Rules** page of the **Properties** dialog box for that rule. You can change the priority (order of execution) of the rules in the list. To do so, use the **Up** and **Down** buttons on this page to change the order of priority of each rule as needed to give the rule a higher or lower priority, respectively. You can also detach rules on this page by selecting each rule that you want to detach and clicking **Detach**. For more information, see Related Topics.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View or change properties of triggers and rules for triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view or change properties of triggers and rules for triggers**

1. Open Computer Management.
2. In the console tree, click **Triggers** or **Rules**, whichever is applicable.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/Triggers/Triggers (or Rules)

3. In the details pane, right-click the applicable trigger or rule, and then click **Properties**.
4. View or change trigger properties as needed. Note that trigger names cannot be changed.

| Trigger Property | Tab |
|---|---|
| Trigger name (view only) | **General** |
| Monitored queue (path name for a user queue) | **General** |
| Message processing type | **General** |
| Enabled or disabled | **General** |
| Serialized or nonserialized | **General** |
| Rules attached to the trigger | **Attached Rules** |
| Rules available for the trigger | **Attached Rules** |

Or, view or change rule properties as needed. Note that rule names cannot be changed.

| Rule property | Tab |
|---|---|
| Rule name (view only) | **General** |
| Rule description | **General** |
| Conditions applied to the rule | **Rule Condition** |
| Whether the rule launches a stand-alone executable or a COM component | **Rule Action** |
| Path of a stand-alone executable | **Rule Action** |
| COM component ProgID | **Rule Action** |
| Method chosen for a COM component | **Rule Action** |
| Parameters used and their order. For types of parameters, see Trigger rules. | **Invocation Parameters** |

**Notes**

- To open Computer Management, right-click **My Computer**, and then click **Manage**.

- Triggers are not installed by default during Message Queuing installation. For information on installing triggers, see Installing Message Queuing triggers.

- The **Properties** dialog box for a specific trigger has **General** and **Attached Rules** tabs. The **Properties** dialog box for a specific rule has **General**, **Rule Condition**, and **Rule Action** tabs, and there is an **Invocation Parameters** dialog box, which can be accessed from the **Rule Action** page.

- The monitored queue of an existing trigger cannot be changed.

- When you delete a queue, the triggers associated with that queue are not deleted. If you later re-create a queue of the same name, any existing triggers will be used by this queue. However, this re-created queue will not be monitored by the Message Queuing Triggers service until the computer is restarted, or the associated triggers disabled, and then enabled again.

- A rule consists of one or more conditions and an action that is executed when the conditions are true. Each condition is applied to a message when it arrives at the monitored queue, and the result is either true or false. The conditions applied to a particular rule are listed in **Condition list** on the **Rule Condition** page of the **Properties** dialog box for that rule. A condition can be eliminated from this list by selecting it and clicking **Remove**. New conditions are composed by selecting a supported initial string in the **New condition** list box and typing a concluding string in the text box below it. Multiple conditions must all be true for an action to be executed. If no condition is specified, a true value will always be returned. This is useful when you want a trigger to fire unconditionally every time a message arrives at the monitored queue.

- The actions performed when the conditions are true are expressed either in the form of an executable file and parameters (arguments) or in the form of a COM component, method, and parameters. You can specify one or more arguments to be passed per action. The supported parameters are listed in the list box on the **Invocation Parameters** dialog box, which can be accessed by clicking **Parameters** on the **Rule Action** page of the **Properties** dialog box for the particular rule.

- The rules displayed on the **Attached Rules** tab are disabled by default, and you must attach them to the trigger to enable them. You can attach multiple rules to a trigger. In this case, the rules are executed in the order in which they are displayed in the **Attached Rules** list. You can change the priority (order of execution) of the rules in the list. To do so, use the **Up** and **Down** buttons on this page to give the rule a higher or lower priority, respectively. You can also detach rules on this page by selecting each rule that you want to detach and clicking **Detach**. For more information, see See Also.

- All triggers and rules for triggers created on the local computer are displayed in the details pane of the Computer Management snap-in when the applicable folder is selected in the console tree.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Delete triggers and rules for triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To delete triggers and rules for triggers**

1. Open Computer Management.
2. In the console tree, click **Triggers** or **Rules**, whichever is applicable.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/Triggers/Triggers (or Rules)

3. In the details pane, right-click the applicable trigger or rule, and then click **Delete**. Alternatively, you can click the applicable trigger or rule, and then press the DELETE key.

## Notes

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- All triggers and rules for triggers created on the local computer are displayed in the Computer Management snap-in.
- To detach rules from a trigger without deleting them, right-click the applicable trigger in the details pane, and then click **Properties**. Click the **Attached Rules** tab, and then select each rule that you want to detach and click **Detach**. For more information, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Change default configuration values for triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To change default configuration values for triggers**

1. Open Computer Management.
2. In the console tree, click to expand **Message Queuing**, and then right-click **Triggers**.

   **Where?**

   - Computer Management/Services and Applications/Message Queuing/Triggers

3. Click **Properties**, and then change the values in **Initial number of threads**, **Max number of threads**, and **Default message body size** as needed.

**Notes**

- To open Computer Management, right-click **My Computer**, and then click **Manage**.
- All configuration information as well as trigger and rule definitions are stored in the local registry.
- The **Default message body** value is the size of the buffer that the Message Queuing Triggers service will allocate for an incoming message. It is recommended that this value be set equal to a size that will accommodate 90% of all messages that are expected to arrive in monitored queues. If this value is set too small, it will force the service to reallocate these buffers for every message. If it is set too large, an excessive amount of memory will be allocated.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Configure trigger resources for server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure trigger resources for server clusters**

1. Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Cluster Administrator**.

2. To create a Message Queuing Triggers resource:

   - When the **Open Connection to Cluster** dialog box appears, in the **Cluster or server name** list box, select the applicable cluster or server. (If you select a server, the name of the cluster to which it belongs will appear in the console tree.)

   - In the console tree, right-click the cluster group to which you want the Message Queuing Triggers resource to belong (console tree location is: *ClusterName/*Groups/*YourGroup*).

   - On the **File** menu, point to **New**, and then click **Resource**.

   - In the New Resource Wizard, type the applicable information in **Name** and **Description**, select **Message Queuing Triggers** in the **Resource type** list box, and then click **Next**.

   - On the **Possible Owners** page, select the set of possible owners to match that of the Message Queuing resource in the same group, and then click **Next**.

   - On the **Dependencies** page, in **Available resources**, select the name of the Message Queuing resource in the group, and then click **Add**.

   - Select the name of the Network Name resource in the group, click **Add**, and then click **Finish**.

3. If Message Queuing has the Active Directory Integration component installed, enable Kerberos authentication for the Network Name resource on which the Message Queuing resources depend:

   - Bring the Network Name resource offline as follows: In the console tree for the cluster group, right-click the Network Name resource in the details pane, and then click **Take Offline**.

   - Right-click the Network Name resource again, and then click **Properties**.

   - On the **Parameters** tab, select the **Enable Kerberos Authentication** check box to enable authentication. The default setting is that Kerberos authentication is not enabled.

   - Bring the Network Name resource online as follows: In the console tree for the cluster group, right-click the Network Name resources in the details pane, and then click **Bring Online**.

   **Caution**

   - Other resources in the group may also depend on the Network Name resource. These will be taken offline automatically when the Network Name resource goes offline. When you bring the Network Name resource online, bring these other resources online too.

4. To bring the Message Queuing Triggers resource online, in the console tree, click the **Resources** folder. In the details

pane, click the Message Queuing Triggers resource. On the **File** menu, click **Bring Online**.

5. To manage the Message Queuing Triggers resource from Computer Management, create a Generic Application resource in the same cluster group, and configure it to launch the Computer Management MMC snap-in:

   - In the Cluster Administrator console tree, click the cluster group to which the Message Queuing Triggers resource belongs.
   - On the **File** menu, point to **New**, and then click **Resource**. The New Resource Wizard launches.
   - In the New Resource Wizard, type **Computer Management** in the **Name** text box and select **Generic Application** in the **Resource type** list box. Then, click **Next**.
   - On the **Possible Owners** page, select possible owners to match those selected for the Message Queuing Triggers resource. Then, click **Next**.
   - On the **Dependencies** page, under **Available resources**, select the name of the Network Name resource in the group and click **Add**, and then select the Message Queuing Triggers resource previously created and click **Add**. Then, click **Next**.
   - On the **Generic Application Parameters** page, in **Command line**, type **mmc compmgmt.msc**
   - In **Current directory**, type **%windir%/system32**.
   - Select the **Allow application to interact with desktop** check box, select the **Use Network Name for computer name** check box, click **Next**, and then click **Finish**.
   - Bring the resource online using the procedure above. The Computer Management snap-in will appear on the desktop of the computer node that owns the resource.

### Notes

- This task is performed on a computer that is running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition as part of a server cluster, has Message Queuing with Triggers already installed, and has a Message Queuing resource already configured.
- Errors occurring during the performance of this task are recorded in a Windows event log. For example, a "device not ready" error indicates that Message Queuing was not installed on the node.
- Once created, do not rename resources for Message Queuing Triggers.
- The trigger and rule definitions for the cluster resource created are stored in subkeys in the local Windows registry under a special key. The Message Queuing Triggers resource is checkpointed with this registry key and the subkeys under it so that when the resource is moved to a new node (during failover, for example), the required keys are propagated to the local registry on the new node. After failover, the Triggers service can thus continue to process the incoming messages in each monitored queue and invoke the applicable stand-alone executable or COM component according to the rules defined.
- You can use the Generic Application resource created with a dependency on the Message Queuing resource to manage Triggers in the applicable resource group from a local Computer Management snap-in. For more information on these resources, see Related Topics.

#### Information about functional differences

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Monitor and Test Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitor and Test Message Queuing**
This section shows you how to:

- View Message Queuing events
- View external transactions
- Track Message Queuing service counters
- Track Message Queuing queue counters
- Enable route tracking and test messages
- Track message routing
- Send test messages
- Test connectivity using MQPing

# View Message Queuing events

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view Message Queuing events**

1. Open Event Viewer.
2. In the console tree, click **Application**.
3. In the details pane, click the **Source** column to gather the **MSMQ** and **MSMQTriggers** events together.
4. Scroll until you see **MSMQ** and **MSMQTriggers** events listed in the column.

## Notes

- To open Event Viewer, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Event Viewer**.
- When viewing events in Event Viewer, you can sort, filter, and search for events, based on event properties.
- Message Queuing service events can be located with the same procedure, by clicking **System** in the console tree, instead of **Application**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# View external transactions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To view external transactions**

1. Open Component Services.
2. In the console tree, double-click **Component Services**, double-click **Computers**, double-click **My Computer**, and then double-click **Distributed Transaction Coordinator**.
3. To view the status of external transactions, double-click **Transaction List**.
4. To view the statistics of external transactions, double-click **Transaction Statistics**.

## Notes

- To open the Component Services snap-in, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Component Services**.
- The Microsoft Distributed Transaction Coordinator (DTC) must be running to implement external transactions.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Track Message Queuing service counters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To track Message Queuing service counters**

1. Open System Monitor.
2. In the details pane, click the **Add** (+) button on the toolbar.
3. In the **Add Counters** dialog box, click **Use local computer counters** to view counters on the computer that you are using. Or, to view counters for another computer, click **Select counters from computer**, and then click the applicable computer.
4. In **Performance object**, click the arrow that opens the list, and then select **MSMQ Service**.
5. Click **All counters**. Or, click **Select counters from list**, and then select the counters that you want to monitor.
6. Click **Add**.
7. To view the definition of a counter, select a counter name, and then click **Explain**.
8. Click **Close**.

   The monitor graphs appear in the details pane.

## Notes

- To open System Monitor, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Performance**.
- To delete a counter from those tracked, in System Monitor, choose the required counter in the details pane, and then click the **Delete** (X) button on the toolbar.
- You can also use this procedure to track other categories of Message Queuing performance objects, including MSMQ Session, MSMQ Incoming HTTP Traffic, MSMQ Outgoing HTTP Session, MSMQ Outgoing Multicast Session, and MSMQ Incoming Multicast Session objects.
- You can view performance data from System Monitor in Chart, Report, or Histogram views, and you can log the performance data to a file. For more information on System Monitor, see System Monitor overview.
- For more information on monitoring Message Queuing, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Track Message Queuing queue counters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To track Message Queuing queue counters**

1. Open System Monitor.
2. In the details pane, click the **Add** (+) button on the toolbar.
3. In the **Add Counters** dialog box, click **Use local computer counters** to view counters on the computer that you are using. Or, to view counters for another computer, click **Select counters from computer**, and then click the applicable computer.
4. In **Performance object**, click the arrow that opens the list, and then select **MSMQ Queue**.
5. Click **All counters**. Or, click **Select counters from list**, and then select the counters that you want to monitor.
6. Click **All instances**. Or, click **Select instances from list**, and then select the instances you want to monitor.
7. Click **Add**.
8. To view the definition of a counter, select a counter name, and then click **Explain**.
9. Click **Close**.

   The monitor graph appears in the details pane.

## Notes

- To open System Monitor, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Performance**.
- To delete a counter from those tracked, in System Monitor, choose the required counter in the details pane, and then click the **Delete** (X) button on the toolbar.
- You can view performance data from System Monitor in Chart, Report, or Histogram views, and you can log the performance data to a file. For more information on System Monitor, see System Monitor overview.
- For more information on monitoring Message Queuing, see Related Topics.

# Enable route tracking and test messages

Updated: September 8, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To enable route tracking and test messages**

1. Click **Start**, click **Run**, type **regedit**, and then click **OK**.
2. Click to expand **My Computer**, click to expand **HKEY_LOCAL_MACHINE**, click to expand **SOFTWARE**, and then click to expand **Microsoft**.
3. Click to expand **MSMQ**, click to expand **Parameters**, and then click **Security**.
4. Right-click the details pane, point to **New**, and then click **DWORD Value**.
5. Type **EnableReportMessages** as the name of the new value, and then press ENTER.
6. Double-click the new **EnableReportMessages** value to change the value data. To enable the sending of test messages, enter a Decimal value of 1 in **Value data**. To disable the sending of test messages, enter a Decimal value of 0 in **Value data**. This is the default value.
7. Click **OK** to save the value. After setting the registry, restart the Message Queuing service for the changes to take effect.

## Caution

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

## Notes

- For instructions on sending test messages after the feature is enabled, see Send test messages.
- By enabling this feature, you also enable the message route tracking feature. For more details, see Track message routing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

Sending test messages

# Track message routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To track message routing**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourComputer/*msmq

4. Click **Properties**.
5. Click the **Diagnostics** tab, and then click **Define Tracking**. The **Message Route Tracking** dialog box appears.
6. In **Path name of report queue**, click the applicable report queue. Or, to create a new queue for report messages, click **New** and type the queue path name (such as *MyComputer**MyQueue* or .*MyQueue*).
7. Click **Track all messages** or click **Track only test message**.

**Notes**

- The tracking message route feature is disabled by default after installing Message Queuing. For instructions on turning on this feature, see Enable route tracking and test messages.
- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- After sending test messages is enabled, you can also send a test message from the Computer Management snap-in. To do this, open **Computer Management**, click **Services and Applications**, right-click **Message Queuing**, and then click **Properties**. On the **Diagnostics** tab, click **Define Tracking**.
- Any public queue can serve as a report queue. For information on how to create a new queue for report messages before performing this procedure, see Related Topics.
- If you click **Track all messages** and if the sending application has set the message route tracking flag and the destination queue is located on another computer, all messages sent by such an application from the source computer have their routes tracked. All report messages sent along the route of each message are then sent to the report queue on the source computer. Tracking occurs both for messages sent by the source computer and for messages routed through a Message Queuing server with routing enabled.
- If you click **Track only test message**, report messages are sent only for test messages. For information on how to send a test message, see Related Topics.
- Messages sent locally to a queue on the same computer are not tracked.
- Messages sent over HTTP/HTTPS transport and messages sent to multiple destinations using IP multicast, distribution

lists, or multiple-element format names cannot be tracked in the current version of Message Queuing.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Send test messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To send test messages**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourSourceComputer*/msmq

4. Click **Properties**.
5. On the **Diagnostics** page, click **Send Test**.
6. In **Destination queue**, click the applicable test queue, and then click **Send**. Or, to create a new queue to send test messages to, click **New Queue**, type the full queue path (such as *DestinationComputer**DestinationQueue*), click **OK**, and then click **Send**.
7. Click **Close** to close the dialog box.

**Notes**

- The ability to send a test message is disabled by default after installing Message Queuing. For instructions on turning on this feature, see Enable route tracking and test messages.
- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- After sending test messages is enabled, you can also send a test message from the Computer Management snap-in. To do this, open **Computer Management**, click **Services and Applications**, right-click **Message Queuing**, and then click **Properties**. On the **Diagnostics** tab, click **Send Test**.
- The computer whose msmq object you select is the source computer used to send a test message.
- You can send test messages only to test queues. All test queues are public queues and have a queue type ID of {55EE8F33-CCE9-11CF-B108-0020AFD61CE9}.
- You cannot use a transactional queue as a test queue. Only transactional messages can be sent to transactional queues, and test messages are not transactional. Similarly, you cannot change the type ID of a queue requiring authentication to that of a test queue and send test messages to the queue, because the messages will not be delivered (unless the queue is located on the source computer).
- Because all test messages are sent with the message route tracking flag set, if the source computer has message route tracking enabled and if the test queue is located on another computer, the route of such test messages is tracked and report messages are sent to the report queue on the source computer. For information on how message route tracking is enabled, see Related Topics.

- If you create a queue and immediately send a test message to it, the receiving computer may not receive the test message because of replication delays. In this case, wait several minutes and send the test message again.

- You can verify that the sent test messages arrived at the destination queue by viewing the properties of the messages in the destination queue or by viewing the contents of the report queue on the source computer if message route tracking is enabled. For information on how to view the properties of messages in a particular queue, see Related Topics.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Test connectivity using MQPing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To test connectivity using MQPing**

1. Open Active Directory Users and Computers.
2. On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**.
3. In the console tree, right-click **msmq**.

   **Where?**

   - Active Directory Users and Computers/*YourDomain*/*YourOrganizationalUnit* (such as Computers or Domain Controllers)/*YourCompute/*msmq

4. Click **Send MQPing message**.

## Notes

- To open Active Directory Users and Computers, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
- You can also send an MQPing message as follows: right-click **msmq**, click **Properties**, click the **Diagnostics** tab, and then click **MQPing**.
- When you send an MQPing message to a computer, Message Queuing waits 45 seconds to receive a response from the computer being tested. A message appears, notifying you whether MQPing succeeded or failed. You may need to send several MQPing messages to determine whether or not a computer is connected.
- You can also send an MQPing message from the Computer Management snap-in. To do this, open **Computer Management**, click **Services and Applications**, right-click **Message Queuing**, and then click **Properties**. On the **Diagnostics** tab, click **MQPing**.

**Information about functional differences**

- Your server might function differently based on the version and edition of the operating system that is installed, your account permissions, and your menu settings. For more information, see Viewing Help on the Web.

# Message Queuing Concepts

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Concepts**

This section is designed to help you understand Message Queuing concepts, and provide background information about installing and administering a Message Queuing network:

- For an overview of Message Queuing features, Message Queuing servers and clients, and Message Queuing with Active Directory, see Introducing Message Queuing.
- For background information about Message Queuing features, see Understanding Message Queuing.
- For information on Message Queuing administration, see Administering Message Queuing.

# Introducing Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Introducing Message Queuing**

This section provides you with an overview of Message Queuing and a summary of Message Queuing features. Information about Message Queuing computers (servers and clients) and Message Queuing objects in Active Directory is also provided. For details, see the following links:

- For a general introduction to Message Queuing, see Message Queuing overview.
- For information about new and legacy features for Message Queuing 3.0, see Message Queuing features.
- For information on Message Queuing and Active Directory, see Message Queuing and Active Directory.
- For an overview of Message Queuing in clusters, see Distributing Message Queuing in a network.
- To learn about the different ways that Message Queuing can be deployed on computers, including information about Message Queuing server, and independent and dependent clients, see Message Queuing Computers.

# Message Queuing overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing overview**

Message Queuing (also known as MSMQ) is a messaging infrastructure and a development tool for creating distributed messaging applications for Microsoft Windows operating systems. Applications developed for Message Queuing send messages to queues, which are temporary storage locations, from which messages can proceed to their final destination as conditions permit. Such applications can communicate across heterogeneous networks and can send messages between computers that may be temporarily unable to connect to one another. Message Queuing provides guaranteed message delivery, efficient routing, security, support for sending messages within transactions, and priority-based messaging. Software products with these features are often referred to in the industry as message-queuing software, store and forward software, or message-oriented middleware.

Message Queuing is not a database and does not provide database functionality, but can be used together with a database, for example for message storage.

With Message Queuing, end users can communicate across networks and computers that may be offline, regardless of the current state of the network and computers. System administrators can use Message Queuing to efficiently manage large, complex networks of computers and message queues. Through Message Queuing, MIS decision makers get more reliable communication and more efficient use of network resources. Developers can focus on business logic instead of networking issues because Message Queuing effectively provides guaranteed network communication.

The current version of Message Queuing introduces a number of new features. For more details, see Message Queuing features. There are also a number of terminology and administrative changes from previous versions. If you are upgrading from a previous version, see the Upgrade overview for a list of changes.

**Message Queuing naming**

In its earliest versions (for Windows NT 4.0, Windows 95, and Windows 98), Message Queuing was called Microsoft Message Queuing Server, or MSMQ 1.0. Similarly, the version for Windows 2000 is officially called Message Queuing 2.0 and is often referred to as MSMQ 2.0 in external literature and other external sources.

The current version of Message Queuing, which is based on the original MSMQ technology and conceptions and is supplemented with numerous new features, is officially called Message Queuing 3.0. This documentation uses the current official name *Message Queuing* as a generic term for all the versions. This is not intended to discourage the use of the already familiar term *MSMQ*. The term MSMQ is used widely by veteran users and in external sources, and it is recommended that all users be familiar with both terms.

# Message Queuing features

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing features**

Following is a summary of the major features of Message Queuing 3.0:

- **Delivering messages over HTTP transport**. New in Message Queuing 3.0, SRMP (SOAP Reliable Messaging Protocol), an XML-based messaging protocol, has been developed for delivering high Quality of Service (QoS) messages. The direct, public, and private format names of administration and response queues can be included in messages sent over HTTP transport. Similarly, the names of administration and response queues in HTTP format can be included in messages sent over ordinary (non-HTTP) transport. For more information about these features, see HTTP/HTTPS messages. For more information on format names, see Queue names.

- **Triggers**. Now a component in Message Queuing 3.0, rather than an add-on module. Triggers provides a mechanism that associates the arrival of each incoming message at a queue with a response that depends on the contents of the message and may invoke either a COM component or a stand-alone executable program. Business rules can be defined and invoked in response to such messages without any additional programming. For more information about this feature, see Triggers.

- **Sending messages to multiple destinations**. New in Message Queuing 3.0, clients are able to send the same message to multiple recipient queues. Lists of destination queues can be specified explicitly by means of distribution group objects (distribution lists) in Active Directory as well as in the form of multiple-element format names. Support for ensuring that messages sent to distribution lists and multiple-element format names will reach queues on downlevel computers is provided. In addition, message delivery to IP multicast destinations using the PGM protocol is supported. For more information about these features, see Multiple Destination Messaging.

- **Message lookup**. Message Queuing 3.0 now provides a way to peek at or retrieve a specific message without using cursors to navigate through the queue until the message sought is located. This functionality is based on a 64-bit lookup identifier that is assigned to each message when it is placed in a destination queue. For more information, see Managing messages.

- **Active Directory Integration**. Message Queuing 3.0 improves integration with, and extension of, the Active Directory service to store all configuration, security, and status information. Message Queuing clients now use the Lightweight Directory Access Protocol (LDAP) to access domain controllers and global catalog servers for Message Queuing-specific information in Active Directory directly without assistance from a Message Queuing server on a domain controller.

- **Microsoft Management Console (MMC) support**. From Message Queuing 3.0, Message Queuing is now administered more completely using snap-ins hosted in an MMC console. Administrative tasks formerly performed in Control Panel are now performed in snap-ins. For more information, see New ways to do familiar Message Queuing tasks.

- **Workgroup support**. Message Queuing can be installed in workgroup mode on computers belonging to a Windows Server 2003 workgroup, rather than to a domain. In addition, a computer on which Message Queuing is installed in a workgroup can later join a domain, and then separate from the domain. For more information about belonging to a workgroup or a domain, see Deploying in a domain environment and Deploying in workgroup mode.

- **Active/active cluster support**. Message Queuing now fully supports the active/active paradigm in a server cluster, which means that Message Queuing can run on all nodes in a server cluster simultaneously. Message Queuing triggers are also integrated with active/active cluster support. For more information on the active/active model in server clusters, see Distributing Message Queuing in a network.

- **Windows CE support**. A special version of a Message Queuing client is preinstalled on handheld and palm-sized computers running the Windows CE 3.0 (or later) operating system. Windows CE also now supports the Message Queuing SRMP protocol, for HTTP messaging.

- **Message backup and restore**. Message storage files, log files, transaction log files, and registry settings can be backed up and restored in case of computer failure. For more information, see Backing up and restoring messages.

- **Message prioritization**. Message prioritization allows urgent or important messages to be sent before less important messages, so you can guarantee adequate response time for critical applications at the expense of less important applications. For more information on sending messages with different priorities, see Message priority.

- **Guaranteed message delivery**. Messages can be stored on a disk-based queue, and then later forwarded to provide guaranteed delivery.

- **Sending messages within transactions**. Using transactional capabilities, you can couple several related actions in a single transaction, ensure messages are delivered in order, ensure messages are delivered only once, and confirm that messages were successfully retrieved from the destination queue. For more information on sending messages within transactions, see Transactional messaging.

- **Dynamic queue creation**. You can create queues or change queue properties on the fly without affecting messaging applications.

- **Message routing**. Message Queuing provides message routing based on the physical topology of the network, session concentration needs, and transport connectivity. Session concentration facilitates the efficient usage of slow communication links. For more information on this subject, see Routing with Message Queuing servers.

- **Cross-platform integration**. Message Queuing can be used across a wide variety of hardware platforms using connectivity products provided by other vendors. For more information on messaging with different platforms, see Cross-Platform Messaging.

These features make Message Queuing ideal for the implementation of semi-independent client/server systems (such as order entry, accounting, and inventory applications), batch processing, queue-based client/server systems (first-come, first-served resource access), and for migration from legacy systems.

# Message Queuing and Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing and Active Directory**

In a domain environment, one or more Message Queuing objects are created in Active Directory during setup for all the types of Message Queuing computers except dependent clients. These objects store various information associated with Message Queuing. The access of users to Message Queuing objects is controlled by assigning security descriptors to the objects. A security descriptor lists the users and groups that are granted or denied access to an object and the specific permissions assigned to those users and groups. For more information about the control of access to Message Queuing objects, see Access control for Message Queuing.

Note that if you install Message Queuing on a computer that is in a domain environment, and later re-image the computer, the new installation of Message Queuing on the computer will create a new Queue Manager globally unique identifier (GUID). This has the following effects:

1. The public queue data from the old installation of Message Queuing will no longer be usable.

2. The new installation of Message Queuing does not recognize the Message Queuing objects in Active Directory that belong to the old installation. This prevents Message Queuing from working in Domain mode, which means that features that require Domain mode, such as access to public queues, authentication, encryption, and routing, will not be available. For more information, see Deploying in a domain environment.

To resolve the latter issue, the domain administrator must delete the Message Queuing objects in Active Directory for the old installation of Message Queuing. Note that this will also delete all public queues for the computer that was re-imaged. For more information about deleting Message Queuing objects, see Remove Message Queuing objects from Active Directory.

Under certain conditions, the name of an object can be changed by the directory service. This can occur if multiple objects with the same name are created simultaneously on different domain controllers. For information about how Active Directory handles object naming and conflicts, see Object names, in the Active Directory online Help file.

The following table lists those objects that are created by Message Queuing by default for each type of Message Queuing computer and that are displayed in the MMC snap-ins. For general information about MMC and snap-ins, see Microsoft Management Console.

| Message Queuing computer | Object name | Object class |
|---|---|---|
| Message Queuing server without directory service functionality or routing services on a domain controller | msmq | MSMQ-Configuration |
| Message Queuing server with directory service functionality on a domain controller | msmq; MSMQ-Settings | MSMQ-Configuration; MSMQ-Settings |
| Message Queuing server with routing services | msmq; MSMQ-Settings | MSMQ-Configuration; MSMQ-Settings |
| Message Queuing server on a nondomain controller | msmq | MSMQ-Configuration |
| Independent client | msmq | MSMQ-Configuration |
| Dependent client | none | not applicable |

When you manually create an object in Active Directory, you are prompted to specify the minimal information needed to establish the object in Active Directory. Each object has many more properties (attributes) that can be set. After an object is created, the values of many of these additional attributes can be viewed and modified in the **Properties** dialog box.

In addition, some information for Message Queuing is also stored in Active Directory in non-Message Queuing objects. Specifically, the User object contains about user certificates, the applicable computer object (above the msmq object) contains certificate information, information related to foreign sites (for cross-platform messaging) is contained in the Sites object, and distribution lists are defined as distribution group objects.

For advanced information about object attributes, see the Active Directory topic in the Microsoft Platform Software Development Kit (SDK). To access the Message Queuing SDK on the Web, refer to the MSDN Library Web site(http://msdn.microsoft.com/library/default.asp).

# Distributing Message Queuing in a network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Distributing Message Queuing in a network**
There are several techniques that you can employ to make a Message Queuing solution highly available to users in a network, and more scaleable.

**Implementing Message Queuing in clusters**
One solution might be to implement the Message Queuing service in clusters. Message Queuing triggers can also be implemented in a cluster. A cluster is a set of computers, known as nodes or hosts, that work together under a common identity to provide a service. All clusters provide load balancing, increased availability, and scalability, but it is important to distinguish the two main cluster solutions. The first, Network Load Balancing, is intended primarily to load balance incoming TCP/IP traffic. Network Load Balancing clusters distribute client connections over multiple servers, providing scalability and high availability for client requests for services and applications, but they do not have failover capabilities. For more information, see Message Queuing in Network Load Balancing clusters.

The second cluster type, a server cluster, is intended primarily to provide failover service from one computer to another. The computers participating in this solution form a different type of cluster. The Network Load Balancing cluster would most commonly be running Web server applications. In contrast, a server cluster would most commonly be running database applications (when used in conjunction with Network Load Balancing). A server cluster appears to network clients as a single, highly available system. For more information, see Message Queuing in server clusters.

Network Load Balancing and the Cluster service can not both be active on the same computer, but by joining the two cluster solutions together to function in a complementary fashion, an overall clustering scheme can be created.

**Web farms**
To increase the availability and scalability of Web server resources, a Web farm is often deployed as a collection of independent servers, to which all HTTP incoming requests are directed. Network Load Balancing clusters, network address translation (NAT), and DNS round robin are some of the methods typically used to deploy Web farm capability.

**DNS round-robin distribution**
Microsoft DNS server supports a process referred to as round-robin distribution, a common session-based load balancing technique that balances the number of clients connecting to an Internet site supported by multiple servers. Round-robin distribution is specified by RFC 1794. With DNS round-robin, a single logical DNS name (such as www.microsoft.com) maps to several IP addresses. When a request is made to resolve the DNS name, the DNS server sends back one of the addresses from the list. Each time a request is made for this DNS name, the DNS server rotates the addresses in round-robin fashion to distribute the set of users across a set of servers. Thus, different users requesting the same DNS name are given different IP addresses to balance the load.

This technique distributes incoming requests evenly among the available IP addresses but does not fully balance the load because it is not interactive. This is because the DNS server does not monitor the loading of each IP address nor does it check whether a particular server is currently running. Round-robin distribution can be a useful starting point for small groups of servers. If you are using round-robin distribution, closely monitor your servers so that you can quickly remove any failed machines from the distribution list.

**Network address translation**
Network address translation (NAT) is a protocol that allows a network with private addresses to access information on the Internet through an IP translation process. NAT can be used to configure a small network to share a single connection to the Internet.

# Message Queuing Computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing Computers**
This section provides information about different ways in which Message Queuing can be configured on a computer. For details, see the following links:

- For information on the functionality provided by configuring a computer as a Message Queuing server, see Message Queuing servers.
- For information on the functionality and advantages of deploying independent clients, see Independent clients.
- For information on dependent client requirements and considerations, see Dependent clients.

For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed on it. The term *Message Queuing client* can refer to either an *independent client*, or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed. Such computers are referred to as having independent client functionality or dependent client functionality.

# Message Queuing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing servers**
For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed on it. The term *Message Queuing client* can refer to either an *independent client*, or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed, and such computers are referred to as having independent client functionality, or dependent client functionality.

Message Queuing servers also provide the following features:

- Directory access for all client computers in the Windows Server 2003 family domain or Windows 2000 domain that are running Message Queuing on Windows NT 4.0, Windows 98, or Windows 95 computers.
- Support for dependent clients.
- Routing capabilities.

**Directory access**
Message Queuing servers enable client computers running MSMQ 1.0 clients running on Windows NT 4.0, Windows 98, or Windows 95 computers, and Message Queuing 2.0 clients running on Windows 2000 computers, to view and change information listed in the Active Directory directory service. To do this, the Message Queuing directory service (Downlevel Client Support) must be installed on a Windows Server 2003 family domain controller. For more information, see Installation requirements and restrictions.

Message Queuing independent clients running on Windows Server 2003 family computers can access Active Directory directly without the aid of a Message Queuing server.

**Routing capability**
Message Queuing servers installed with routing services enabled provide message routing and intermediate store-and-forward message queuing. Such Message Queuing servers can route messages within a site or between different sites when there is no direct connectivity between client computers. Message Queuing servers that provide message routing functions within the same site are called *in-routing servers* (InRS) or *out-routing servers* (OutRS). Intersite connectivity is defined by a *routing link*. A server through which the message traffic from one site to another can be configured to pass in a routing link is called a *site gate*. A site gate can belong to either or both of the sites connected by a routing link. A routing link can be configured with any number of site gates or no site gate. For more information, see Routing with Message Queuing servers.

For information on sites, see Deploying in a domain environment.

**Dependent client support**
Every dependent client in your network needs a supporting server, which can be any Message Queuing server with or without routing enabled. By default, following installation, Message Queuing servers are not enabled to support dependent clients. For instructions on enabling a Message Queuing server to act as a supporting server, see Enable a supporting server.

# Independent clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Independent clients**

For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed. The term *Message Queuing client* can refer to either an *independent client*, or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed, and such computers are referred to as having independent client functionality, or dependent client functionality.

Computers defined as running with independent client functionality do not have the following features:

- They do not have the Routing component enabled, and thus do not have the message routing capabilities of a Message Queuing server with this component.
- They do not have the Downlevel Client Support component enabled, and thus cannot provide Active Directory access for MSMQ 1.0 clients running on Windows NT 4.0, Windows 98, or Windows 95 computers, or MSMQ 2.0 clients running on Windows 2000.

Message Queuing computers configured with independent client functionality run the Message Queuing service, host queues, send and receive messages, and can operate while disconnected from the network. They do not require synchronous access to a Message Queuing server to send or receive messages, or to query Active Directory. However, if you choose to install an independent client in a workgroup environment or any other environment that does not provide a directory service, such as Active Directory, direct connectivity is required to send messages. Any Windows Server 2003 family computer running Message Queuing and operating in domain mode, including independent clients, can act as a supporting server for dependent clients.

If an independent client is disconnected from the network, it can continue to generate messages destined for other computers. The independent client stores these messages locally and automatically sends them as soon as the network connection is reestablished.

**Independent client advantages**

The advantages of deploying independent clients in your organization are as follows:

- They are not dependent on a Message Queuing server to send or receive messages, and synchronous communications with a Message Queuing server are not required.
- The messaging load can be distributed across several Message Queuing servers by configuring independent clients to use specific Message Queuing servers (in-routing servers and out-routing servers).
- They support mobility; independent clients can move from site to site.

**Mobile usage**

Mobile independent clients, such as those installed on laptop computers, can send and receive messages when they move around. When an independent client connects to a new Windows Server 2003 family site, it automatically detects the domain controllers in its new domain and queries the directory service to determine the new site in which it resides. After the new site is established, all messages that were sent to the client while it was disconnected from the network are automatically rerouted from the previous site to the new site. Note that mobile users that run Message Queuing applications while disconnected from the network can place an additional load on the network. This happens when they attempt to send or receive a large number of messages when they reconnect to the network. This temporary load can be transferred to additional Message Queuing servers to prevent reduced performance.

A Message Queuing 3.0 computer that belongs to a Windows NT 4.0 enterprise and is capable of connecting to MSMQ 1.0 controller servers is not capable of automatically revealing its new site. In this case, you can provide the name of the new site either before disconnecting the computer from the network or after reconnecting to the network. Selecting a new site enables your computer to connect to the closest controller server and thus optimizes access to the MQIS database. If you specify the new site before disconnecting from the network, messages sent to the computer while it is disconnected are routed directly to the new site while the computer is en route.

As stated previously, clients can be configured to use Message Queuing servers (in-routing and out-routing servers) for intrasite routing. When such a client moves to a different site, those in-routing or out-routing servers are not used for routing messages in the new site. When the independent client returns to its original site, those same Message Queuing servers are again used for routing messages.

**Windows CE usage**

A special version of the independent client is also available on handheld and palm-sized computers that are running Windows CE 3.0 or later. Because of capacity requirements and lack of RPC support, the following limitations apply to the Windows CE version of the independent client:

- No Active Directory support. Windows CE independent clients cannot query Message Queuing servers running on Windows Server 2003 family domain controllers.
- Limited message routing support.
- Limited public queue support.
- No message authentication or encryption. All messages sent to or received by other Message Queuing computers travel as plaintext.
- No remote retrieval of messages. Messages stored on another Message Queuing computer cannot be retrieved from the Windows CE independent client.
- No multi-message transactions.
- No cross-platform support. Messages cannot be sent to computers running other messaging systems.

# Dependent clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dependent clients**

For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed. The term *Message Queuing client* can refer to either an *independent client*, or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed, and such computers are referred to as having independent client functionality, or dependent client functionality.

Message Queuing servers with dependent client functionality require synchronous access to a Message Queuing server, called a *supporting server*, for all messaging functions. The supporting server can be any Message Queuing computer operating in domain mode with at least independent client functionality, preferably in the local site, but also in a nearby site. Note that computers configured as independent clients cannot provide Active Directory access for MSMQ 1.0 clients. These clients require Message Queuing servers running on a domain controller.

A dependent client relies on its supporting server to perform all messaging functions on its behalf, such as hosting queues, storing messages, sending messages, and receiving messages. If the supporting server goes offline, the dependent client will be unable to send and receive messages. By default, following installation, Message Queuing computers are not enabled to support dependent clients. For instructions on enabling a Message Queuing server to act as a supporting server, see Enable a supporting server. If you want to specify a Message Queuing server to act as a supporting server for a dependent client, you must also change the security configuration of the Microsoft Distributed Transaction Coordinator (DTC) on the Windows Server 2003 family computer to enable network transactions. The DTC is automatically installed on each computer during Windows Server 2003 family operating system installation for local transactions, and you need to enable network DTC. For instructions, see Enable network DTC access.

When you install a dependent client, you designate its supporting server. You can also later change the supporting server. Note that if you have the early version of a dependent client running on Windows NT 4.0 and you want to change its supporting server to a Message Queuing server running on Windows 2000 or Windows Server 2003 family, the dependent client must have Windows NT 4.0 Service Pack 4 or higher installed or else transactional messaging will not function. For instructions on changing the supporting server for a dependent client, see Change the supporting server for a dependent client.

For information on how to view the list of dependent clients currently supported by a Message Queuing server, see View the dependent client list for a server.

**Dependent client considerations**

Decide whether or not you want to deploy dependent clients in your organization. The advantages of using dependent clients are as follows:

- Server disk space is used to store messages. When necessary, you upgrade only the server resources (such as memory and hard disk space) to improve Message Queuing performance, instead of upgrading all the client computers.
- With fewer points of administration, you have fewer computers to back up and fewer journals and dead-letter queues to monitor.
- Fewer resources are used if the dependent client is frequently offline and the server is not.

Dependent clients also have the following disadvantages:

- Because the Message Queuing service runs on the supporting server, encrypted messages sent to or received by dependent clients travel between the dependent client and supporting server as plaintext.
- Queue access time is slower for a dependent client than it is for an independent client. This is because queue access is through an RPC-based connection.
- There may be performance issues if multiple dependent clients connect to their supporting server at the same time to send or receive messages.
- Dependent client queues are located on their supporting server, and it is not obvious which queues belong to which

dependent clients.

- When dependent client software is uninstalled, the associated queues are not automatically deleted from the supporting server.

- Because communication from a dependent client goes through the supporting server, if the communication to the supporting server is slow or expensive (such as between two sites), all dependent client communications are also slow or expensive.

- Dependent clients cannot run under a local user account.

- New Windows Server 2003 family Message Queuing features, such as HTTP transport, Message Queuing Triggers, and sending messages to multiple destinations, are not available to dependent clients. Thus, distribution lists, multiple-element format names, and multicast messaging are not supported for dependent clients.

- Dependent clients cannot be installed on computers in workgroup mode or on 64-bit computers.

- Transactional messaging is not supported for dependent clients running on Windows NT 4.0, Windows Milleninum Edition (ME), and Windows 98, Windows 95 computers that use a supporting Message Queuing server running on Windows XP Professional or Windows Server 2003 family operating systems.

# Understanding Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Understanding Message Queuing**
This section provides detailed information that you will need to understand before administering a Message Queuing network. For details, see the following links:

- To learn about message routing within and between sites, and deploying routing on Message Queuing servers, see Message Queuing routing.
- For information on security concepts that you must understand when administering a Message Queuing network, see Message Queuing security.
- To learn about different queue types, queue format names, and queue aliases, see Queues.
- For information about message types and properties, see Messages.
- For information about Message Queuing triggers, and trigger rules and conditions, see Triggers.
- For information about one-to-many messaging, see Multiple Destination Messaging.
- For an overview of using Message Queuing over the Internet and through firewalls, see Internet Messaging.
- For information on implementing Message Queuing in clusters, see Message Queuing in Clusters.
- For details of messaging between systems running Message Queuing and systems running different messaging applications, see Cross-Platform Messaging.

# Message Queuing routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing**

This section provides information about routing, and how you can deploy routing-enabled Message Queuing servers in your messaging network. For details, see the following links:

- For an overview of message routing, see Message Queuing routing overview.
- For information about routing messages within a site, see Intrasite routing.
- For information about routing messages between sites, see Intersite routing.
- To learn about routing links and routing-link costs, see Routing links.
- For information on deploying routing on Message Queuing servers, see Routing with Message Queuing servers.

# Message Queuing routing overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing overview**

A Message Queuing client always tries to establish a direct connection, or *session*, with the destination computer using the underlying IP network protocol. If a direct connection is not possible or not allowed, Message Queuing servers with routing enabled (routing servers) can temporarily store messages and subsequently forward them to the destination computer or to another routing server. In this way, they establish the route taken by messages as they proceed from the source computer to the destination computer. Specifically, message routing can occur when one or both of the following conditions exist:

- A session cannot be established between the source computer and the destination computer (for example, if the destination computer is offline).
- Specific Message Queuing routing servers are designated to store and forward messages on behalf of the source or destination computer.

**Message routing between networks**

Message Queuing can be used to send messages to and receive messages from external networks, such as other organizations or other Windows Server 2003 family forests. Message Queuing computers can use various service ports to communicate with external networks through properly configured firewalls that allow communication over those ports. For more information, see Internet messaging overview.

Although clients within a site that use the same network protocol are assumed to have direct connectivity, using in-routing and out-routing servers to route messages within a site may reduce the bandwidth requirements in your network. Clients can be configured to use in-routing and out-routing servers to provide message routing on their behalf. In that case, all messages sent or received by a client are routed first through such a Message Queuing server. The term client here refers to any Message Queuing computer that cannot route messages on its own, such as independent clients and Message Queuing servers without routing enabled. This feature is not applicable to dependent clients. Dependent clients require a supporting server to send and receive messages on their behalf. A supporting server without routing enabled, rather than its dependent clients, can be configured to use in-routing and out-routing servers.

If site gates are used to route messages between sites, only those assigned Message Queuing servers can route messages between the sites.

**Note**

- Message routing is not applicable in a workgroup environment. Thus, in-routing servers, out-routing servers, and site gates cannot be used, and direct connectivity between the source and destination computers is required.

# Intrasite routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Intrasite routing**

Message routing within a site is called *intrasite routing*. In the simplest case, the source and destination computers are not configured to use in-routing or out-routing servers. In this case, as a first choice, Message Queuing tries to deliver a message to the destination computer directly (one hop), and as a second choice, it delivers the message to one randomly chosen Message Queuing routing server that resides in the site (two hops).

This diagram shows one possibility for routing a message from one computer to another computer within a site. Although the number of hops can vary, here, a message sent from one computer in the site to another computer in the same site makes two hops: one hop to get to the Message Queuing routing server and one hop to get to the destination computer. Because each hop is within a site, the performance overhead of each hop is minimal.

**In-routing and out-routing servers**

In the context of intrasite routing, independent clients and Message Queuing servers without routing enabled are functionally equivalent. These computers can be configured to use in-routing servers (InRS) or out-routing servers (OutRS) to store and forward messages on their behalf. Dependent clients cannot be configured to use in-routing or out-routing servers because all messaging functions are performed by a supporting server.

If an independent client or a Message Queuing server without routing enabled is configured to use an out-routing server, every outgoing message sent by that computer is routed through that server. Likewise, if such a computer is configured to use an in-routing server, every message sent to it is routed through that server. Such a computer can use the same Message Queuing routing server as both its in-routing and out-routing server.

All in-routing and out-routing servers must be in the original site of the computer that they serve. When a mobile client moves to another site, these servers are not used for message routing until the client returns to its original site.

**Network bandwidth**

Intrasite routing can reduce the usage of network bandwidth by providing session concentration. For example, if you use a star topology within a site and each independent client usually communicates directly with all other independent clients, you can reduce your bandwidth usage through session concentration by configuring each client to use in-routing and out-routing servers.

In this figure, the same Message Queuing routing server is configured as both an in-routing server and an out-routing server for each client.

# Intersite routing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Intersite routing**

Message routing between different sites, called *intersite routing,* requires connectivity between those sites. Connectivity between different sites can be defined by logical communications links, called *routing links*. If the message traffic between two specific sites can be configured to pass through a specific Message Queuing routing server or one of several such servers, that routing server is called a *site gate*. Routing links can use site gates to route messages between two sites.

If your organization has more than one Windows Server 2003 family site, you must create routing links to guarantee that messages can be routed between different Windows Server 2003 family sites. The route taken by messages between sites can be determined by the routing-link costs. All routing links are assigned a default cost of 1.

Link costs can be used to select the best intersite message route and may be based on the speed or the monetary cost of the underlying physical communication link. After you determine the number of Windows Server 2003 family sites in your forest, decide if you need to specify different costs for routing links. For information on how to change routing-link costs, see Change the cost for a routing link.

For information on sites, see Deploying in a domain environment.

In a domain environment with more than one Windows Server 2003 family site, you must create routing links to guarantee that messages can be routed between different sites. In the absence of a routing link, Message Queuing will usually attempt to establish a direct connection with the destination computer in an unconnected site.

Each routing link is assigned a relative cost, which may reflect the speed or the monetary cost of the underlying physical communication link. The default value is 1, and costs can range from 1 to 999999. Change routing-link costs only in cases where alternative intersite routes are possible over the existing routing links and you want to enforce one route over another route using the costs of the individual links.

**Notes**

- A site gate can belong to either or both of the sites connected by a routing link. A routing link can be configured with any number of site gates or no site gate.
- Do not confuse routing links with site links. Routing links are used by Message Queuing servers to route messages between sites. Site links are used by domain controllers to replicate Active Directory information between sites.

When a message is sent from an independent client in one site to a computer in another site, the source computer first tries to connect directly to the destination computer, and only as a second choice, delivers the message to a routing server in its site, which delivers the message to a site gate. This process continues until the message reaches the destination computer.

**Session reduction**

Intersite routing typically reduces the number of sessions created by clients. In the following figure, the routing beyond the site is transparent to the computers within the site, with the exception of the site gate. This simplifies the message route and reduces site-to-site sessions. Only the designated Message Queuing server can establish a session between different sites.

# Routing links

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing links**

If your organization has more than one Windows Server 2003 family site, you must create routing links to guarantee that messages can be routed between different Windows Server 2003 family sites. The route taken by messages between sites can be determined by the routing-link costs. All routing links are assigned a default cost of 1. Change routing-link costs only in the case where alternative routes are possible over the existing routing links and you want to enforce one route over another route using the costs of the individual links. For more information on configuring routing links, see Configuring routing links.

Link costs can be used to select the best intersite message route and may be based on the speed or the monetary cost of the underlying physical communication link. After you determine the number of Windows Server 2003 family sites in your forest, decide if you need to specify different costs for routing links. For information on how to change routing-link costs, see Change the cost for a routing link.

For information on sites, see Deploying in a domain environment.

**Routing link example**

A routing link that connects sites A and B has four site gates (SG1-SG4). If SG1 and SG2 belong to site A, SG3 belongs to both sites A and B, and SG4 belongs to site B, messages can be routed through one of the site gates of site A (SG1, SG2 or SG3) and then through one of the site gates of site B (SG3 or SG4). However, if the messages are routed through SG3, which belongs to both sites, they will reach the destination computer in one less hop. Thus, messages are routed preferentially through SG3. In the general case, if a routing link is associated with only a pair of site gates, one in each site, only those servers can route messages between the designated sites in that routing link.

Multiple routing links can be used to route messages between sites in your network for load balancing or redundancy. In this case, if you want to enforce one route over another route using link costs (for example, to specify a default link), you can change the routing-link costs to determine the route that messages take.

For example, if the cost associated with the A-B routing link is set to 3 and the cost associated with the other three routing links (B-C, B-D, and C-D) is 1, messages routed from site A to C always travel from site A to site B and then to site C. However, if the cost associated with the A-B and B-C routing links is 3 and the cost associated to the C-D and B-D routing links is 1, messages routed from site A to C always travel from site A to site B, to site D, and then to site C.

The route that a message takes to get from site A to site C depends on the costs of the routing links.

| Routing link | Cost |
|---|---|
| A-B | 3 |
| B-C | 1 |
| B-D | 1 |
| C-D | 1 |

In this situation, messages routed from site A to site C always travel from site A to site B and then to site C.

| Routing link | Cost |
| --- | --- |
| A-B | 3 |
| B-C | 3 |
| B-D | 1 |
| C-D | 1 |

In this situation, messages routed from site A to site C always travel from site A to site B, then to site D, and finally to site C.

# Routing with Message Queuing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Routing with Message Queuing servers**

The number of Message Queuing servers with routing enabled (routing servers) that you deploy in your organization can depend on the following factors:

- The number of sites among which you are routing messages.
- How frequently client computers are offline. Message Queuing servers with routing services are needed for message store-and-forward capability when the source and destination computers may not be online at the same time.

It is recommended that at least one routing server be installed in each Windows Server 2003 site to ensure that messages are forwarded successfully. For performance and scalability reasons, it is recommended that multiple Message Queuing routing servers be installed in each site.

A source computer will successfully forward a message to a destination computer when a direct connection is established and when the destination site has no site gate. If the destination site has a site gate, the messages will not be forwarded and will accumulate at the source.

It is recommended that in-routing and out-routing servers be available for mobile clients that are mostly disconnected from the network or connect to the network through a remote access server.

There is no technical restriction or limitation on installing Message Queuing routing servers on domain controllers. However, because the main roles of domain controllers include authenticating users, handling queries to Active Directory, and maintaining domain security, it is recommended that you carefully consider how installing Message Queuing routing servers on domain controllers may influence their performance and security.

By providing session concentration, the use of Message Queuing routing servers may reduce operating costs. Such servers can reduce bandwidth needs within a site and reduce the number of sessions between different sites. Intrasite routing is considered relatively fast and inexpensive, while intersite routing is considered relatively slow and expensive.

In addition, when Message Queuing routing servers are available, messages do not accumulate in independent clients, which generally have a small storage capacity, but can be delivered to an out-routing server, which stores them until the destination computer becomes online.

Message Queuing routing servers that provide intrasite message routing are called *in-routing servers* (InRS) or *out-routing servers* (OutRS). Message Queuing servers providing message routing on a routing link, which defines connectivity between sites, are called *site gates*. For more information on intrasite routing, see Intrasite routing. For more information on intersite routing, see Intersite routing.

The relative cost of using a given route to reach a destination computer is commonly measured in *hops*, where each hop represents the delivery of a message from one computer to another. If there are multiple routes with the same destination, the route with the lowest *hop count* is the best.

# Message Queuing security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security**

Message Queuing uses security features provided by Windows Server 2003 family operating systems, including access control and auditing for Message Queuing objects, message authentication, and encryption. For details, see the following links:

- For a general overview of security features for Message Queuing, see Message Queuing security overview.
- For information on implementing authentication to check who sent messages, and message integrity, see Authentication for Message Queuing.
- For information on encrypting private messages, see Encryption for Message Queuing.
- For information on restricting operations of Message Queuing objects to specific groups or users, see Access control for Message Queuing.
- For information on auditing access operations of Message Queuing objects, see Auditing Message Queuing objects.
- Message Queuing can be deployed in hardened MSMQ mode to enhance the security of Message Queuing computers using HTTP messaging over the Internet. For more information, see Message Queuing in hardened MSMQ mode.

# Message Queuing security overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Security overview**

Message Queuing takes advantage of the various built-in security features of the Windows Server 2003 family operating systems. Specifically, Message Queuing uses access control, message authentication, encryption, and auditing for security. In Message Queuing 3.0, 128-bit encryption is supported in addition to 40-bit encryption. By managing security properties for objects, you can set permissions, assign ownership, and monitor user access.

Access control is used to restrict user access to Message Queuing objects in Active Directory and is implemented by assigning security descriptors to objects. Message Queuing objects include the MsmqServices, msmq, Queue, routing link, and MSMQ Settings objects. The msmq object for the local computer is also known as the MSMQ configuration object, for example, in names of specific permissions for this object and in the Delegation of Control Wizard. A security descriptor lists the users and groups that are granted or denied access to an object as well as the specific permissions assigned to those users and groups. For more information, see Access control for Message Queuing.

Security queries to Active Directory and other directory services, in which the client and server are online and talk to one another, are implemented using the Kerberos V5 security protocol (between Windows Server 2003 computers) or server authentication (for compatibility with MSMQ 1.0 running on Windows NT 4.0).

Message authentication, which verifies the identity of the sender of a message to the receiver, is implemented using certificates. Messages are authenticated asynchronously without the sender and the receiver communicating with one another. For more information, see Authentication for Message Queuing.

Encryption is implemented using both public/private key (asymmetric) and secret key (symmetric) algorithms. Encryption is used by Message Queuing applications to encrypt messages sent between Message Queuing computers. For more information, see Encryption for Message Queuing.

Security auditing is used to record which users attempt to access Message Queuing objects in Active Directory. The security descriptor for an object specifies the various security events to be audited for the object. For more information, see Auditing Message Queuing objects.

**Message security**

Message Queuing ensures the security of messages sent from a source computer to a destination computer. Applications can perform a *local read* or a *remote read* when accessing queues. A local read is performed when the receiving application accesses a destination queue that resides on the same computer. In this case, message security can be guaranteed.

A remote read is performed when the contents of a queue are accessed from a computer other than the one on which the queue is located. For remote reading, Message Queuing 3.0 uses encrypted RPC by default. This feature is available when a Windows Server 2003 family client computer does a remote read against a Message Queuing computer running on Windows Server 2003 family computers, Windows 2000, or Windows NT 4.0. Note that in situations where encrypted RPC cannot be used, (for example, where a workgroup computer is part of the remote read process) the message will be passed to the remote computer as clear text and message security is not guaranteed. A clear text message that has reached its destination queue can be read only by users that have the necessary access rights to read messages from the queue.

**Secured remote read**

Message Queuing 3.0 on Windows Server 2003 family computers provides a new secure remote read interface that enhances the security of the old remote read interface used by Message Queuing running on earlier versions of Windows operating systems, and allows Message Queuing servers to expose remote-read functionality in a more secure way.

Following Message Queuing installation, Message Queuing 3.0 on Windows Server 2003 family computers listens for both the old remote read interface and the new secure remote read interface, and the following default settings are applied:

- Message Queuing 3.0 clients on Windows Server 2003 family computers in the same forest as the Message Queuing 3.0 server will use the secure remote read interface with an encrypted channel.

- Message Queuing 3.0 clients across forests on Windows Server 2003 family computers in non-trusted domains will use the secure remote read interface. By default, the Message Queuing 3.0 server requires domain clients to establish an encrypted channel, and such a channel cannot be established between non-trusted domains. Thus remote read requests from such clients will be rejected. To modify this default behavior and allow the Message Queuing server to accept

domain clients that do not establish an encrypted channel, create a DWORD value **Security\NewRemoteReadServerAllowNoneSecurityClient** in the registry and set it to 1. Creation of this registry key causes clients from non-trusted domains to be validated using Anonymous logon credentials. After creating this registry key, the Anonymous logon account must be granted Peek or Receive permissions in order to accommodate remote read requests for clients from non-trusted domains. After implementing this registry key and granting permissions to the Anonymous logon account, Message Queuing server accepts Peek or Receive requests from everyone without authentication checks. Therefore, these changes should only be implemented when absolutely necessary.

- Message Queuing 3.0 workgroup clients on Windows Server 2003 family computers will use the secure remote read interface. Workgroup clients cannot establish an encrypted channel for remote reading, and by default, the Message Queuing server accepts workgroup clients on a non-encrypted channel using Anonymous logon credentials. In this scenario, the Anonymous logon account must be granted Peek or Receive permissions in order to accommodate remote read requests from workgroup clients. To modify this default behavior so that the Message Queuing 3.0 server rejects workgroup clients, create a DWORD value **Security\NewRemoteReadServerDenyWorkgroupClient** in the registry and set it to 1.

- MSMQ 1.0 and MSMQ 2.0 clients, and Message Queuing 3.0 clients on Windows XP computers, will use the old remote read interface. If you enable your Message Queuing 3.0 server to use only the secure remote read interface, the computer does not listen on the old remote read interface, and remote reads from these clients are not supported.

You can enable your Message Queuing 3.0 server to use only secured remote reading mode in the Server Security tab of Message Queuing properties in Computer Management. In secured remote reading mode, your computer will only listen on the new secure remote read interface, and not on the old remote read interface. The effect of this is that only Message Queuing 3.0 servers on Windows Server 2003 family computers can remotely receive messages from queues on your computer, and remote reads from MSMQ 1.0 clients, MSMQ 2.0 clients, and Message Queuing 3.0 clients running on Windows XP computers are not supported. For instructions on enabling your server to use only the new secured mode, see Enable secured remote read.

# Authentication for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authentication for Message Queuing**
The following sections describe the various types of authentication available for Message Queuing.

**Server authentication**
*Server authentication* is used by clients to authenticate queries sent to domain controllers and Message Queuing servers. A client can verify that the query results have not been tampered with and that the results were returned by the correct domain controller or Message Queuing server. Security queries to Active Directory and other directory services, in which the client and server are online and talk to one another, are implemented using the Kerberos V5 security protocol (between Windows Server 2003 family and/or Windows 2000 computers), or with server certificates (for compatibility with MSMQ 1.0 running on Windows NT 4.0). The method used depends on the version of Message Queuing (and hence the operating system) running on the server and the client. For more information on server authentication, see Managing server authentication.

**Message authentication**
*Message authentication*, which confirms that a message has not been tampered with and can be used to verify the identity of the sender of a message to the receiver, is implemented using certificates. Messages are authenticated asynchronously without the sender and the receiver communicating with one another. The use of message authentication is optional. Message Queuing applications are not required to use authentication when sending or receiving messages. Note that the use of message authentication slows the transfer of messages. When used, however, Message Queuing applications that send or receive authenticated messages must use the cryptographic service provider installed by default with Windows Server 2003 family, which is needed for both message authentication and encryption. For more information on message encryption, see Encryption for Message Queuing. For more information on message authentication, see Managing message authentication.

For more information on authentication for Windows Server 2003 family, see Authentication, in the Windows Help file.

For more information on certificates for Windows Server 2003 family, see Certificates overview in the Windows Help file.

**HTTPS authentication**
Using HTTPS to send messages ensures authentication of users requesting access to Message Queuing resources by means of a Web server, by establishing a Secure Sockets Layer (SSL) connection for secure communication between a sender and recipient. Authentication for an SSL connection is done using server and client certificates. For more information, see HTTPS authentication.

# Encryption for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Encryption for Message Queuing**

In the context of Message Queuing, encryption is the process for encoding and decoding messages, ensuring they cannot be read or used by unauthorized persons. Message Queuing implements message encryption through the use of symmetric and asymmetric (public/private) key encryption algorithms. The encryption implementation used is based on the CryptoAPI (Microsoft Cryptographic Application Program Interface), which in turn uses a cryptographic service provider (CSP) installed on the computer.

The use of message encryption is optional. Message Queuing applications are not required to use encryption when sending or receiving messages. Note that the use of message encryption slows the transfer of messages. When used, however, Message Queuing applications that send or receive encrypted messages must use the CSP installed by default with Windows Server 2003 family, which is needed for both message authentication and encryption. For more information on message authentication, see Authentication for Message Queuing.

Although other CSPs can be used for the encryption of data that does not involve Message Queuing, the CSP provided with Windows Server 2003 family must be used for any Message Queuing application that sends or receives encrypted messages. Non-Message Queuing applications can continue to use other CSPs for encryption.

**How message encryption works**

Messages are encrypted by the Message Queuing service on the source computer and decrypted by the Message Queuing service on the destination computer. Decrypted messages are stored in the destination queue as plaintext. Message encryption is designed to prevent unauthorized viewing of messages in transit.

When message encryption is used, performance is reduced, although typically not as much as when using message authentication. Performance losses due to encryption are most significant when you send encrypted messages to many different computers. However, when you send multiple messages to the same destination computer, only the first message sent takes significantly longer than usual to send.

To see why message throughput is reduced, it is important to understand the encryption mechanism that Message Queuing uses. On the source computer, Message Queuing does the following:

1. Creates a secret key.
2. Encrypts the message body by using the secret key.
3. Encrypts the secret key by using the public key of the destination computer.
4. Attaches the encrypted secret key to the encrypted message.

On the destination computer, Message Queuing does the following:

1. Decrypts the secret key by using its private key (of the key pair).
2. Decrypts the message body using the secret key.

Secret keys can be used for both encryption and decryption, hence they are called symmetric. Public keys can be used for encryption only, while private keys can be used for decryption only.

Asymmetric key encryption has more overhead than symmetric key encryption. Sending the first message incurs the most overhead because the secret key is encrypted with the public key of the destination computer. By default, Message Queuing stores the encrypted secret key on the source computer for 10 minutes. If you send additional messages to the same computer within 10 minutes after sending the first message, Message Queuing reuses the same secret key. Consequently, the overhead for each subsequent message will be just the overhead needed to encrypt the message body using the secret key. In this case, Message Queuing does not need to encrypt the secret key with the public key of the destination computer again. The same performance results are realized on the destination computer. Upon receiving the first message, Message Queuing decrypts

the secret key by using its own private key. Message Queuing then stores the decrypted secret key and can reuse it later for subsequent messages without any additional overhead.

You can specify whether a queue accepts encrypted messages, unencrypted messages, or both by selecting the *privacy level* for the queue. If the queue privacy level is set to **None**, the queue accepts only unencrypted messages. If the queue privacy level is set to **Body**, the queue accepts only encrypted messages. If the queue privacy level is set to **Optional**, the queue accepts both unencrypted and encrypted messages. You can check whether a message sent to the queue was encrypted or unencrypted using Active Directory Users and Computers (or programmatically by checking the PROPID_M_PRIV_LEVEL message property).

For information on how to set the privacy level for a queue, see Change the privacy level for queues.

**Notes**

- When messaging across different messaging platforms, encrypted messages sent to foreign computers stay encrypted on the intermediary Message Queuing server running the connector application. The connector application can forward the encrypted messages to the foreign computer or can decrypt the messages first before forwarding.

- Because encryption requires queries to Active Directory, it cannot be used in workgroup or offline mode.

**Cryptographic keys**

Public/private cryptographic key pairs for a computer are created for you during Message Queuing Setup and can be renewed using the **Message Queuing Properties** dialog box, which can be opened from Computer Management. All Message Queuing computers except dependent clients use cryptographic keys.

For more information on encryption keys for Windows Server 2003 family, see Generating encryption keys and certificate requests.

Cryptographic key renewal is a security feature used by Message Queuing. It is a good idea to renew your cryptographic keys periodically, such as once a year. It is also recommended that you renew your cryptographic keys any time you suspect they have been compromised. In particular, this will reduce the chance that your private key has been compromised.

When you renew the cryptographic keys for a Message Queuing computer, any messages that were encrypted using the previous public keys cannot be decrypted. This occurs only until the new public keys are replicated in Active Directory to all Message Queuing servers and the source computers can start using the new public keys.

For information on how to renew your cryptographic keys, see Renew cryptographic keys for Message Queuing.

# Access control for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Access control for Message Queuing**

Access control is used to restrict user access to Message Queuing objects in Active Directory and can be implemented by assigning security descriptors to objects. A security descriptor lists the users and groups that are granted or denied access to an object and the specific permissions assigned to those users and groups. This part of the security descriptor is known as a discretionary access control list (DACL). By setting the permissions on an object, the *owner* of the object controls which access is allowed. The Message Queuing objects include computer (msmq), queue, routing link, and MSMQ Settings objects. For more information on Message Queuing objects, where they are created, and where they are located in Active Directory, see Message Queuing and Active Directory.

Permissions can also be used to restrict users from sending messages to, or retrieving messages from, a particular queue on a computer. Although messages are not objects in Active Directory, they are protected through the security descriptor of the queue object.

Because Message Queuing provides asynchronous messaging, the source and destination computers do not need to be online at the same time. In this case, Message Queuing can implement access control for offline users through the use of sender security IDs (SIDs). For example, because a queue can restrict access to itself, the sending application must attach the sender's SID to any message directed to that queue. The Message Queuing service on the destination computer then checks the SID to verify that the sender has the proper permissions to access the queue.

**Note**

- You must also be granted certain permissions to be able to install and uninstall Message Queuing. For more information, see Installation permissions.

For more information on access control for the Windows Server 2003 family, see Access Control, in the Windows Help file.

# Auditing Message Queuing objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Auditing Message Queuing objects**

You can use auditing to record which users attempt to access Message Queuing objects, the type of operation attempted, and whether that access succeeded or failed. The security descriptor for an object specifies the various access events to be audited for the object. This part of the security descriptor is known as a system access control list (SACL). More specifically, a SACL specifies the following:

- The users or groups to audit when accessing the object.
- The access events to be audited for each group or user.
- A Success or Failure attribute for each access event, based on the permissions granted to each group or user in the object's discretionary access control list (DACL).

For more information on auditing for Windows Server 2003 family, see Auditing overview, in the Windows Help file.

The security log records audited operations, called *security events*, which you can view using Event Viewer. For more information on Event Viewer, see Event Viewer, in the Windows Help file.

**Configuring auditing**

To implement auditing, you must establish an audit policy. An audit policy specifies categories of security-related events that you want to audit. For instructions, see Define or modify auditing policy settings for an event category, in the Windows Help file. To audit "object open" security events such as *Peek Message*, *Receive Message*, and *Send Message*, you grant the Message Queuing service of a specific computer security permissions to access SACL information for its public queue. For more information, see Enable Message Queuing to access SACL information.

Next, you select the access entries to be audited for success or failure for a user or group on a specific object or resource. For information on how to set auditing options for a Message Queuing computer or queue object, see Audit access to computer and queue objects. For information on how to set auditing options for a routing link object, see Audit access to routing link objects.

If auditing options are specified for a Message Queuing object but an audit policy has not been established on the Message Queuing server that carries out the operation, a security event is not created.

**Security events**

Security events are created in the security log on the computer that performs the operation, which is not necessarily the computer that is the *owner* of the object. Because of this, audit messages for a single Message Queuing object can be scattered across a network. For example, in this figure, if the public test queue located on client 1 in the San Francisco site is deleted by client 2 in the Seattle site, the audit message is created on server 2 of the Seattle site. The following diagram illustrates this:

# Message Queuing in hardened MSMQ mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing in hardened MSMQ mode**
The purpose of Message Queuing in hardened MSMQ mode (a new feature in Message Queuing 3.0) is to enhance the security of Message Queuing computers running on the Internet. Hardened MSMQ mode is intended to support scenarios that employ only HTTP (SRMP) messages.

Message Queuing in hardened MSMQ mode imposes the following restrictions:

- The Message Queuing service does not listen directly to any ports. Thus, only messages arriving from remote computers through IIS are accepted and placed in their destination queues. Remote RPC calls are ignored (remote reading is blocked), and dependent clients are not supported.

- Attempts to open remote queues with non-HTTP format names and send messages to them succeed. However, all the outgoing queues created on the local computer that correspond to remote destination queues specified by non-HTTP format names are in the locked state. Messages, including acknowledgment and response messages, that reside in locked outgoing queues are not transmitted to their destinations.

- Messages intended for remote destination queues with non-HTTP format names, including remote queues designated by non-HTTP elements of a multiple-element format name, remain in the locked outgoing queues until hardened MSMQ mode is canceled and the Message Queuing service is restarted.

In hardened MSMQ mode, messages can still be placed in local queues with non-HTTP format names and received from them.

**Security considerations in hardened MSMQ mode**
When deploying a domain controller with the Downlevel Client Support component in a perimeter network, be aware that this component listens to the RPC interface, and that it is not governed by hardened MSMQ mode. For reducing the attack surface, you may want to remove the Message Queuing Downlevel Client Support component from the domain controller.

For instructions on enabling or canceling hardened MSMQ mode on the local computer, see Enable hardened MSMQ mode.

# Queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Queues**

In the context of Message Queuing, queues are temporary storage locations for different types of messages. The following sections provide information about different types of queues that can be deployed in a messaging infrastructure. Queues can be created by applications and by Message Queuing. Queues created by applications or by administrators are referred to as application queues. Queues created by Message Queuing are known as system queues. For details, see the following links:

- For information on the different types of application-generated queues used by Message Queuing, see Application Queues.
- For information on journal queues, outgoing queues, dead-letter queues, and other types of system queues created and used by Message Queuing, see System Queues.
- For information on the names that can be used to designate Message Queuing queues, see Queue names.
- For information on referencing queues by queue alias names, see Queue aliases.
- For information on target journaling, see Target journaling.
- For information on source journaling, see Source journaling.

# Application Queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Application Queues**
Queues that are created by an application or by the Message Queuing administrator are referred to as application queues. For information on different types of application queues, see the following links:

- Destination queues are any application queue that sending applications send messages to, or that receiving applications receive messages from. For more information, see:
    - Public and private queues
    - Transactional and nontransactional queues
- Administration queues are application-generated queues used to store system-generated negative and positive acknowledgment messages that are created by Message Queuing or connector applications. Any available nontransactional queue can be used as an administration queue. For more information, see Administration queues.
- Response queues are application-generated queues used to store application-generated response messages that are typically returned by an application that is reading messages from a queue. Any available queue can be specified as a response queue. For more information, see Response queues.
- Report queues are application-generated queues used to store report messages generated by Message Queuing or connector applications when tracing is requested by the sending application. When a message is sent with tracing enabled, a report message is generated each time the message leaves or arrives at a Message Queuing computer. For more information, see Report queues.

# Public and private queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Public and private queues**

**Private queues**
*Private queues* are queues that are not published in Active Directory and are displayed only on the local computer that contains them. Private queues have the following features:

- Message Queuing registers private queues locally by storing a description of the queue in the LQS (local queue storage) directory on the local computer. In MSMQ 2.0, and Message Queuing 3.0, the default location is %windir%\system32\msmq\storage\lqs. Note that a description of each public queue created on the local computer is also stored locally in a separate file in the LQS folder.

- Private queues are registered on the local computer, not in the directory service, and typically cannot be located by other Message Queuing applications.

- Private queues are accessible only by Message Queuing applications that know the full path name, the direct format name, or the private format name of the queue, as follows:

  - **Path name:***ComputerName*\private$*QueueName*.

  - **Path name on local computer:** \private$*QueueName*.

  - **Direct format name:**: DIRECT=*ComputerAddress*\PRIVATE$*PrivateQueueName*.

  - **Private format name:** PRIVATE=*ComputerGUID**QueueNumber*.

  For more information on path names and format names, see Queue names.

- Private queues have the advantage of no directory service overhead, making them quicker to create, no latency in accessing them, and no replication overhead.

- Private queues are not dependent on the directory service, and thus can be created and deleted when the directory service is not working. This is useful for offline operation.

- One way that private queues can be exposed to other applications is by setting a message property. To distribute the location of a private queue, an application can send a format name of the private queue as the response queue property of a message.

- In a workgroup environment, only private queues are available.

- For a Message Queuing application on the local computer to access a private queue, the application only needs to know the path name of the queue. For a Message Queuing application on a remote computer, the application requires a direct or private format name to access such a queue. To read messages from the queue, the remote Message Queuing application requires the Receive Message permission for that queue. By default, everyone has permissions to send messages to public and private queues.

**Public queues**
In a domain environment, *public queues* are queues that are published in Active Directory and hence are replicated throughout your Windows Server 2003 family forest. Note that only the properties for these queues are replicated, not the actual queues themselves or their contents. Any computer within your forest can potentially access information regarding public queues provided the user has sufficient permissions to access the applicable queue objects. Generally speaking, any user in the forest with access to Active Directory and the Send To permission for a given public queue can send messages to it.

In an Active Directory environment, defining public queues ensures that queues are registered in the directory service, and that their registration is backed up. They are persistent and available to other applications.

**Creating local public queues**

By default, in Active Directory, the Create Child Object permission that is required to create local public queues is granted to:

- The Domain Administrator account
- The domain user account of the local administrator that installed Message Queuing
- Local System and Network Service accounts

To permit all other users to create local public queues by default, Message Queuing uses Message Queuing service elevation of privilege. The effect of this is that if the user account does not have Active Directory permissions for this action, the user account privilege is elevated and the local public queue is created using Message Queuing service's Local System account. This is the default Message Queuing setting. If you want to disable this behavior, and restrict the creation of local public queues, set the following key:
**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\EnableCreateQueueThroughService**. To disable the key, set the DWORD value to 0. After setting the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

Default security access for public queues gives everyone permission to send messages to a public queue. Specific permissions must be granted for read access.

The advantage of public destination queues is that they are registered in the directory service, where they can be located by other Message Queuing applications. Public queues are persistent, and their registration information can be backed up on the enterprise, making them good for long-term use.

# Transactional and nontransactional queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Transactional and nontransactional queues**
A transactional queue is one that only contains transactional messages, which are messages sent within a transaction. The requirements for sending and retrieving messages are based on the type of queue used (transactional or nontransactional) and the queue's location (local or remote).

**Sending messages**
When using transactions to send messages, the messages can be sent to any transactional queue regardless of where the queue is located, but only transactional queues can accept messages sent in the context of a transaction. In a similar way, nontransactional queues can only accept messages sent outside the context of a transaction. Note that only transactional messages are delivered with Exactly-Once In-Order Delivery (EOD) guarantees. For more information on transactional messaging, see Transactional messaging.

**Receiving messages**
When using a transaction to retrieve messages, the queue must be a local transactional queue. You cannot retrieve a message from a remote transactional queue or from a local nontransactional queue within a transaction. Message Queuing does not provide support for transactional remote-read operations (accessing the contents of a queue from a computer other than the one on which the queue is located). However, this same functionality can be achieved by using a transactional read-response application.

Note that nontransactional receive operations are allowed from any queue (transactional or nontransactional, local or remote). In particular, a nontransactional receive operation from a transactional queue is essentially a transaction consisting of a single receive operation.

**Transactional read-response applications**
A transactional read-response application is used when you need to retrieve transactional messages from a remote transaction queue. It uses transactions to redirect the messages from the remote queues on the sending computer to local queues on the receiving computer.

A read-response application resides on a server that contains two transactional queues:

- An input queue for collecting messages from sending applications.
- A read-request queue for collecting read-requests from the receiving application.

The read-response application does the following in a single transaction:

- Retrieves a request made by the receiving application from the read-request queue.
- Retrieves a message sent by the sending application from the input queue.
- Forwards the message from the input queue to the receiving application that made the request.

In this way, the receiving application gets its messages within a transaction, without needing to perform a transactional remote-read operation.

The receiving application sends a request message to the read-request queue on the server, specifying the response queue to which the input message will be sent. This request can be made within the context of its own transaction. Note that it is independent of the transaction used to send the message back to the receiving application.

# Administration queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administration queues**

*Administration queues* are application-generated queues used to store system-generated negative and positive acknowledgment messages that are created by Message Queuing or connector applications. They are specified programmatically in the original messages by the sending application. Any available nontransactional queue can be specified as an administration queue. Administration queues do not contain administrative messages, which are stored in internal private queues. For more information on acknowledgment messages, see Message types.

The system-generated acknowledgment messages returned to these queues can indicate whether a message arrived at its destination queue, whether it was retrieved from the destination queue, or both. Each acknowledgment message contains information that describes what triggered the acknowledgment and to which message the acknowledgment refers. When requesting acknowledgment messages, the sending application must specify the queue to be used as the administration queue and the acknowledgment level of the message. Typically, an administration queue is a local queue so that the sending application can read the acknowledgment messages locally.

# Response queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Response queues**

*Response queues* are application-generated queues used to store application-generated response messages that are typically returned by an application that is reading messages from a queue. Response queues are specified programmatically by the sending application when a message is sent. Any available queue can be specified as a response queue. Response messages are not the same as administrative response messages, which are stored in an internal private queue.

The response messages returned to these queues must be understood by the application returning the response messages and the application reading the response messages. Message Queuing has no control over what information is sent in response messages. When requesting response messages, the sending application must specify the queues that it wants to use as response queues. Typically, response queues are local queues so that the sending application can read the response messages locally.

When a response queue and an administration queue are both needed, their functionality can be combined into a single queue. However, because all administration queues must be nontransactional, this queue will accept only nontransactional messages. For more information on administration queues, see Administration queues.

# Report queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Report queues**

*Report queues* are application-generated queues used to store report messages generated by Message Queuing or connector applications when tracing is requested by the sending application. They indicate the route that a message took to its destination on a remote computer or the route that a test message took to a test queue on a remote computer. There can be only one report queue per computer.

All report queues must have the following label and queue type identifier:

- Label: MQReport Queue
- Queue type identifier (GUID):

```
{55EE8F32-CCE9-11CF-B108-0020AFD61CE9}
```

Report queues are typically created by the Message Queuing administrator using Active Directory Users and Computers, but they can also be generated by an application as long as the correct label and queue type identifier is specified when the queue is created. Message Queuing uses the label and queue type identifier to locate and open the appropriate queue when sending report messages.

Report queues are not limited to report messages. Application-generated messages can be sent to report queues as well. When a message is sent with tracing enabled, a report message is generated each time the message leaves or arrives at a Message Queuing computer. Report messages are sent to a report queue only if message route tracking is enabled on the host computer and the message route tracking flag is set. Typically a single report queue is specified by the source computer where the message is sent. However, each Message Queuing computer can specify its own report queue.

# System Queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**System Queues**

Queues that are created by Message Queuing are referred to as system queues. Applications can read the messages in system queues, but cannot address messages to them. For information on different types of system queues, see the following links:

- Queue journals contain copies of all messages removed from a queue. Computer journals contain copies of all messages sent from a computer. For more information, see Journals.
- Message Queuing uses internal private queues as interim queues for storing and forwarding messages in transit to a destination queue. These queues are not published in Active Directory. Outgoing queues are local internal queues, generated automatically to store messages sent to remote queues. For more information, see Internal private queues and outgoing queues.
- Dead-letter queues contain messages that cannot be delivered. Message Queuing provides a transactional dead-letter queue and a nontransactional dead-letter queue. For more information, see Dead-letter queues.
- Connector queues are used for cross-platform messaging. For more information, see Connector queues.

# Journals

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Journals**

Queue and computer journals are system queues that are automatically created by Message Queuing. When a sending application sends a message, a copy of the message is optionally stored in the computer journal of each computer it passes through. When a receiving application removes the message from the destination queue, a copy of the message is optionally sent to the queue journal. Applications can only read the messages in queue and computer journals. They cannot send messages to queue or computer journals. In contrast, Message Queuing never removes messages from queue or computer journals. It is up to the application reading the messages to clear the messages from the queues. If an application uses journaling and no provisions are made to clean up the journals used, Message Queuing disk storage will quickly be consumed.

**Computer journals**

A computer journal is created whenever a Message Queuing computer is added to a Windows Server 2003 enterprise. It is used to store copies of all messages successfully sent from the computer. Message Queuing stores copies of the messages sent from the computer whenever positive source journaling is specified by the sending application. For more information, see Source journaling.

Computer journals can be referenced by a machine format name or a direct format name. The following lines show the syntax of these format names:

MACHINE=ComputerGUID;JOURNAL

DIRECT=AddressSpecification\SYSTEM$;JOURNAL (Introduced in MSMQ 2.0)

For instructions on setting the computer journal size, see Set the journal storage size for computers.

A computer journal is not created for computers operating in workgroup mode or virtual servers in clusters. You can set the computer quota of a workgroup computer using the **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\MachineCache\MachineJournalQuota** registry key. To change the quota for a virtual server, you need to change the analogous registry key for clustered servers. After setting the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

**Queue journals**

Queue journals are created whenever an application queue is created. Message queuing creates the queue journal on the same computer where the messages for the application-generated queue are stored.

Message Queuing stores copies of the messages removed from the application queue whenever target journaling is enabled on the queue. This does not include messages removed from the queue when their time-to-be-received elapses or messages purged from the queue in the Message Queuing MMC snap-in. For more information, see Target journaling.

For instructions on setting the queue journal size, see Set the journal storage size for queues.

# Internal private queues and outgoing queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internal private queues and outgoing queues**

The following sections describe internal private queues and outgoing queues.

**Internal private queues**

*Private queues* are queues that are not published in Active Directory. Private queues are accessible only by Message Queuing applications that know the full path name or format name of the queue. Internal private queues are not listed in the Private Queues folder, and any information on these queues and their contents can be obtained only programmatically. You cannot delete internal private queues.

**Outgoing queues**

*Outgoing queues* are local internal queues that are used to store messages sent to remote queues. Messages can be stored in outgoing queues under offline conditions and then sent to target queues on remote computers when connectivity is re-established. Outgoing queues are listed in the Outgoing Queues folder. These queues are generated automatically and cannot be created or deleted manually. Outgoing queues can be in any of the following states:

- **Connected**. The outgoing queue is connected to the queue manager on the computer. This state indicates the local queue manager is sending messages and that the messages will be going out immediately.
- **Disconnected**. The outgoing queue is not connected nor is it in the process of being connected. This state indicates that the queue manager on the computer is not sending messages to the destination queue nor in the process of connecting the applicable outgoing queue.
- **Disconnecting**. The queue manager is in the process of disconnecting the applicable outgoing queue, or the computer is in the process of disconnecting from the applicable session. The queue manager cannot send messages to the destination queue in this state.
- **Inactive**. The applicable outgoing queue is in a state in which the queue manager does not attempt to connect it to any session.
- **Local connection**. The queue is a local queue on the computer. This state indicates that sending messages to the queue does not require a network connection.
- **Locked**. The outgoing queue is in the state defined by hardened MSMQ mode for outgoing queues that correspond to destination queues specified by non-HTTP format names. Messages in locked outgoing queues are not transmitted to their destinations.
- **Need Validation**. The queue was opened when the queue manager was offline.
- **On hold**. The outgoing queue is paused.
- **Waiting**. The queue manager is in the process of connecting the outgoing queue.

# Dead-letter queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Dead-letter queues**

Undeliverable and expired nontransactional messages are stored in nontransactional dead-letter queues. Undeliverable and expired transactional messages are stored in transactional dead-letter queues. Such messages are stored in the applicable queues on the computer on which the message expired (or failed to be delivered or forwarded). This can be the source computer, the target computer, or an intermediate Message Queuing server.

There is one nontransactional dead-letter queue and one transactional dead-letter queue on each Message Queuing server and independent client. These queues are created automatically and are listed in the System Queues folder of the applicable computer in MMC snap-ins.

Messages are considered undeliverable when the following conditions apply:

- The destination queue is unknown by the sender.
- The message exceeds its maximum number of allowed hops.
- The queue storage limit, or quota, is reached.
- A nontransactional message is sent to a transactional queue or vice versa.
- For transactional messages, the sending or receiving transaction failed. However, when the receiving transaction fails, these messages are not placed in the transactional dead-letter queue.

Messages are considered expired when:

- The lifetime of messages on the network, called the time-to-reach-queue (TTRQ), elapses. This can be set programmatically by a Message Queuing application.
- Their time-to-be-received (TTBR) elapses. This is always set programmatically by a Message Queuing application.

When a sending application is not allowed to send messages to a particular queue because of a lack of the necessary access rights, those messages are not stored in the nontransactional dead-letter or transactional dead-letter queues. However, negative acknowledgment messages may be generated if the original messages are so configured.

Messages in nontransactional dead-letter and transactional dead-letter queues are always written to disk and are therefore recoverable.

For more information on transactional messaging, see Transactional messaging.

# Connector queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Connector queues**

*Connector queues* receive messages sent to destinations on foreign computers. Such queues reside on Message Queuing servers running a connector application, which enables the foreign computers to communicate with other Message Queuing computers in your network. Such servers typically have two connector queues: one used for transactional messages and one used for nontransactional messages. When a Message Queuing client sends a message to a foreign computer, the message is first routed to a connector queue. The connector application then retrieves, converts, and forwards the message to the foreign computer.

Connector queues are created implicitly. They are not published in Active Directory and are transparent to the Message Queuing applications sending messages to a foreign queue. From the standpoint of applications, sending a message to a foreign queue is identical to sending a message to a Message Queuing queue. A *foreign queue* is a part of the foreign messaging system but is exposed to the Message Queuing environment.

For more information on communicating with foreign computers, see Foreign computers and sites.

# Queue names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Queue names**

The following sections describe the various ways to designate Message Queuing queues. Queues are specified using *path names*, *format names*, and *queue aliases*. For more information about the types of queues mentioned here, see Queues.

**Path names**

The path name of a queue consists of the name of the computer hosting the queue and the name of the queue separated by a slash in the form *ComputerName**QueueName*, except for a public queue located on the local computer where the path name is in the form .*QueueName*. The names of private queues are prefixed by the string private$ separated by a slash. Thus, the path name of a private queue has the form *ComputerName*\private$*QueueName* or .\private$*QueueName* for a private queue located on the local computer.

**Format names**

Format names are used mostly by Message Queuing applications to perform tasks programmatically. However, they are also used in some administrative tasks (for example, in creating queue aliases and multiple-element format names), and administrators must have an understanding of format names to make correct decisions. The following sections describe most of the types of format names used in Message Queuing.

**Direct format names**

Direct format names are used to reference public or private queues without accessing the directory service. Message Queuing can use the information provided by direct format names to send messages directly to their destination. Thus, direct format names can be used to send and receive messages in workgroup mode, to send messages to computers on the Internet, and to send messages directly to a computer.

**Note** Direct format names that specify the HTTP or HTTPS protocol cannot be used to peek at or receive messages, only to send them.The following is the general format of direct format names. Note that public, private, and (for MSMQ 2.0 or later clients and servers) computer system queues can be accessed directly.

Direct format names contain the string `DIRECT=` followed by the location of the queue and its name. The following is the general format of direct format names for public, private, system, and URL-named queues (note that the format name string is a null-terminated Unicode string):

```
DIRECT=ComputerAddress\PublicQueueName

DIRECT=ComputerAddress\PRIVATE$\PrivateQueueName

DIRECT=ComputerAddress\SYSTEM$;SystemQueueName

DIRECT=HTTP://URL_Address/msmq/PublicQueueName

DIRECT=HTTPS://URL_Address/msmq/PublicQueueName

DIRECT=HTTPS://URL_Address/msmq/private$\PrivateQueueName
```

The computer address can be specified in two forms: as the network address of the target computer, which includes the network protocol TCP, or as any name for the target computer that is supported natively by the underlying operating system, where OS is used to indicate that the computer's native protocol will be used. The following examples illustrate these two forms:

```
DIRECT=TCP:157.18.3.1\MyPublicQueue

DIRECT=OS:pc001.microsoft.com\MyPublicQueue
```

In the case of a URL-named queue, the queue name is preceded by the string `msmq` separated by a slash. For example, the following format name can be used to reference "MyPublicQueue"

```
DIRECT=HTTP://URL_Address/msmq/MyPublicQueue
```

**Public format names**

Public format names and direct format names are used to reference public queues. When a public format name is used, Message Queuing uses its internal routing algorithm to define the route to the destination queue. When a direct format name is used, the message is sent directly to the destination queue.

When Message Queuing detects a public format name, it queries the directory service to determine what computer is currently hosting the queue, what protocol the host computer uses, and any other information it needs to rout a message to the queue.

Public format names contain the string `PUBLIC=` followed by the identifier assigned to the queue when it was created. This identifier is the GUID listed for the queue object in Active Directory. The following is the general format used to reference a public queue and its associated queue journal:

```
PUBLIC=QueueGUID
```

```
PUBLIC=QueueGUID;JOURNAL
```

A public format name is strictly equivalent to the identifier of the queue except that a public format name is formatted as a string rather than as binary data. The following is an example of a public format name string (note that the format name string is a null-terminated Unicode string).

```
PUBLIC=308FB580-1EB2-11CA-923B-08002B1075A7
```

**Private format names**

Private format names and direct format names are used to reference private queues. When a private format name is used, Message Queuing uses its internal routing algorithm to define the route to the destination queue. When a direct format name is used, the message is sent directly to the destination queue.

When Message Queuing detects a private format name, it does not refer to the directory service for information about the queue. However, it does use the directory service to look up information about the computer for routing purposes.

Private format names contain the string `PRIVATE=` followed by the identifier of the computer where the queue is registered and a hexadecimal number that identifies the queue. The following is the general format used to reference a private queue and its associated journal:

```
PRIVATE=ComputerGUID\QueueNumber
```

```
PRIVATE=ComputerGUID\QueueNumber;JOURNAL
```

The following is an example of a private format name string (note that the format name string is a null-terminated Unicode string).

```
PRIVATE=ae0c5671-f190-12ce-ae10-00dd0114290f\0000000d
```

**Distribution list format names**

Distribution list format names are used to reference distribution lists (group objects) stored in Active Directory. The distribution list identifier is the GUID listed for the distribution list (group) object in Active Directory.

Distribution list format names contain the string `DL=` followed by the distribution list identifier. This identifier is the GUID listed for the distribution list (group) object in Active Directory. The following is the general format used to reference a distribution list with optional inclusion of the domain name:

```
DL=DistributionListGUID[@DomainName]
```

The following is an example of a distribution list format name string (note that the format name string is a null-terminated Unicode string).

```
DL=ae0c5671-f190-12ce-ae10-00dd0114290f
```

To retrieve information about a distribution list, Message Queuing tries to resolve the DL format name to the corresponding Active Directory object in three steps:

1. If the domain name is included, it tries to bind to the Active Directory group object using this domain name.

2. If this attempt fails or the domain name is not specified, it allows Active Directory to use serverless binding to find the best domain controller in the default domain.

3. If this also fails, it tries to query the global catalog.

A distribution list format name can be an element of a multiple-element format name. In this respect, the analogy to a queue format name is preserved.

For more information about distribution lists, see Distribution lists.

**Multiple-element format names**

A multiple-element format name is formed as a concatenation of one or more public, private, direct, or distribution list format names separated by commas. Thus, different kinds of format names used in Message Queuing can be used together as elements of a multiple-element format name. The following example shows a multiple-element format name that contains a direct format name, a public format name, and a distribution list format name.

```
DIRECT=ComputerAddress\QueueName,PUBLIC=QueueGUID,DL=DL_GUID
```

Note that a multiple-element format name containing an element that points to a public queue or a distribution list cannot be used when there is no access to Active Directory.

Multiple-element format names cannot contain the format names of read-only queues, such as queue journals, computer journals, or dead-letter queues. An error is returned if the format name of a read-only queue is included in the multiple-element format name.

For more information about multiple-element format names, see Multiple-element format names.

For more information about these and other types of format names, such as machine and connector format names, refer to the Message Queuing Software Development Kit (SDK). For information about accessing the Message Queuing SDK, see Additional Message Queuing resources.

# Queue aliases

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Queue aliases**

Message Queuing 3.0 provides support for referencing queues with an Active Directory object called a queue alias, which can be used to reference queues that might not be listed in Active Directory.

Queue aliases are published in Active Directory, and in this respect, they resemble public queues.

Using a queue alias provides the following benefits:

- A queue alias can point to a public, private, or direct single-element format name used to reference a queue. Messages are sent to the queue or queues named in the corresponding format name. The validity of the format name and the existence of the queue to which a queue alias points are not tested when the alias is created. A queue alias thus points to a single queue, but it does not function as a queue because messages are not sent to it, but only to the queue or queues named in the corresponding format name. For more information about format names, see Queue names.

- A queue alias can serve as a tool to reference a private queue and URL-named queues included in distribution lists. While queue aliases can point to any queue, including private and URL-named queues, distribution lists can only include explicit references to destinations published in Active Directory; that is, to public queues, queue aliases, and other distribution lists, but not to private and URL-named queues. Thus, a queue alias can serve as a tool for including private and URL-named queues in distribution lists.

- When a queue alias object is deleted, the alias is automatically removed from all distribution lists that reference the alias. A queue referenced by a queue alias can be changed without having to change a distribution list that references it.

- A queue referenced by the queue alias can be changed without changing the alias reference. The alias can be used as a constant reference, as in a distribution list, even though the queue it represents may change.

- Queue aliases can be used to reference a queue that is not listed in the directory service. This includes private queues or queues from another organization.

- Queue aliases can be used to send HTTP messages by referencing the destination queue using a direct format name.

- Multiple aliases can be created for a single physical queue.

User interfaces are provided in Active Directory Users and Computers for creating and deleting queue aliases as well as for viewing and changing their properties. For more information about performing these tasks, see Create queue aliases, View or change properties of queue aliases, and Delete queue aliases.

The queue alias is a new object in Windows Server 2003 family. Thus, it can be used only in Windows Server 2003 family domains and cannot be accessed by computers running earlier versions of Windows.

# Target journaling

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Target journaling**

*Target journaling* is the process of storing copies of incoming messages on the computer hosting the applicable destination queue. Target journaling is configured on a per-queue basis. If you enable target journaling, Message Queuing sends a copy of any message you retrieve from a queue to the corresponding queue journal. Target journaling lets you keep track of messages even after they have been retrieved. Note that this does not include messages purged from the queue. For more information, see Purge all messages in a queue. Peeking at messages does not remove them from the queue. For more details, see Managing messages.

When enabling target journaling, consider the following:

- Target journaling is enabled by setting the journaling level of the queue. This can be set both when the queue is created or later.
- You must periodically clear messages from the queue journal to remove messages that are no longer needed. Message stored in the queue journal count against the quota of the journal and the quota of the computer where the queue journal resides (the computer quota is set by the administrator).
- If the journal or computer quota is exceeded, Message Queuing will not send copies of the messages to the journal when the messages are received, and those messages will be lost.
- A copy of each message retrieved from the applicable queue is transferred to the corresponding queue journal. This does not include messages removed from the queue when their time-to-reach-queue lifetime expires. For more information, see Message timers.

A queue journal is automatically created for each queue. It is listed as *Journal messages* under the applicable queue in Computer Management and Active Directory Users and Computers. Target journaling is disabled by default. For information on how to enable target journaling, see Enable or disable target journaling.

# Source journaling

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Source journaling**

*Source journaling* is the process of storing copies of outgoing messages on the source computer. It is configured on a per-message basis and is a property that is set programmatically by a Message Queuing application. Source journaling allows you to track the messages sent by a computer, and can be used to track messages that were sent successfully, messages that could not be delivered, or both. Source journaling is disabled by default.

There are two types of sources journaling, *positive source journaling* and *negative source journaling*.

**Positive source journaling**

You can track messages that were successfully sent by the local computer, so that when you send the message to remote destination queues, a copy of the message is placed in the source computer's journal if the message is sent successfully. This is known as *positive source journaling*. Note that this does not mean the message has successfully reached its destination queues, only that the local computer was able to send the message.

When messages are sent to local destination queues, the message can be placed in one of two journal queues:

- If the local destination queue has not enabled target journaling, a copy of the message is saved to the computer's journal queue only after the message has been removed from the local destination queue. This is the default setting.

- If the local destination queue has enabled target journaling, a copy of the message is saved to the queue's journal after the message is removed from the queue. The message is not, in this case, stored in the computer's journal queue. Message Queuing never stores more than one copy of a message on a single computer at one time.

**Negative source journaling**

You can track messages that were not delivered. This type of journaling is known as *negative source journaling*. When you specify this type of source journaling, Message Queuing reacts differently depending on the type of message you send:

- For nontransactional messages, a copy of the message is placed in the dead-letter queue of any computer that cannot deliver the message. This can be the source computer, or any routing server used to pass the message on to its destination. Failure indicates that the source queue manager on the computer cannot pass the message to the next hop.

- For transactional messages, a copy of the message is placed in the transactional dead-letter queue of the source computer only if Message Queuing does not confirm that the message was retrieved from its destination queue.

**Source journaling for transactional messages**

For transactional messages sent to transactional queues, journaling can be applied by setting the journal property of a transactional message. The following property values can be set programmatically:

- The default value. Source journaling is disabled. Message Queuing does not store copies of the message in the computer journal on success nor in the applicable dead-letter queue on failure.

- *Negative source journaling* is requested. The message is stored in the applicable dead-letter queue on failure, but no copy is stored in the source computer journal on success.

- *Positive source journaling* is requested. A copy of the message is stored in the source computer journal if the message was successfully delivered to the target computer, but no copy is stored in the applicable dead-letter queue on failure.

- Both *negative source journaling* and *positive source journaling* are requested. Copies of the message are stored in the source computer journal on success and in the applicable dead-letter queue on failure. This is the recommended setting.

**Differences in source journaling for transactional messages between MSMQ 1.0 and later versions**

MSMQ 1.0 treated source journaling for transactional messaging differently than MSMQ 2.0 and Message Queuing 3.0.

MSMQ 1.0 only allows you to specify *positive source journaling* to choose if you want to save copies of messages sent successfully. MSMQ 1.0 always uses *negative source journaling*, and places a copy of a non-confirmed transactional message in the transactional dead-letter queue.

MSMQ 2.0 and later versions allow complete control over source journaling. (If you are running MSMQ 1.0 applications on an MSMQ 2.0 computer, you can force the computer to use the MSMQ 1.0 semantics by setting the **XactDeadLetterAlways** registry entry to 1. After setting the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

**Managing source journals**

When you store messages in a journal or dead-letter queue, clear these queues periodically to remove messages that are no longer needed. Messages stored in journal and dead-letter queues count against the quota for the computer where the queues reside (the computer quota is set by the administrator).

When source journaling is enabled, a copy of the outgoing message is placed in the single computer journal of the source computer, which is listed as the *Journal messages* queue in the System Queues folder in Computer Management and Active Directory Users and Computers. This occurs either when the message arrives at the computer hosting the destination queue or when the message reaches a Message Queuing routing server that is one hop closer to the target computer. A Message Queuing server that routes messages for clients does not store copies of those messages in its computer journal.

Outgoing messages sent by dependent clients are placed in the computer journal on the supporting Message Queuing server.

# Messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Messages**

In the context of Message Queuing, messages consist of a body and a set of properties. Message bodies can contain text or any form of binary information, and can be encrypted. Most message properties are specified programmatically by Message Queuing applications. Some properties, such as the sender's security ID (SID) and the message ID, are specified by Message Queuing. Message properties cannot be encrypted. A message, including the body and all specified properties, can be no larger than 4 megabytes (MB) in size. For details, see the following links:

- For information about different types of message classes, see Message types.
- For information about message properties and the default lifetime of a message, see Message properties.
- For information about setting default lifetimes for messages, see Message timers.
- For information about how message priority is determined, see Message priority.
- For information about express and recoverable message delivery, see Message delivery methods.
- To learn about the characteristics of transactional messages, see Transactional messaging.
- To learn about message storage and message storage quotas, see Message storage.

# Message types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message types**

In the context of Message Queuing, messages can be of different types, and consist of a body and a set of properties. Message types, also called message classes, indicate the message function or disposition. The following message types are supported:

- **Normal messages**. All messages created by Message Queuing applications are normal messages. Normal messages can be sent to public, private, and dead-letter queues of both the nontransactional and transactional types, and copies of normal messages, which are themselves normal messages, can be sent to journals when source or target journaling is enabled. Normal messages do not contain status information; such information is contained in acknowledgment, report, and response messages.

- **Acknowledgment messages**. Acknowledgment messages report the status of normal messages. These messages are nontransactional messages that are sent to the administration queues specified in the original messages by the sending application. Acknowledgment messages can be either positive or negative. A positive acknowledgment message indicates that the original message arrived at the target queue and that it was received (removed by the receiving application). A negative acknowledgment message indicates that the original message did not reach the target queue before its time-to-reach-queue (TTRQ) elapsed, did not reach the target queue for a specified reason, that it was not received before its time-to-be-received (TTBR) elapsed, or was not received for a specified reason.

- **Report messages**. Report messages indicate the route followed by a message as it proceeds from a source computer with tracking enabled to its destination on a remote computer. Report messages are sent to the report queue on a source computer for all messages sent from that computer with the message route tracking flag set or for only test messages sent from it.

- **Response messages**. Response messages are messages sent by a receiving application to response queues specified by a sending application.

For more information on the various types of queues that these messages can be sent to, see Queues.

For more information on the various reasons why messages do not reach the target queue or are not received that can be specified in the message class, refer to the Message Queuing Software Development Kit (SDK).

# Message properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message properties**
In the context of Message Queuing, messages consist of a body and a set of properties, and can be of various types. Message bodies can contain text or any form of binary information, and can be encrypted.

Every message has properties. Some message properties are read-only, and the majority can only be modified programmatically. For more information, refer to the Message Queuing Software Development Kit (SDK).

**Default message lifetime**
Through the Computer Management snap-in, you can set the default lifetime of messages in your network, also known as the time-to-reach-queue (TTRQ) value. Messages are considered expired when the TTRQ value is reached. If you do not specify a TTRQ value, the following default setting apply:

- 4 days for messages sent from the following types of computers:
    - Computers running Message Queuing 3.0 in workgroup mode.
    - Clients running Message Queuing 3.0 that belong to a completely new Windows Server 2003 domain.
    - Clients running Message Queuing 3.0 that join an existing domain provided weakened security was not enabled for that forest.
- 90 days for messages sent from the following types of computers:
    - Any computer in a migrated enterprise and computers running MSMQ 1.0 or MSMQ 2.0 in Windows 2000 and Windows NT 4.0.

For information on how to set the lifetime of messages on your network, see Set the default lifetime for messages.

You can view the properties of messages, and you can choose which message property columns appear by default in the details pane (usually the right pane) of the snap-in and in what order. For instructions on how to view message properties, see View message properties. You can choose the columns to be displayed by selecting a message in the Computer Management snap-in, and then clicking the **View** menu, and selecting **Add/Remove Columns**. The following message properties are available for selection.

| Message property | Explanation |
|---|---|
| Admin Queue | Specifies the name of the administration queue used for system-generated acknowledgment messages. |
| Admin Queue Name Length | Indicates the length (in Unicode characters) of the format name buffer of the administration queue. |
| Application-specific | Specifies application-generated information such as single integer values or application-defined message classes. |
| Authenticated | Indicates whether the message was authenticated at the request of the sending application. |
| Correlation | Specifies an application-generated correlation identifier that the receiving application can use to sort messages. |
| Delivery Mode | Specifies how Message Queuing delivers the message to the queue, in either recoverable, or express mode. For more information, see Message delivery methods. |
| Destination Queue Format Name | Indicates the name of the destination queues to which the message was sent. |

| | |
|---|---|
| Destination Queue Format Name Length | Indicates the length of the format name buffer (in Unicode characters) allocated by the receiving application. |
| Encrypted | Specifies whether the message body of a private message was encrypted. |
| Encryption Algorithm | Specifies the encryption algorithm used to encrypt the message body of a private message. |
| Hash Algorithm | Identifies the hashing algorithm that Message Queuing uses when authenticating the message. |
| Label | Specifies the label of the message. |
| Label Length | Identifies the length (in Unicode characters) of the message label buffer. |
| Message ID | Indicates a unique identifier for each message in your enterprise. This includes application-generated and system-generated messages sent by Message Queuing. |
| Message Lookup ID | Indicates the lookup identifier of the message. The receiving application can use this identifier to peek at or retrieve the message from the queue without navigating the queue. |
| Priority | Indicates the message priority. A higher number indicates a higher priority message. The default value is 3. |
| Recipient Queue | Specifies the queue to which application-generated response messages are returned. |
| Recipient Queue Name Length | Indicates the length (in Unicode characters) of the response queue format name buffer. This is used by the receiving application to allocate a buffer for the response queue specified by the sending application. |
| Response Queue | Specifies the response queues used for returning application-generated response messages. |
| Response Queue Format Name | Specifies the response queues used for returning application-generated response messages. |
| Response Queue Format Name Length | Indicates the length (in Unicode characters) of the format name buffer allocated by the receiving application. |
| Response Queue Name Length | Indicates the length (in Unicode characters) of the format name buffer of the response queue format name buffer. |
| Sender ID | Identifies who sent the message, and used primarily by the receiving queue manager when authenticating a message. |
| Sender ID exists | Identifies who sent the message, and used primarily by the receiving queue manager when authenticating a message. |
| Sender ID Length | Indicates the length of the Sender ID. |
| Size | Indicates the size of the message body. |
| Source Computer | Provides the globally unique identifier (GUID) of the computer that sent the message. |
| Time Arrived | Indicates the date and time that the message was received. |
| Time Sent | Indicates the date and time that the message was sent by the source. |
| Tracked | Specifies whether Message Queuing traces the route of the message. |

# Message timers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message timers**

Message Queuing provides two timers to help you maintain better control of your messages: a *time-to-reach-queue* and a *time-to-be-received* timer.

The time-to-reach-queue (TTRQ) timer determines how long a message has to reach the queue manager of the target queue. Typically, this timer is set to a value less than the time-to-be-received setting.

The time-to-be-received timer determines how long a message remains in the system, starting from the time the message is sent to the time it is removed from the target queue.

Through the Computer Management snap-in, you can set the TTRQ value. If you do not specify a TTRQ value, the following default settings apply:

- 4 days for messages sent from the following types of computers:
    - Computers running Message Queuing 3.0 in workgroup mode.
    - Clients running Message Queuing 3.0 that belong to a completely new Windows Server 2003 domain.
    - Clients running Message Queuing 3.0 that join an existing domain provided weakened security was not enabled for that forest.
- 90 days for messages sent from the following types of computers:
    - Any computer in a migrated enterprise and computers running MSMQ 1.0 or MSMQ 2.0 in Windows 2000 and Windows NT 4.0.

For information on how to set the lifetime of messages on your network, see Set the default lifetime for messages.

The default setting for the time-to-be-received timer is that no limit is set.

When both timers are used and the time-to-be-received timer is set to a smaller value than the TTRQ timer, the time-to-be-received timer takes precedence. For example, if the time-to-be-received timer is set to 3 minutes and the TTRQ timer is set to 10 minutes, Message Queuing will discard the message after 3 minutes. A message is not allowed to remain in the system longer than the time specified by the time-to-be-received timer.

When a timer expires, Message Queuing discards the message. However, Message Queuing can also send a copy of the discarded message to the applicable dead-letter queue or it can send a negative acknowledgment message to an administration queue.

Discarded messages can be sent to dead-letter queues if the journal property of the message specifies a dead-letter queue. Copies of nontransactional messages are sent to the dead-letter queue on the computer where the timer expired. Copies of transactional messages are sent to the transactional dead-letter queue on the source machine.

Acknowledgment messages are returned if a timer expires and the acknowledgment property of the message specifies full or negative acknowledgments. Message Queuing sends the appropriate negative acknowledgment message to the administration queue specified by the message.

# Message priority

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message priority**
The order in which messages are sent to a queue on the destination computer, their *priority*, is determined first by the queue priority (also known as the base priority), and then by the message priority. The queue priority for public queues listed in Active Directory can be set to any number from -32768 to 32767. The default queue priority is 0.

Message priority affects how Message Queuing handles the message while it is in route, as well as where the message is placed in the queue. Higher priority messages are given preference during routing, and inserted toward the front of the queue. Message Queuing applications can set the message priority for nontransactional messages in the range from 0 to 7, where 7 represents the highest priority. The default value is 3. Messages with the same priority are placed in the queue according to their arrival time. Message Queuing automatically sets the priority level of transactional messages to 0.

Messages are sent to public queues based on the sum of the destination queue's priority and each message's priority. Messages with the highest resultant priority value are sent first.

Private queues do not support queue priority. Messages are sent to private queues based only on message priority.

# Message delivery methods

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message delivery methods**
Two basic message delivery methods are supported: express and recoverable. The choice between the two is essentially a choice between better performance with minimal resource use (express delivery), and reliability and recovery after a failure (recoverable delivery). The message delivery method is specified programmatically by the sending application. Recoverable messaging can also be further differentiated into transactional and nontransactional messaging.

**Express messaging**
Using express messaging means that messages are stored in RAM memory during routing and delivery, providing extremely fast performance but no recoverability if any computer that the message passes through fails. Notably, express messages are lost whenever the Message Queuing service is stopped.

Too many express messages accumulating in RAM may cause paging out to disk, leading to performance degradation. Thus, it is not recommended to store more express messages than physical memory can hold.

Express messages can, however, survive a network failure. For example, if a Message Queuing application sends express messages through a Message Queuing server and the network link between the Message Queuing server and the destination computer fails, the Message Queuing server continues to store the messages in memory. However, if the Message Queuing server fails before the network link is restored, the express messages are lost.

**Caution**

- If you are running Message Queuing in a server cluster, express messages will be lost during a failover from one node to another.

**Recoverable messaging**
Using recoverable messaging means that messages are written to disk during routing and delivery, making delivery somewhat slower than the use of express messaging, but ideal when failures cannot be tolerated or when computers shut down while messages remain in queues (such as for mobile clients on laptop computers). If a computer fails or is shut down while sending a message, the message is stored on disk. When the computer is restarted and the Message Queuing service restarts, the sending process is automatically resumed.

All recoverable messages are stored on disks in memory-mapped files. Performance gains can be realized by employing several physical disks to store recoverable messages. For more information, see "Disk considerations" in Planning overview.

# Transactional messaging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Transactional messaging**

Sending and receiving applications can indicate that they want to send or retrieve messages within the context of a transaction, known as transactional messaging. Sending or retrieving messages outside the context of a transaction is referred to as nontransactional messaging. Transactional message is only used when you want to perform several tasks in such as way that all tasks, including non-Message Queuing operations, will all succeed or all fail.

Transactions are characterized by their ACID (atomicity, consistency, isolation, durability) properties:

- **Atomicity.** Atomicity refers to the all-or-nothing behavior of a transaction. When a transaction consists of a series of actions, all the actions are treated as a single operation that is either completed successfully or not executed at all.
- **Consistency.** Transactions transform a system from one valid state to another.
- **Isolation.** Multiple transactions that are executed concurrently have no effect on one another during their execution. It appears to each transaction that the other transactions are executed either before or after it.
- **Durability.** After transactions are executed, their effects are permanent despite system or network failures.

When transactional messaging is used, the sending or receiving application has the opportunity to commit to the transaction (all the operations have succeeded), or to abort the transaction (one of the operations failed) so all changes are rolled back. When a transaction is aborted all operations are rolled back to the state when the transaction was invoked.

When sending messages within a transaction, all the messages are sent together and in the order they were sent, or they are not sent at all. Message Queuing guarantees that all messages sent within the transaction will arrive exactly once if they can be delivered, and in the order that they were sent. When retrieving messages within a transaction, all the messages are removed from the queue or they are placed back in the queue in their original position in the queue. Note that transactional messages cannot be sent to a multicast address, and that peeking at messages make no sense in the context of a transaction.

In Message Queuing, a transaction can encompass multiple sending and receiving operations. However, the same message cannot be sent and received within a single transaction. In a case where a transaction consists of sending multiple messages, either all the messages are transmitted in the order in which they were sent (if the transaction is committed), or none of the messages are transmitted (if the transaction is aborted). If multiple messages are sent to the same queue, Message Queuing guarantees that they arrive in the destination queue exactly once and in the order in which they were sent within the transaction. For more information, see Sending transactional messages to multiple destinations.

**Message order**

Messages that are to be delivered in the order in which they were sent belong to the same *message stream*. Each message in a stream carries a *sequence number*, identifying the message in the stream, and a previous number, which equals the sequence number of a previous message in the stream. The message whose sequence number equals the previous number of a message must be present in the destination queue before the message can be delivered. The first message in a stream always carries a previous number equal to zero.

Likewise, a transaction can consist of removing multiple messages from a queue. The messages are removed from the queue only if and when the transaction is committed; otherwise, they are returned to the queue and can be subsequently read during another transaction.

In addition, Message Queuing guarantees that messages sent in consecutive transactions initiated from the same computer to the same destination queue will arrive in the order in which the transactions were committed. Moreover, as in the other cases of sending transactional messages, each message, if it arrives at the destination queue, will arrive exactly once.

**Transaction performance**

Transactional messaging is slower than nontransactional messaging because messages are written to disk more than once and greater computer resources are required. Transactional messages can be sent only to transactional queues on the local computer or a remote computer (and nontransactional messages cannot be sent to transactional queues). When messages are received within a transaction, they can be retrieved only from a local transactional queue. However, messages can be retrieved

in nontransactional operations from local and remote transactional queues.

In the general case, there are two ways to implement transactional messaging, as follows:

- As external transactions
- As internal transactions

**External transactions**
External transactions are used if resources other than those that Message Queuing can provide need to be part of the transaction. They are coordinated by the Microsoft Distributed Transaction Coordinator (DTC), which is now part of Component Services (formerly known as Transaction Server). Message Queuing then serves as a *resource manager* under the control of the DTC. Using the DTC as the *transaction manager* for Message Queuing, transaction-based applications can be implemented, ensuring that all actions either all succeed or all fail. For example, a Message Queuing application can send a message and update a database in the same transaction. The DTC ensures that either both actions succeed (both actions are committed) or neither action is executed (both actions are aborted). The DTC is automatically installed on each computer during Windows Server 2003 family operating system installation for local transactions. To enable network DTC required for Message Queuing transactions across the network, see Enable network DTC access.

For more information on the DTC, see Using Component Services.

You can use external transactions to send or receive a message that is part of any COM-compliant resource operation and to send or receive multiple messages that are part of a single transaction.

**COM+ Transactions**
When your application is running in the COM+ (Component Services) environment, Message Queuing can send and receive messages within a COM+ transaction by using the current COM+ transaction object if it is available. Message Queuing, COM+ (Component Services), and DTC work together for this type of transaction.

**XA-Compliant Transactions**
Message Queuing can work in transaction systems that have an XA-compliant transaction manager. Because of this, DTC is used as a transaction process monitor and Message Queuing is a resource manager.

**Internal transactions**
Because they have less overhead, internal transactions execute much faster than external transactions coordinated by the DTC. Use internal transactions if there is no need to coordinate Message Queuing operations with operations involving external resources that require the use of the DTC. Message Queuing provides a transaction coordinator that supports only itself as a resource manager.

You can use internal transactions to do the following:

- Ensure that a message is delivered only once (called *exactly-once delivery*).
- Ensure that all messages sent from one computer to another are delivered in order (called *in-order delivery*).
- Using acknowledgments, confirm that the transaction was successful (messages were received). You can also use acknowledgments to confirm that messages reached (or were removed from) the destination queue.

There is a special type of internal transaction that Message Queuing provides when sending a single message:

**Single-message transactions**
When sending a single message, Message Queuing provides a single-message transaction that implicitly uses the Message Queuing internal transaction, and consists of a single operation performed on a single message. A single-message transaction can be used to request guaranteed exactly-once delivery of a single message sent to a transactional queue. The single-message transaction provides the best performance of all transaction types for sending a message. In addition to exactly-once delivery, a single-message transaction is faster than an external transaction.

For more information on transaction types, see "Microsoft Platform Software Development Kit (SDK)" in Additional Message Queuing resources.

**Order acknowledgment messages for transactional HTTP messages**
Transactional messages are to be delivered exactly once and in the order in which they are sent. When transactional messages

are sent over HTTP from the internal network of an enterprise to the Internet, the internal name of the sender's order queue must be translated into a logical address using a mapping to direct the order acknowledgment messages from the receiving computer outside the sender's enterprise, back to the sender's order queue. For more information, see Store and forward servers.

# Message storage

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message storage**
Message storage size limits, or quotas, specify the maximum cumulative storage size for all messages contained in a particular queue or on a computer. There are additional storage size limits, or quotas, that specify the maximum cumulative storage size for all journal messages contained in a particular queue journal or for messages contained in the computer journal and the dead-letter queues.

By understanding how messages are stored locally, you can determine the disk space being used to store messages, and you can inspect the properties of local queues.

The following sections discuss these concepts.

**Quotas for messages**
Quotas for messages can be divided into computer quotas and queue quotas. These quotas specify the cumulative size for all messages (including journal messages) contained in a particular queue or on a computer.

**Computer quotas**
Computer quotas specify the cumulative limit for all messages stored in destination queues, outgoing queues, and queue journals on a computer. Computer quotas are not applied towards internal private queues. Unlike queue quotas, when a computer quota is reached, no messages can be delivered to any queue or journal on the computer. No negative acknowledgment message is generated, and an error is returned for messages sent locally, while a remote computer tries to resend until one or more messages are removed (read) from a queue on the computer. Computer quotas are set for Message Queuing servers and independent clients. Computer quotas set on Message Queuing servers that support dependent clients apply both to the server and to all its dependent clients. Computer quotas for message storage and journal storage are set separately. For instructions on setting the message storage size for a computer, see Set the message storage size for computers. For instructions on setting the journal storage size for computers, see Set the journal storage size for computers. Following a new installation of Message Queuing, or an upgrade from Windows 2000, the default limit for these storage sizes is 8 gigabytes (GB).

**Queue quotas**
A queue quota specifies the cumulative storage size (number of bytes) available for all messages stored in a particular queue, whereas a computer quota limits the total storage available for all messages in destination queues, outgoing queues, and queue journals on the computer. When a queue quota is reached, messages can no longer be sent to the queue until one or more messages are retrieved (removed from the queue by a Message Queuing application). Queue quotas can be set for all queues. Queue quotas for message queues and journal queues are set separately. For instructions on setting the quotas for regular messages, see Set the message storage size for queues. For instructions on setting the storage size for the computer journal and dead-letter queues, see Set the journal storage size for queues.

Queue quotas and computer quotas can be set independently, and only on Message Queuing servers and independent clients. Message Queuing servers and independent clients can store messages only up to a certain limited maximum number on each computer, which depends on several factors. Quotas set on Message Queuing servers that support dependent clients apply both to the server and to all its dependent clients, since dependent clients do not store messages locally. Thus, a Message Queuing server supporting several dependent clients can hold no more than its own maximum number of messages divided by the number of dependent clients. For example, if the computer quota for the server is 50 megabytes (MB) and one dependent client creates 50 MB of messages, the server and the other dependent clients supported by the server cannot send messages until the total message storage size drops below that quota.

The computer quota is enforced first, regardless of the cumulative queue quotas. For example, if you specify a 10 MB quota for each of six queues on a computer and a 50 MB quota for the computer, Message Queuing enforces the 50 MB computer quota first before each queue quota is reached. However, each queue quota still prevents any one queue from storing more than 10 MB of messages.

**Local message storage**
The files used to store messages are located in the Msmq\Storage and Msmq\Storage\Lqs folders (under \Windows\System32 by default).

Messages are stored in memory-mapped files (.mq files) on the hard disk of the source computer, destination computer, or intermediate Message Queuing server with routing services enabled. Disk space is allocated for both express and recoverable

messages in 4 MB increments as needed. For each recoverable message, the memory-mapped message file is written to disk, ensuring that the message is recoverable. For express messages, memory-mapped files are written to disk only when the computer does not have sufficient resources to hold the message in memory.

The computer sending the message creates the memory-mapped files. Message Queuing servers used to route messages also store messages in memory-mapped files. If source journaling is used, the memory-mapped files are located on the source computer. If target journaling is used, they are located on the destination computers. Message Queuing servers store all message files for the dependent clients they support.

To help safeguard your system against attacks by intruders, deleting, editing, or adding any file under the Msmq\Storage folder generates an audit entry in the security log.

The memory-mapped files can be stored using any file system supported by Windows Server 2003 family. However, because the NTFS file system for Windows Server 2003 family provides more reliable file recovery after a power failure or system crash, it is highly recommended for Message Queuing servers. In addition, it is recommended that you back up the folders where the message storage files are kept for fault tolerance. If the hard disk that contains the message files fails and if the data cannot be recovered using a backup program or the message backup/restore utility provided with Message Queuing, the messages will be lost. For more information on the message backup and restore utility, see Backing up and restoring messages.

**Files in the Msmq\Storage folder**
Files with an .mq extension represent memory-mapped files in which messages are stored. The .mq file name extension is prefixed with a letter representing the type of message it is currently storing, as follows:

- **r** — Express messages (Express messages are normally stored in RAM, not on disk. This file is used when there is no more available RAM.)
- **p** — Recoverable messages.
- **j** — Journal messages.
- **l** — Message logger file for interpreting recoverable and journal message files.

An .mq file does not represent one particular queue. Messages from multiple queues can be stored in one .mq file, and messages from a single queue can be stored in multiple .mq files. However, a single message cannot span multiple files. This is the reason for the 4 MB limit in message size.

The QMLog file is a history of all transactional processing. When the log is full, the oldest data are overwritten as new entries are made. To allow such continuous cyclic writing to the QMLog file, the message sequence and the state of all active transactions are periodically saved to the following files, respectively:

- MQInSeqs.lg1
- MQInSeqs.lg2
- MQTrans.lg1
- MQTrans.lg2

The MQInSeqs.* files are referred to as the message logger files, and the MQTrans.* files are referred to as the transaction logger files.

The *.lg1 and *.lg2 files are written to in an alternating pattern to ensure that one file in each pair is recoverable if the other is corrupted during a write operation.

**Files in the Msmq\Storage\Lqs folder**
Files in the Lqs (local queue storage) folder are text files that describe properties of the local queues.

File names with the *nnnnnnnn.hhhhhhhh* format represent private queues. The *nnnnnnnn* portion is the queue number (which is included in the direct format name of the queue). The *hhhhhhhh* extension is a hash of the queue path and is used for quick lookup.

File names with the *aaaaaaaabbbbccccddddeeeeeeeeeeee.hhhhhhhh* format represent local public queues. The left-hand 32-character portion of the file name is the globally unique identifier (GUID) of the queue. The *hhhhhhhh* extension is a hash of the queue path.

Warning

- If you delete the files in the Lqs folder, you will destroy the internal private queues, in which messages needed for internal Message Queuing operations are stored and without which the Message Queuing service cannot start running. Check for Message Queuing events in Event Viewer. The most common symptoms of the loss of these queues are events with IDs 2020 and 2052.

- The message store location must only be modified using the **Storage** tab, in **Computer Management**, **Services and Applications**, Message Queuing properties.

# Triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Triggers**

Message Queuing Triggers is a service that you can use to associate the arrival of each incoming message at a queue with a response. The response depends on the contents of the message and may invoke either a COM component or a stand-alone executable program. For details, see the following links:

- For an overview of what triggers are and how to define them, see Triggers overview.
- For more detailed information on conditions and actions you can specify when creating rules for triggers, see Trigger rules.

# Triggers overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Triggers overview**

Message Queuing Triggers is a service that allows you to associate the arrival of each incoming message at a queue with a response that depends on the contents of the message and may invoke either a COM component or a stand-alone executable program. You can use Message Queuing Triggers to define business rules that can be invoked in response to such messages without any additional programming. Ordinarily, to provide such message-handling functionality, application developers would have to create a receiving application that invokes specific behavior on a per-message basis. By using Message Queuing Triggers, specific behavior can be invoked at the queue level. Application developers no longer need to write any infrastructure code to provide such message-handling functionality. Triggers can be associated with queues located on the local computer and a remote computer.

Triggers are not installed by default during Message Queuing installation. For information on installing triggers, see Installing Message Queuing triggers.

**Triggers security**

By default, the Message Queuing Triggers service runs under the Network Service account. Services that are running under this account interact with the network using the credentials of the computer account, and this account has the same level of access to resources and objects as members of the Users group accounts. You can specify a less secure account for the Triggers service; for example, the Local System account, allowing access to the entire domain. Note that the Triggers service running under the Network Service account does not interact with the desktop. If this functionality is required, you can configure the Triggers service to run under the Local System account and enable interaction with the desktop in Computer Management.

The account used must be able to access the queues with which triggers are associated. Specifically, the account must be granted the **Log On As A Service** permission and the **Peek Message** permission for all applicable queues. If the message processing type of a trigger is "retrieval" or "transactional retrieval," the user must be granted the **Receive Message** permission for that queue. If you change the security settings for a queue to enable a trigger to monitor it, you must stop and start Triggers to update the service's configuration before the trigger will start to work. Note that executable files invoked by triggers are invoked with the same security privileges as those assigned to the Triggers service.

The Triggers service must run under an account with administrator permissions.

**Serialized and nonserialized triggers**

Message Queuing triggers can be serialized or nonserialized. The type of triggers you define for a specific queue will affect how the Message Queuing Triggers service processes incoming messages. If you create multiple triggers for a particular queue and at least one of them is serialized, all the triggers will behave as serialized triggers, even if they are not defined as serialized. Triggers with the transactional-retrieval processing type can only be serialized.

A serialized trigger processes messages in the order in which they arrive, testing each message for the conditions of all the rules associated with it and performing all the applicable actions before moving on to the next message. When serialized triggers are defined, the throughput of the Message Queuing Triggers service is lower than for nonserialized triggers because the messages are processed one at a time and the service must wait until all the operations performed on each message are completed.

Nonserialized triggers process messages faster, but the messages are not necessarily processed in the order in which they arrived. Nonserialized triggers provide a faster throughput because the Message Queuing Triggers service does not wait for all the operations performed on one message to be completed before starting to process the next message. It is recommended that you use only one trigger with the serialized option because the order of trigger firing is random with respect to their GUIDs.

**Trigger elements**

Each trigger is associated with a specific *monitored queue* on the local computer and is invoked by the Message Queuing Triggers service for every Message Queuing message arriving at that queue. A trigger is configured to obey one or more *rules*. A rule is defined by one or more *conditions* and an *action* in the form of an executable file or COM component that is executed when all the conditions associated with the rule are evaluated as true.

A *trigger* is an automatic mechanism for implementing a specific action in response to a message event. In the context of Message Queuing Triggers, an event is defined as a set of one or more conditions that may be satisfied by a message arriving in a queue. The collection of all triggers on a particular computer is called the *trigger set*.

A *condition* is a criterion that is applied to a message when it arrives at a monitored queue. A condition can test only for a property of the message. Every condition or set of multiple conditions is associated with an action.

An *action* results when a condition or a set of multiple conditions is true. An action can be expressed as an executable and a parameter list, or as a COM component, a method, and a parameter list. You can also invoke other types of files by making them parameters of an .exe file. For example, you can invoke an .msc file by specifying mmc.exe as the executable file and the full path of the .msc file as a parameter.

A *rule* is a condition-action pair. A rule specifies the action that will be taken when a specific condition or set of conditions is true. The collection of all rules (for all triggers) on a particular computer is called the *rule set*.

# Trigger rules

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Trigger rules**

All rules created on the local computer are displayed in the Computer Management snap-in. You can attach multiple rules to a trigger. If you do so, the rules are executed in the order in which they are displayed in the **Attached rules** list on the second page of the **New Trigger** dialog box or on the **Attached Rules** tab of the ***YourTrigger*** **Properties** dialog box. You can change the priority (order of execution) of rules in this list by selecting a rule and clicking the applicable button. The rules displayed in the **Rules** list are disabled by default. To enable a rule for use with a trigger, you must attach the rule to the applicable trigger. For more information, see View or change properties of triggers and rules for triggers.

A rule is composed of one or more conditions and an action that is executed when the conditions are true. Each condition is applied to every message arriving at the monitored queue, and the result is either true or false. Multiple conditions must all be true for an action to be executed. If no condition is specified, a true value will always be returned. This is useful when you want a trigger to fire unconditionally every time a message arrives at the monitored queue. The conditions applied to a particular rule are listed in the **Condition list** on the **Conditions** page of the **Properties** dialog box for that rule. New rules are composed by selecting a supported initial string in the **New condition** list box and typing a concluding string in the text box below it. These conditions are summarized in the following table.

| Condition | Description |
|---|---|
| Message label contains/does not contain | Tests whether the label of the newly arrived message contains (or does not contain) the string you specified. This string is case-sensitive. |
| Message body contains/does not contain | This applies only to messages with a string body type (VT_BSTR, VT_LPWSTR). Otherwise, the condition will always be false, and no action is invoked. |
| Message priority equals/does not equal/is greater than/is less than | Tests whether the priority of the newly arrived message satisfies the mathematical expression you specified. |
| Application-specific message number (AppSpecific) equals/does not equal/is greater than/is less than | Tests whether an application-specific message number satisfies the mathematical expression you specified. |
| Message source computer ID (SourceMachineGuid) equals/does not equal | Tests whether the source computer GUID equals (or does not equal) the value you specified. |

The actions performed when a condition or set of conditions is true are expressed either in the form of a stand-alone executable file and parameters (arguments), or in the form of a COM component, a method, and parameters. You can specify one or more parameters to be passed per action.

The supported parameters are:

- Message ID (as variant)
- Message label (as string)
- Message body (as variant)
- Message body (as string)
- Message priority (as number)
- Message sending time (as date variant)
- Message arrival time (as date variant)

- Message correlation ID (as variant)
- Message lookup ID (as variant)
- Queue path name (as string)
- Queue format name (as string)
- Response queue format name (as string)
- Administration queue format name (as string)
- Application-specific message number (AppSpecific as long)
- Trigger name (as string)
- Trigger ID (as string)
- Message source computer ID (SourceMachineGuid as string)
- String literal
- Numeric literal

These parameters are presented in the list box under **Parameter** on the **Invocation Parameters** dialog box, which can be accessed by clicking **Parameters** on the third page of the **New Rule** dialog box, as well as on the **Action** page of the **Properties** dialog box for a particular rule. Note that the Message Queuing Triggers service runs under the Network Service account, and that executable files invoked by triggers are invoked with the same security privileges as those assigned to the Triggers service. If your rule invokes a COM component, make sure that it can be successfully invoked from the security context used by the Triggers service, is properly registered, and has suitable dependencies.

By default, the Message Queuing Triggers service runs under the Network Service account. Services that are running under this account interact with the network using the credentials of the computer account, and this account has the same level of access to resources and objects as members of the Users group accounts. For heightened security, you can change the default Triggers service account to a more secure setting; for example, the Local Service account, which limits access to the local computer. You can also specify a less secure account for the Triggers service; for example, the Local System account, allowing access to the entire domain. Note that the Triggers service running under the Network Service account does not interact with the desktop. If this functionality is required, you can configure the Triggers service to run under the Local System account, and enable interaction with the desktop in Computer Management.

If your trigger invokes an executable file with command-line arguments, these arguments can be included as parameters of the string literal type. However, you must add a separate parameter for each command-line argument.

You can also use parameters to invoke other types of files that can be included as a command-line argument of an .exe file. For example, you can invoke an .msc file by specifying mmc.exe as the executable file and the full path of the .msc file as an invocation parameter of the string literal type.

Triggers and rules are created and modified by mqtrig.dll, but the service is implemented by mqtgsvc.exe. Therefore, information about the state of any new or modified trigger or rule must be passed to the service. This is done by sending a notification message to a specific internal private queue. The service reads each message sent to this queue, updates its internal data accordingly, and then deletes the message.

For more information on how to create rules, see Create and attach rules to triggers.

# Multiple Destination Messaging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multiple Destination Messaging**

Message Queuing 3.0 includes a new model for one-to-many messaging. In previous versions of MSMQ, a single message could be sent to a single queue. Now, one-to-many messaging enables the same message to be sent to multiple recipient queues. This can be implemented in a number of ways. For details, see the following links:

- To learn about implementing one-to-many messaging using an Active Directory distribution group object to encapsulate a collection of destination queues that can serve as a distribution list in Message Queuing, see Distribution lists.
- To learn how messages can be sent programmatically to multiple destinations specified in the form of a multiple-element format name, see Multiple-element format names.
- For information on how to send messages to a single destination IP address, to be received and processed by multiple IP hosts, see IP multicasting.

# Distribution lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Distribution lists**

Message Queuing 3.0 allows sending applications to send a single message to a list of destination queues. That list can be constructed dynamically in the form of a multiple-element format name or can be published and kept in Active Directory in the form of a distribution list. For more information on multiple-element format names, see Multiple-element format names.

A distribution list is a set of target queues and/or distribution lists that can be used to do the following:

- Send transactional and nontransactional messages to multiple destinations.
- Specify one or more administration queues for sending application-generated acknowledgment messages, when acknowledgment messages are requested.
- Specify one or more response queues for sending application-generated response messages, when response messages are requested.

**Distribution lists and Active Directory**

Distribution lists are public lists that are published as distribution group objects in Active Directory. For more information, see Message Queuing objects. The explicit members of a distribution list must be destinations published in Active Directory; that is, public queues, queue aliases, and other distribution lists. Private queues and URL-named queues cannot be elements of a distribution list.

Private queues and URL-named queues, however, can be referenced indirectly in a distribution list through queue aliases. Queue aliases provide additional benefits when they are used in distribution lists. When a queue alias object is deleted, the alias is automatically removed from all distribution lists that reference the alias. A queue referenced by a queue alias can be modified without having to change a distribution list that references it. For more information on queue aliases, see Queue aliases.

Since distribution lists are objects in Active Directory, they cannot be used in workgroup or offline mode, in which there is no access to Active Directory. In these modes, messages can be sent to multiple destinations by using multiple-element format names, provided they do not contain an element that points to a public queue or a distribution list.

**Distribution list security**

Because distribution lists are objects in Active Directory, security attributes can be attached to control access to them, and their properties can be queried in Active Directory. In addition, they support encryption similar to queues. Each copy of a message can be encrypted using the public key of the destination computer for that copy.

A security descriptor is assigned to each queue and distribution list. This security descriptor lists the users and groups that are granted or denied access to the queue or distribution list, and the specific permissions assigned to those users and groups. The following specific permissions are associated with distribution lists:

- **Send To permission**. Allows a group or user to send messages to the applicable distribution list. By default, this permission is granted to everyone.
- **Add/Remove Self as Member permission for a public queue or queue alias**. Allows a group or user to add or remove the applicable public queue or queue alias as a member in a distribution list. All users are granted this permission by default.
- **Add/Remove Self as Member permission for a distribution list**. Allows a group or user to add or remove the applicable distribution list as a member in another distribution list. Only the owner of a distribution list has the Add/Remove Self as Member permission for it.

When a queue or distribution list member is added to a distribution list, the set of users with the Send To permission for the distribution list containing the new member is not altered. Thus, in particular, when a distribution list with more restricted access is added to a distribution list with less restricted access, it becomes possible for clients of the expanded distribution list

to access the new distribution list with more restricted access. This does not create a security risk because each distribution list can still control the set of users allowed to add members to it.

When a message is sent to a distribution list, Message Queuing verifies that the sender has the Send To permission to each of the top-level members (queues or distribution lists) in the distribution list. This is a compromise for achieving network traffic optimization. When a message is received, Message Queuing verifies that the sender has the Send To permission to the top-level members and to the destination queue itself.

To achieve security in sending operations, member containment in a distribution list is defined to be bidirectional: a member references its container and the container references its members. To respect the security restrictions on members, a member cannot be added to a member of a distribution list without permission from that member and its prospective container. In other words, both the container and the member must agree. For example, if a user wants to insert distribution list DL2 into DL1, the user must have the Add/Remove-Element permission for DL1 and the Add/Remove-Container permission for DL2. However, for the user to remove DL2 from DL1, only one of these permissions is required.

You can use Active Directory Users and Computers to create and delete distribution lists as distribution group objects, to add and delete members, and to view their properties. For more information on performing these tasks, see Create distribution lists, Delete distribution lists, and View, add, or delete elements in a distribution list.

Distribution lists can be referenced programmatically through distribution list format names. For more information on using distribution list format names and their syntax, refer to the Message Queuing Software Development Kit (SDK).

**Distribution list scope**

Distribution lists can be domain-scoped, global, or universal:

- **Universal**. Members of universal groups can include other groups and accounts from any domain in the domain tree or forest and can be granted permissions in any domain in the domain tree or forest.

- **Global**. Members of global groups can include other groups and accounts only from the domain in which the group is defined and can be granted permissions in any domain in the forest. Thus, distribution lists with global scope can include queues and distribution lists from the local domain, and queues and global distribution lists from other domains in the forest. They can be moved to another domain.

- **Domain-scoped**. Members of domain local groups can include other groups and accounts from Windows Server 2003, Windows 2000, or Windows NT domains and can be granted permissions only within a domain. Thus domain-scoped distribution lists can only contain queues and distribution lists from the local domain as members, and cannot be moved to another domain.

**Sending messages to distribution lists**

When a message is sent to a distribution list, Active Directory is queried to ascertain its members and to translate any queue aliases into queues. Thus, the distribution list is expanded to a list of target queues. Distribution list members can be added or removed dynamically during the expansion process. Then a copy of the message with the same message ID is sent to each of those queues. If a distribution list contains multiple references to the same destination, duplicate references are ignored when the destinations are opened for sending messages. For example, if the members of distribution list D1 include queue Q1 and another distribution list D2, it may turn out that D2 also contains Q1 or D1. If this is the case, the second reference to Q1 or D1 is ignored. Thus, recursive cycles specified by distribution lists containing other distribution lists are broken.

Distribution lists may reference a mixture of transactional and nontransactional target queues. When a nontransactional message is sent to such a mixture of targets, the message is allowed to be sent to all the transactional and nontransactional target queues on the local or a remote computer. However, when the nontransactional message reaches a transactional queue, it is rejected and transferred to the nontransactional dead-letter queue on the computer hosting the transactional queue for storage, and a negative acknowledgement message indicating that a nontransactional message was sent to a transactional queue is sent to the administration queue specified in the original message.

**Sending transactional messages to distribution lists**

Message Queuing guarantees that all messages sent within a transaction will arrive exactly once and in the order in which they were sent. Message Queuing also guarantees that all messages sent in consecutive transactions from a given computer to the same destination queue will also arrive exactly once and in the order in which they were sent. This means that the messages sent within the first transaction will arrive before those sent within a subsequent transaction.

These transactional semantics are also supported for distribution lists. Messages sent to the same distribution list within a transaction will be delivered to the distribution list exactly once and in the order in which they were sent. In addition, messages sent within multiple transactions from the same source computer to the same distribution list will be delivered to the

distribution list exactly once and in the order in which they were sent. Thus, the delivery of transactional messages to distribution lists and to queues is identical.

This equivalence, however, does not extend to the queues referenced by distribution lists. There is no guarantee of in-order delivery to a queue for transactional messages sent to different distribution lists, even if they contain the same elements (queues). Nevertheless, the messages will be delivered exactly once. In the case of delivery failures, Message Queuing places the original message with an indication of the first failed delivery in the source computer's transactional dead-letter queue.

Consider the following examples:

- Example: In-order delivery to the same distribution list:
    - Distribution list DL1 = Queue Q1
    - Send message M1 to DL1
    - Send message M2 to DL1
- In this case, Message Queuing guarantees both in-order and exactly-once delivery.
- Example: Out of order delivery to different distribution lists:
    - Distribution list DL1 = Queue Q1
    - Distribution list DL2 = Queue Q1
    - Send message M1 to DL1
    - Send message M2 to DL2
- In this case, even though both distribution lists contain the same elements, messages to Q1 will not necessarily arrive in-order to Q1. However, exactly-once delivery is guaranteed, so that M1 and M2 will arrive once and only once.

In contrast, using multiple-element format names can provide this in-order guarantee for messages sent to different distribution lists, since each message sent to a multiple-element format name containing a list of target queues. For more information, see Multiple-element format names.

**Dynamic distribution lists and transactions**
Because distribution lists are dynamic, recipients can be added while transactional messages are in transit. Such new recipients will start to receive transactional messages on the next appropriate transaction boundary. Only messages sent after a new queue joins a distribution list will reach the new member.

**Distribution list acknowledgements**
When a message is sent to a distribution list, potentially a set of different acknowledgements can be generated, since some target queues might receive the message successfully, while others may not. A sender should expect at least *n* acknowledgment messages for a message sent to a distribution list with *n* ultimate recipients when acknowledgment messages are requested. More than *n* acknowledgment messages should be expected when a single message generates a positive acknowledgment message upon arrival at its destination and a positive or negative read acknowledgment message. Note that all distribution lists and embedded distribution lists are expanded and duplicate recipients are eliminated before any messages are sent. However, to optimize message traffic, acknowledgment messages of the same class and generated for the same original message are combined into a single acknowledgment message containing a list of the queue GUIDs that acknowledged the message.

# Multiple-element format names

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Multiple-element format names**

Message Queuing 3.0 allows a sending application to send a single message to a list of destination queues. That list can be constructed dynamically in the form of a multiple-element format name or can be published and kept in Active Directory in the form of a distribution list. For more information on distribution lists, see Distribution lists.

A multiple-element format name can be constructed to do the following:

- Send transactional and nontransactional messages to multiple destinations.
- Specify multiple administration queues for sending acknowledgment messages.
- Specify multiple response queues for sending response messages.

A multiple-element format name is formed as a concatenation of one or more public, private, direct, or distribution list format names separated by commas (for more information on format names, see Format names in Queue names). Thus, different kinds of format names used in Message Queuing can be used together as elements of a multiple-element format name. The following example shows a multiple-element format name that contains a direct format name, a public format name, and a distribution list format name.

```
DIRECT=ComputerAddress\QueueName,PUBLIC=QueueGUID,DL=DL_GUID
```

Multiple-element format names can be used to send messages to multiple destinations even in workgroup or offline mode provided they do not contain an element that points to a public queue or a distribution list. For example, if a multiple-element format name references a private queue and a distribution list, no message will be sent to either target when there is no access to Active Directory.

Multiple-element format names can be used to reference multiple administration and response queues. However, they cannot contain format names of read-only queues, such as queue journals, computer journals, or dead-letter queues. An error is returned if a format name of a read-only queue is included in a multiple-element format name.

To enable downlevel compatibility, a list of explicit destinations is derived from every distribution list or multiple-element format name used to send a message in the source computer, and this information is included along with the distribution list or multiple-element format name in each message packet that is sent. For example, when a message is sent to distribution list D1 that references three queues (Q1, Q2, and Q3), the message packet sent to the three computers contains the explicit destinations Q1, Q2, and Q3 as well as the original distribution list D1. If any of the destination computers is running Message Queuing 2.0 or earlier, it will use the explicit destinations Q1, Q2, or Q3. Any computer that is running Message Queuing 3.0 will use D1 and disregard the repeated destinations.

**Sending transactional messages to multiple-element format names**

When a transactional message is sent to a multiple-element format name, appropriate guaranteed positive or negative acknowledgment messages can be returned to the sending application. In addition, Message Queuing guarantees that messages sent in consecutive transactions initiated from the same computer to the same destination queue will arrive exactly once and in the order in which the transactions were committed regardless of the way in which the target queue was addressed: either as an element of a multiple-element format name or as an individual queue.

When a transactional message is sent to a multiple-element format name, Message Queuing logically constructs a single transaction that consists of a series of discrete operations for sending the message to each of the target queues contained in the multiple-element format name and then either commits or aborts the entire transaction. This means that sending a message to a multiple-element format name within a transaction is semantically equivalent to sending a series of messages to individual queues within a single transaction.

Consider, for example, a multiple-element format name N1, which contains two queues Q1 and Q2, and a second multiple-element format name N2, which contains Q2 and Q3. Now consider a transaction consisting of the following three actions:

1. Sending message M1 to N1.

2. Sending message M2 to N2.

3. Sending message M3 to Q2.

Messages M1, M2, and M3 will arrive at queue Q2 exactly once and in the order in which they were sent.

However, the guarantee of exactly-once and in-order delivery applies only to identical top-level elements of multiple-element format names and does not extend to queues that are members of different distribution lists referenced by multiple-element format names. Consider the case of two distribution lists D1 and D2, each of which contains queue Q1 as a member, a multiple-element format name N1, which contains D1 and another queue Q2 as elements, and another multiple-element format name N2, which contains D2 and Q2 as elements. If message M1 is sent to N1 and message M2 is sent to N2 within the same transaction, the messages will arrive at Q2 in the order in which they were sent, but they will not necessarily arrive at Q1 in that order. Nevertheless, the messages will be delivered to both queues exactly once.

# IP multicasting

Updated: March 19, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**IP multicasting**

Message Queuing provides a mechanism to send and receive IP multicast traffic using the Pragmatic General Multicast (PGM) driver, which is installed and configured as part of the Core subcomponent during every installation of Message Queuing. Messages can be sent to a single destination IP address and then received and processed by multiple IP hosts. A host listens for a specific IP multicast address and receives all packets sent to it. The set of hosts listening on a specific IP multicast address is called the host group.

Using this method, a single copy of the message is sent on the network, and this message can then be received and processed by numerous destination applications. This method is especially useful if the same message has to be delivered to large numbers of receiving applications.

The sender specifies a target IP multicast address. An IP multicast address property is attached to a queue. Subsequently, every message that is sent to that multicast address is inserted into the queue by Message Queuing. Applications continue to read messages from the queue using standard Message Queuing features. The Message Queuing service on a specific host listens to all multicast addresses to which its local queues are bound, routes incoming messages to the appropriate queues, duplicates messages that are sent to multiple queues, and dynamically starts and stops listening to a multicast address as local queues become bound and unbound.

Be aware of the security implications of multicasting. Messages cannot be encrypted, and messages could be read or used by unauthorized persons. Ensure that the specified address is used only for Message Queuing multicasting.

The following are some of the specific features of IP multicast messaging:

- Only one copy of the message is sent, and it is received and processed only by computers, or hosts, that are listening for it.
- Hosts can join and leave the host group dynamically at any time.
- There are no limitations on the size of a host group.
- A host can send messages to an IP multicast address without belonging to the corresponding host group.
- Transactional sending is not supported.

A multicast address and a port number in the *IP_Address*: *PortNumber* syntax can be associated with any public or private queue. For public queues, this information is stored in Active Directory. For a private queue, this information is stored on the computer where messages sent to the queue are stored. Therefore, in workgroup mode, multicast addresses can be associated only with private queues, and in domain mode, a Windows Server 2003 family domain controller must be available to associate multicast addresses with public queues.

IP multicast addresses must be in the class D range from 224.0.0.0 to 239.255.255.255, which corresponds to setting the first four high-order bits equal to 1110. However, only certain ranges of addresses in this range are available for sending multicast messages. For the latest list of reserved multicast addresses, see the link to Internet Assigned Number Authority (IANA) Internet Multicast Addresses at Windows 2000 Resource Kits - Web Resources (http://go.microsoft.com/fwlink/?LinkID=291).

For information about how to specify or view the multicast address and port number for a specific queue, see Specify or view queue multicast addresses and ports.

No additional security mechanisms are provided for multicast messaging. Security is achieved through authorization and authentication based on the mechanisms for one-to-one messaging. Each target queue is protected by authentication based on sender and access based on sender and receiver. Encryption and decryption are not supported.

**Multicast messaging with multiple network adapters**

On a computer with multiple network adapters, a problem will occur when the computer tries to send multicast messages by means of these multiple network adapters. In effect, Message Queuing randomly chooses a network adapter for sending multicast messages. If the private network adapter is chosen, multicast recipients will not receive the message. To work around

this issue, you can specify the source IP address to be used for sending multicast messages. To do this, create the **REG_SZ** value **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\MulticastBindIP** in the usual IP address format. After setting the registry, restart the Message Queuing service for the changes to take effect.

| ⚠**Caution** |
| --- |
| Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry. |

**Multicast messaging on a cluster node**

For multicast messaging on a cluster node, if no IP address is specified in the **MulticastBindIP** key, the IP address is derived in the following way:

- On a virtual server, the virtual server's IP address that is defined for the IP address resource is used.
- If the cluster node has only one IP address, that address is used.
- If an IP address is specified in the registry, that address is used. If the IP address that is specified cannot be found on the node, an event is issued and the registry entry is ignored.
- If a node has multiple IP addresses, the cluster application programming interface (API) is used to make two lists—a first list of all private (not static) IP addresses, and a second list of all the node's IP addresses. These two lists are then compared to select an address that is in the second list but not in the first list. An informational event is issued with the IP address that is chosen. If the only IP addresses available are the addresses in the first list, one of those addresses is used and an event is issued.

To specify an IP address, create a **REG_SZ** value **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\ClusterBindIP** in the usual IP address format. After editing the registry, restart the Message Queuing service for the changes to take effect.

| ⚠**Caution** |
| --- |
| Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry. |

# Internet Messaging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

**Internet Messaging**

Message Queuing 3.0 provides Internet-messaging support. This section provides information about the basic concepts and features introduced in Message Queuing 3.0 to provide this support. Message Queuing sends messages over HTTP transport to URL-named queues. Message Queuing 3.0 provides Internet-messaging support with the following features:

- For an overview of Internet messaging, see Internet messaging overview.
- Message Queuing provides messaging over HTTP as an optional transport protocol. For more information, see HTTP/HTTPS messages.
- HTTPS provides access control and authentication when messaging with HTTP. For more information, see HTTPS authentication.
- When messages are sent over HTTP transport, external logical names or aliases can be mapped to internal physical queue locations, protecting internal resources and providing a solution for messaging through firewalls. For more information, see Store and forward servers.
- HTTP messages are formatted using the SOAP Reliable Messaging Protocol (SRMP) extensions of the SOAP protocol. To read more about the Message Queuing implementation of the SOAP protocol, see SRMP messages.
- For information on deploying HTTP messaging in Network Load Balancing clusters, see HTTP/HTTPS messaging in Network Load Balancing clusters.
- For information on HTTP messages in server clusters, see HTTP/HTTPS messaging in server clusters.

# Internet messaging overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet messaging overview**

Message Queuing 3.0 provides support for Internet and intranet messaging, with the following features:

- Reference queues using URL addresses.
- Send and receive HTTP messages to destination queues on an intranet or over the Internet in XML-based, SOAP Reliable Messaging Protocol (SRMP) format.
- Authenticate messages sent over HTTPS.
- Support for messaging through firewalls and perimeter networks.
- Web farm support, including a facility for mapping between external logical queue names and internal queue names, so that internal names do not need to be exposed to message senders.
- Support for deployment of Message Queuing in hardened MSMQ mode, to enhance the security of Message Queuing computers on the Internet.

**HTTP messages**

Message Queuing 3.0 includes an optional HTTP Support component, to send and receive messages in an intranet or over the Internet with the HTTP/HTTPS protocol, in addition to the Message Queuing protocol. Messages can be sent over HTTP/HTTPS to destination queues on an intranet within an enterprise or over the Internet, and the sender and recipient can be in different forests or organizations. HTTP/HTTPS is automatically chosen as the transport for any Message Queuing message sent using an HTTP/HTTPS format name. For more information, see HTTP/HTTPS messages.

**SRMP messages**

SRMP is an extension of the SOAP Message Exchange Protocol (SMXP) that defines a reliable end-to-end messaging protocol for sending HTTP messages. Message properties are transmitted in XML, rather than in binary form. Message Queuing transforms message properties to specific SRMP and SMXP elements, and then on the receiver side, maps these elements to the respective Message Queuing properties before storing the message. For more information, see SRMP messages.

**HTTPS authentication**

Using HTTPS to send messages ensures authentication of users requesting access to Message Queuing resources by means of a Web server, and establishes a Secure Sockets Layer (SSL) connection for secure communication. A direct format name containing HTTPS as the protocol name invokes a secure HTTP transport through an SSL channel. SSL uses certificates to allow clients and Web servers to authenticate each other, and encryption keys to establish a secure communication connection. For more information, see HTTPS authentication.

**Message Queuing in hardened MSMQ mode**

To enhance the security of Message Queuing computers in an Internet environment and when sending and receiving HTTP messages, Message Queuing can be deployed in hardened MSMQ mode. Hardened MSMQ mode imposes restrictions on non-HTTP messaging. For more information, see Message Queuing in hardened MSMQ mode.

**Messaging with perimeter networks**

Most organizations connect to the Internet using a proxy server and a perimeter network protected by firewalls. Incoming messages pass through the firewall, and outgoing messages are sent through a proxy server. The proxy server is a mediator between the organization's intranet and the Internet world. It provides caching and decoupling. Message Queuing uses an HTTP proxy to connect to Web addresses for delivering HTTP messages. Message Queuing thus needs to know the name of the proxy server and the applicable port to which it must connect. At the same time, there may be a list of target names for which the proxy connection is bypassed; that is, Web addresses that do not need to be accessed through the proxy server. An attempt is made to establish a direct connection with such targets. All of the information regarding proxy servers is stored in registry keys. For more information, see Configuring firewalls for Message Queuing and Configuring Message Queuing with a proxy server.

**Message Queuing with ISA Server**
To use Message Queuing with ISA Server, install ISA Server Service Pack 1 or later. For more information, see ISA Server Service Pack 1.(http://www.microsoft.com/isaserver/downloads/sp1.asp)

**Web farm support**
For increased scalability and availability, Message Queuing with HTTP Support installed integrates with common network load-balancing mechanisms. Message Queuing applications can be deployed on the nodes of a Network Load Balancing cluster to receive and process messages sent to the cluster. When messages are sent over HTTP transport to a queue at a virtual URL address, a TCP session is established with one of the nodes in the cluster. For more information, see Message Queuing in Network Load Balancing clusters.

Similar Web farms can also be implemented using other load-balancing mechanisms, such as DNS round-robin distribution, and network address translation (NAT). For information on load-balancing Web farms, see Distributing Message Queuing in a network.

When messages are sent over HTTP transport, the network names of the computers within an organization and the names of the queues hosted on them do not need to be disclosed to message senders. Message Queuing provides a store and forward feature to map external and internal names, protecting internal resources. Mapping is enabled on a store-and-forward Message Queuing server, positioned in the front-end of the enterprise, where all incoming HTTP requests are directed. If messages meet mapping criteria, they are forwarded further into the enterprise. For more information, see Store and forward servers.

# HTTP/HTTPS messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**HTTP/HTTPS messages**

Message Queuing includes support for delivering messages over HTTP, in addition to the Message Queuing protocol. Messages can be sent over HTTP transport to destination queues on an intranet within an enterprise or over the Internet, and the sender and recipient can be in different forests or organizations. For Message Queuing to send messages over HTTP, you must install the Message Queuing HTTP Support subcomponent. This subcomponent installs Internet Information Services (IIS) and creates an IIS extension for Message Queuing. For more information, see Choosing installation subcomponents. This subcomponent is not installed during a default Message Queuing installation.

Message Queuing formats messages using the XML-based SOAP Reliable Messaging Protocol (SRMP), an open general-purpose extension of the SOAP Message Exchange Protocol (SMXP). SRMP defines an open implementation-independent protocol for the reliable one-way delivery of SOAP 1.1 messages. For more information, see SRMP messages. Using SRMP, applications can also be written to create messages that are indistinguishable from Message Queuing-generated HTTP messages on computers that do not have HTTP Support installed, such as computers running MSMQ 1.0 or MSMQ 2.0. These messages can be sent as HTTP packets and accepted by queues hosted on computers with HTTP Support installed. They can then be received as HTTP messages by applications running on those computers.

To send messages to a destination queue over HTTP, the target computer must have Message Queuing's HTTP Support subcomponent and IIS installed. Access to the queue can be restricted to specific users by changing the permissions of the virtual directory in the IIS snap-in.

For secure HTTP messaging, HTTPS provides authentication and a Secure Sockets Layer (SSL) connection between a sender and recipient. For more information, see HTTPS authentication.

**HTTP message formats**

Destination queues for HTTP messages are opened using direct format names that include the URL address of the target computer, the virtual directory name, and the queue name separated by slashes. The default virtual directory name is msmq, but Message Queuing can be configured by IIS to use a different virtual directory. The format names used to send messages over the Internet must include the IP address or complete DNS name of the target computer, while the computer name is sufficient for sending messages within the enterprise. Examples of these direct format names include:

- DIRECT=HTTP://157.18.3.1/msmq/MyQueue (Single computer or cluster)
- DIRECT=HTTP://Mike01/msmq/MyQueue (Within the enterprise)
- DIRECT=HTTP://mail.www.northwindtraders.com/msmq/MyQueue (Over the Internet)
- DIRECT=HTTPS://mail.www.northwindtraders.com/msmq/MyQueue (Over the Internet)
- DIRECT=HTTP://193.2.34.5/msmq/MyQueue (Over the Internet)

The public, private, and direct format names of administration or response queues can be included in messages sent over HTTP. Conversely, the names of administration or response queues in HTTP format can be included in messages sent over an ordinary (non-HTTP) transport. However, the use of distribution lists and multiple-element format names for these purposes is not supported.

For information on direct format names, see "Direct format names" in Queue names.

**Pipelining**

Sending a new request before finishing to read all the responses from previous requests is called pipelining. Because proxies do not always support pipelining and because IIS HTTPS currently does not support it, the pipeline modes of HTTP and HTTPS delivery are controlled by two subkeys, namely HttpPipeLine and HttpsPipeline (of type DWORD), under the HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters registry entry. When they are set equal to 1, pipelining is enabled. By default, HTTP delivery works in pipeline mode, while HTTPS delivery does not. After setting the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

# HTTPS authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**HTTPS authentication**

Using HTTPS to send messages ensures authentication of users requesting access to Message Queuing resources by means of a Web server, by establishing a Secure Sockets Layer (SSL) connection for secure communication between a sender and recipient. The sender is always regarded as the SSL client, and the recipient is regarded as the SSL server, regardless of whether the computers are running Message Queuing server or client software. Note that authentication for the purpose of establishing an SSL session is not the same as message authentication, which confirms that a message has not been tampered with and can be used to verify the identity of the message sender. For information about message authentication, see Managing message authentication.

Two kinds of certificates are used in HTTPS authentication:

- **Server certificates**. This certificate contains information about the server that allows a client to identify the server before sharing sensitive information.
- **Client certificates**. This certificate contains personal information about the user and identifies the SSL client (the sender) to the server.

**Server certificates**

Before an SSL connection can be established for sending messages, the recipient computer requires a server certificate that resides in the **Personal** store under **Certificates (Local Computer)** in the Certificates snap-in on the recipient computer.

For instructions on obtaining a server certificate from a CA and installing it, see Obtain server certificates for HTTPS messaging.

A server certificate obtained from a CA can be issued to the NetBIOS name or full DNS name of a computer. However, when HTTPS messages are sent, the destination specified in messages must be identical to the computer name in the recipient's server certificate. Thus, when only the NetBIOS name of the destination (for example, with a direct format name of the form DIRECT=HTTPS://msmqserv/msmq/private$/q1) is used to send messages within the same forest over an intranet to a computer whose server certificate contains the full DNS name, authentication fails. Consequently, when Message Queuing tries to create an SSL session, it receives a warning that the name in the certificate does not match the name of the destination, and the messages sent in this way accumulate in the outgoing queue.

**Verifying server certificates on the sender computer**

IIS on the recipient side must send the recipient's server certificate to the sender for authentication. This server certificate, which contains the signature of the certification authority (CA), the recipient's public key, additional information about the recipient, and an expiration date, must be from a CA that the sender trusts. To authenticate the recipient computer, the sender verifies that it trusts the CA and validates the signature in the recipient's server certificate.

When a sender computer trusts a CA, such as VeriSign or Microsoft Certificate Services, it has a certificate from that CA containing the CA's signature and public key in the **Trusted Root Certification Authorities** store under **Certificates (Local Computer)** in the Certificates snap-in. For instructions on importing a CA certificate on the sender computer from Microsoft Certificate Services, see Import a CA certificate from Microsoft Certificate Services.

**Client certificates**

An additional optional security component can be required for SSL sessions if IIS on the recipient side also requests the sender's client certificate for authentication. Client certificates are also obtained from a trusted CA and are stored in the MSMQ\Personal store under Certificates - Service (Message Queuing) on Local Computer in the Certificates snap-in on the sending computer. For information about obtaining and installing a client certificate, see Obtain client certificates.

**Mapping client certificates**

After a Web resource is configured to require an SSL channel, it still needs to be protected from unauthorized access. Since the anonymous user account has default write permissions for the physical MSMQ directory in IIS, and default IIS behavior is to ignore client certificate authentication, any user can send HTTPS messages. After client certificates are enabled, you can further protect content by creating mappings that relate the information contained in a client certificate to a Windows user account. For instructions, see Enable client certificates. Mapping is flexible, with one-to-one mapping to map individual client certificates to accounts, or many-to-one mapping to accept a wide range of certificates that meet specific criteria. For more information about mapping client certificates, see IIS online Help. After this is done, you can restrict or allow access to the MSMQ virtual

directory by configuring security settings for the corresponding physical directory.

When all the conditions imposed by IIS are satisfied, the sender (SSL client) and recipient (SSL server) create and exchange SSL session keys, which are used to encrypt all packets sent over the SSL connection. For more information about certificates and SSL connections, see IIS online Help.

**Access control with HTTPS**

For messages sent with the https transport (DIRECT=HTTPS) there are two unrelated levels of authentication used.

### Hop to Hop Authentication

Hop to hop authentication is performed on the wire between hops through the use of an ISAPI filter (mqis.dll) installed on the destination IIS Server as follows:

- The Message Queuing service on hop N-1 authenticates the identity of IIS on hop N via the server certificate installed on the IIS Server.

- The IIS Server on hop N authenticates the identity of hop N-1 using client certificate mapping. In the absence of client certificate mapping, the IIS Server on hop N sets the identity of the Message Queuing service on hop N-1 to the guest account configured for the IIS Server. The IIS Server on hop N then performs an access check of the specified account against the MSMQ web directory.

Hop to hop authentication is performed before the message ever reaches the MSMQ service on hop N.

| **Note** |
| --- |
| Hop to hop authentication is performed per hop, if store and forward director (SFD) redirection is used then each hop may authenticate differently. |

### End to End Authentication

Once hop-to-hop authentication has been successfully negotiated, the Message Queuing service on the destination computer authenticates the user that sent the message as follows:

- The destination Message Queuing service checks the message for a signature.

- If the message is signed then the destination Message Queuing service authenticates the user as the account specified in the message signature.

  | **Note** |
  | --- |
  | Specify whether a message should be authenticated and what digital signature is used by setting the appropriate value for the PROPID_M_AUTH_LEVEL property. |

- If the message is not signed then the destination computer authenticates the message using anonymous access credentials.

For more information about how users sending authenticated messages over HTTP/HTTPS transport can be validated, see Authenticating HTTP/HTTPS messages.

# Store and forward servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Store and forward servers**
When messages are sent over HTTP transport, the network names of the computers within an organization and the names of the queues hosted on them do not need to be disclosed to message senders. Message Queuing 3.0 can map external and internal names, protecting internal resources, and providing a solution for messaging through firewalls. Mapping is enabled on a store and forward server, positioned in the front-end of the enterprise, where all incoming HTTP requests are directed. If messages meet mapping criteria, they are forwarded further into the enterprise. For instance, only messages arriving by means of an HTTPS session, or messages whose sender can be authenticated, or messages selected by another security criterion will be forwarded. This ensures that only authorized messages are ever presented to corporate servers.

**Logical and physical addresses**
Using this mapping facility, HTTP messages can be redirected from a logical address, accessible from the Internet, to a corresponding internal physical address. These are defined as follows:

- **Logical address**. Contained in URL format in the **<to>** subelement of the **<path>** element of the SRMP Message.
- **Physical address can be any of the following**:
  - A queue on the target computer specified in the logical address, to which the message must be written by the Message Queuing service.
  - A queue on a computer in the internal network. To deliver the message, an HTTP/HTTPS request call is made by the Message Queuing service handling the message.

Mappings are created manually by including **<Redirections>** entries in XML *mapping files*. Each **<Redirections>** element contains 0 or more **<redirection>** elements, each of which contains exactly one **<from>** subelement and exactly one **<to>** subelement. Each **<redirection>** element describes a map from a logical address (**<from>**), to a physical address (**<to>**). These XML mapping files must be stored in the \Windows\System32\Msmq\Mapping folder. A sample mapping template is provided in this folder.

The following example illustrates an XML mapping file:

```
<Redirections>
    <redirection>
      <from>http://www.fabrikam.com/accounts</from>
      <to>http://Accounts01/msmq/private$/DestQ</to>
    </redirection>
  </Redirections>
```

When an SRMP message reaches the computer specified as the logical address, the Message Queuing service uses a *local resolution algorithm* to map the logical address to the physical address.

**Local resolution algorithm**
A *local resolution algorithm* defines how the local Message Queuing service on the target computer specified in the logical address resolves the logical address into its physical address.

**Transparent mapping**
By default, if a message arriving from a remote computer address cannot be matched with a physical address in the mapping file, the message is discarded. However, if transparent mapping is enabled, a physical address for the message is set to the message's logical address. To enable transparent mapping, create the **MQS_TransparentSFD** registry value as indicated in the **Outbound message redirection** section of this topic.

The local resolution algorithm works as follows:

- If the logical address specifies a public or private queue on the local computer, and the queue exists, the physical address is set to the logical address of the queue.

- Otherwise, the Message Queuing service searches through all the **<redirection>** elements in its local mapping files to try to match the logical address with a **<from>** subelement in one of the local mapping files, but the corresponding **<to>** subelement does not indicate a local public or private queue, it sets the physical address to match this **<to>** subelement, and forwards the message to the remote computer specified in this **<to>** subelement. This process is called *redirection*.

- If transparent mapping is enabled, and the logical address of a message arriving from a remote computer cannot be resolved by any of the above methods, the physical address of the message is set to its logical address and the message is stored on the local computer.

- If transparent mapping is not enabled, and the logical address of a message arriving from a remote computer cannot be resolved by any of the above methods, the message is discarded.

- If the logical address of a message arriving from a local application cannot be resolved by any of the above methods, the physical address will be set to the logical address.

Hence if in the example above http://Accounts01/msmq/private$/DestQ does not point to a local private queue, then any SRMP message that is sent to the logical address specified will be forwarded to the computer Accounts01, where it will be written into the local private queue DestQ if such a local queue exists (subject to the normal authorization process) or it will be discarded silently if such a queue does not exist. If this **<redirection>** element is present in a mapping file on some other computer, the physical address of the message will be set to http://Accounts01/msmq/private$/DestQ and the message will be forwarded to this URL.

This provides a means to put HTTP messages sent to a logical address into an interim queue on the store and forward server in the receiving side of a perimeter network. From here they can be directed to the corresponding queue on a computer in the internal network.

**Using wildcards**

Limited use of regular expressions in **<from>** elements are supported. Asterisk-terminated URLs can define a redirection from multiple logical addresses to a single physical address. Only this type regular expression can be used, and only in the **<from>** element:

```
<Redirections>
  <redirection>
    <from>https://www.fabrikam.*</from>
    <to>http://Accounts01/msmq/private$/DestQ</to>
  </redirection>
</Redirections>
```

In this example, any message with a logical address that starts with the string https://www.fabrikam. will be redirected to the physical address in the <to> element. Thus, for example, messages with logical addresses https://www.fabrikam.com/accounts and https://www.fabrikam.net/data will be both redirected to the physical address http://Accounts01/msmq/private$/DestQ.

This functionality is based on software provided by J. Kanza. For copyright information for this software, see Message Queuing: External software copyright and permission notice.

**Order acknowledgment messages for transactional HTTP messages**

Transactional messages are to be delivered exactly once and in the order in which they are sent. When transactional messages (streamed HTTP messages) are sent over HTTP from the internal network of an enterprise to the Internet, the physical address of the sender's order queue must be translated into a logical address using a mapping, to direct the order acknowledgment messages (stream receipts) from the receiving computer (outside the sender's enterprise), back to the sender's order queue.

Mappings between logical addresses for sending streamed HTTP messages from local applications and logical addresses for returning order acknowledgment messages (stream receipts) from the recipient computers are created manually by including **<StreamReceiptSetup>** entries in an XML mapping file that is stored on the local computer. Each **<StreamReceiptSetup>** entry contains 0 or more **<setup>** elements, each of which contains exactly one **<LogicalAddress>** subelement and exactly one **<StreamReceiptURL>** subelement. In each **<setup>** entry, the **<StreamReceiptURL>** element specifies the URL that will be included in streamed (transactional) HTTP messages sent from a local application to a logical address matching the URL specified in the **<LogicalAddress>** element.

When a streamed HTTP message is sent from a local application, the local Message Queuing service searches the **<setup>** entries in the mapping file. If a URL matching the logical address of the message is found in the **<LogicalAddress>** element of one of the **<setup>** entries, the URL specified in the accompanying **<StreamReceiptURL>** element is inserted into the

**<sendReceiptsTo>** element of the **<Stream>** entry in the SOAP envelope of the message.

Each **<setup>** element also defines an implicit mapping that redirects every HTTP message arriving at the local computer with the destination specified in **<StreamReceiptURL>** to the physical address of the local order queue. Such messages are normally stream receipts (order acknowledgment messages).

A **<StreamReceiptSetup>** entry may contain one **<default>** element, which defines the default stream receipt URL that the local Message Queuing service inserts into every outgoing streamed (transactional) HTTP message, unless the logical address of the message matches the **<LogicalAddress>** element in one of the **<setup>** elements.

The following is an example of an XML mapping file that specifies the correspondence between a logical address for sending streamed HTTP messages from local applications and the logical address for returning stream receipts from the recipient computer along with the default URL for returning stream receipts:

```
<StreamReceiptSetup xmlns="msmq-streamreceipt-mapping.xml">
  <setup>
    <LogicalAddress>
      https://http://www.fabrikam.com/accounts
    </LogicalAddress>
    <StreamReceiptURL>
      https://www.fabrikam.com/StreamReceipts
    </StreamReceiptURL>
  </setup>
  <default>
    http://Accounts01/msmq/PRIVATE$/order_queue$
  </default>
</StreamReceiptSetup>
```

The limited use of regular expressions in the context of **<LogicalAddress>** elements is supported. Asterisk-terminated URLs can define the correspondence of multiple logical addresses to a single stream receipt URL. This is the only type of regular expression supported in **<StreamReceiptSetup>** entries, and it is allowed only in the **<LogicalAddress>** element.

In following example, any message with a logical address that starts with the string http://www.fabrikam.com/* will use the stream receipt URL specified in the **<StreamReceiptURL>** element.

```
<StreamReceiptSetup xmlns="msmq-streamreceipt-mapping.xml">
  <setup>
    <LogicalAddress>
      http://www.fabrikam.com/*
    </LogicalAddress>
    <StreamReceiptURL>
      http://www.fabrikam.com/StreamReceipts
    </StreamReceiptURL>
  </setup>
</StreamReceiptSetup>
```

**Outbound message redirection**

The number of HTTP/HTTPS sessions established and the number of client certificates needed can be minimized by routing all outbound messages (messages sent out of the enterprise) through a dedicated intermediate host. This dedicated intermediate host is called a transparent store and forward server (TSFD).

A computer with HTTP Support installed is configured as an intermediate host TSFD by creating the following REG_DWORD value in the registry and setting it to a value of 1:

```
HKLM\SOFTWARE\Microsoft\MSMQ\Parameters\MachineCache\MQS_TransparentSFD
```

After setting the registry, restart the Message Queuing service for the changes to take effect. After setting the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

Any other value or a lack of this registry key indicates that the computer will not function as a TSFD and that all messages sent to remote queues will be discarded if the computer does not have a regular XML mapping file for them.

For a source computer to be able to redirect its messages through an intermediate host, a special XML configuration file needs

to be added. This configuration file defines which messages will be redirected through an intermediate host and which will not. This XML configuration file must be stored in the \Windows\System32\Msmq\Mapping folder and is loaded when the Message Queuing service starts.

The following is an example of an XML configuration file that specifies the correspondence between the address of a destination queue and an intermediate host:

```
<outbound_redirections xmlns="msmq_outbound_mapping.xml">
  <redirection>
    <destination>http://target_host/msmq/private$/DestQ</destination>
    <through>http://intermediate_host/msmq</through>
  </redirection>
</outbound_redirections>
```

The **<outbound_redirections>** element contains 0 or more **<redirection>** subelements, each of which in turn contains exactly one **<destination>** subelement and exactly one **<through>** subelement. Each **<redirection>** element describes a redirection (or mapping) of the physical address of the destination queue given in the **<destination>** subelement to the virtual directory on the intermediate host given in the **<through>** subelement.

MSMQ 3.0 supports a limited use of regular expressions in a **<destination>** element. Users can use an asterisk-terminated URL to define a redirection of multiple physical addresses of destination queues to a single address of a virtual directory on an intermediate host.

In the following example, all messages sent using the HTTP protocol will be redirected through the intermediate host:

```
<redirection>
  <destination>http://*</destination>
  <through>http://intermediate_host/msmq</through>
</redirection>
```

Each **<outbound_redirections>** element may contain 0 or more **<exception>** subelements. You can use **<exception>** elements to exclude messages sent to specific queues from being redirected by outbound **<redirection>** rules.

MSMQ 3.0 supports a limited use of regular expressions in an **<exception>** element with the same restrictions as for the previously described **<destination>** element.

In the following example, all messages sent to private queues on special_host will not be redirected through the intermediate host:

```
<exception>http://special_host/msmq/private$/*</exception>
```

You can use the keyword **local_names** in an **<exception>** element to exclude messages sent to any internal (intranet) host from being redirected by outbound **<redirection>** rules.

In the following example, no messages sent to internal hosts will be redirected through the intermediate host:

```
<exception>local_names</exception>
</outbound_redirections>
```

# SRMP messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**SRMP messages**

Internet messaging is increasingly using the medium of XML, particularly the XML messaging framework of SOAP 1.1. The Web Services Routing Protocol (WS-Routing) supports both one-way and request/response message exchange paradigms. However, it is explicitly not a goal of WS-Routing to provide reliability. The SOAP Reliable Messaging Protocol (SRMP) is an open general-purpose extension of WS-Routing that adds reliability to WS-Routing and SOAP.

Message Queuing uses both WS-Routing and SRMP elements as well as elements defined in the MSMQ namespace to specify its message properties in HTTP messages. Some Message Queuing message properties have equivalents defined by WS-Routing, and others have equivalents defined by SRMP.

When sending an HTTP message, Message Queuing automatically transforms the individual binary message properties to specific WS-Routing elements, SRMP elements, and elements of the MSMQ namespace, and includes them in the header portion of the *SOAP envelope*. On the receiver side, Message Queuing maps these XML elements to the respective binary message properties before storing the message. The end-to-end semantics for transmitting message properties over a non-HTTP transport are preserved for messages sent over an HTTP transport.

The header portion of the SOAP envelope in an HTTP message contains two required entries and up to seven optional entries in the following order:

- **<path>**

  (Required.) Contains WS-Routing subelements.

- **<properties>**

  (Required.) Contains SRMP subelements.

- **<services>**

  (Optional.) Contains SRMP subelements.

- **<Stream>**

  (Optional.) Contains SRMP subelements. This entry is generated only in transactional messages.

- **<streamReceipt>**

  (Optional.) Contains SRMP subelements. A **<streamReceipt>** entry is generated only in order acknowledgment messages (stream receipts) sent for transactional messages (streamed HTTP messages).

- **<deliveryReceipt>**

  (Optional.) Contains SRMP subelements. A **<deliveryReceipt>** entry is generated only in acknowledgment messages sent in response to a request to indicate that the original message reached the destination queue.

- **<commitmentReceipt>**

  (Optional.) Contains SRMP subelements. A **<commitmentReceipt>** entry is generated only in acknowledgment messages sent in response to a request to indicate whether or not the original message is received from the destination queue before its time-to-be-received timer expires.

- **<Msmq>**

(Optional.) Contains subelements defined in the MSMQ namespace.

- **<Signature>**

  (Optional.) Contains subelements that specify an XML digital signature.

For more information about SRMP elements and the equivalent Message Queuing properties, see the Message Queuing Software Development Kit (SDK). For details of how to access the SDK, see Additional Message Queuing resources.

Applications can be written to create messages that are indistinguishable from Message Queuing-generated HTTP messages on computers that do not have HTTP Support installed, such as computers running MSMQ 1.0 or MSMQ 2.0. These messages can be sent as HTTP packets and accepted by queues hosted on computers with HTTP Support installed. They can then be received as HTTP messages by applications running on those computers.

# HTTP/HTTPS messaging in Network Load Balancing clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**HTTP/HTTPS messaging in Network Load Balancing clusters**

Message Queuing can be implemented in Network Load Balancing clusters to receive and process messages sent to the cluster. To implement Message Queuing in a Network Load Balancing cluster, Message Queuing is installed with the same set of subcomponents on all nodes in a cluster. So that if you install Message Queuing with HTTP support on one node, install Message Queuing with the same functionality on all other nodes.

All computers in the cluster are addressed by the same virtual cluster IP address or set of virtual cluster IP addresses, and when messages are sent over HTTP transport to a queue at a cluster IP address, a TCP session is established with one of the hosts in the cluster. Messages can be sent only to destinations specified by direct format names that include a URL or IP address of the cluster.

In a Web farm implementation, such as a Network Load Balancing cluster, successive HTTP connections from the same source might be directed to two different servers. This means that end-to-end reliable messaging is difficult, and Message Queuing does not guarantee exactly-once delivery through a Web farm, although a best-effort attempt is made by means of a lightweight nonpersistent duplicate removal mechanism. This issue can be addressed by the use of Message Queuing's store and forward feature. Store and forward mapping uses XML files located on Message Queuing computers, with Message Queuing usually installed on each host in the Network Load Balancing cluster. These XML files maintain a mapping between the logical external URL or IP address to which the message is sent, and the physical internal address of a queue. For every incoming message arriving at a Network Load Balancing host running Message Queuing with store and forward functionality, the Message Queuing service will read the logical address to which it was sent. If a message meets mapping criteria, it is forwarded further into the enterprise. For more information, see Store and forward servers.

Similar Web farms and store and forward functionality can also be implemented using DNS round-robin distribution, and network address translation (NAT). For an overview of these, see Distributing Message Queuing in a network.

# HTTP/HTTPS messaging in server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**HTTP/HTTPS messaging in server clusters**

This section applies only to users running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition in a server cluster configuration. To implement Message Queuing in a server cluster, Message Queuing is installed with the same set of subcomponents on all nodes in a server cluster. This means that if you install Message Queuing with HTTP Support on one node, install Message Queuing with the same functionality on all other nodes.

When you install Message Queuing with the HTTP component on a cluster node, IIS will also be installed on that node, if it is not already installed. You then define cluster groups for Message Queuing, and create a virtual server - a cluster group that will contain the Message Queuing resource, plus other resources upon which the Message Queuing resource depends. For further information, see Message Queuing in server clusters. Each virtual server is associated with a network name and an IP address. To support these virtual servers, IIS must assign a Web site for all virtual server IP addresses. To do this, configure the default Web site setting to *All Unassigned*, which assigns to the default Web site all IP addresses that are not assigned to a specific site. Alternatively, you can specify the IP address of a particular virtual server as the default Web site. For instructions on setting these options, see Configure Message Queuing with HTTP for server clusters.

**Failover for the Message Queuing resource with HTTP**

If the IIS service on the cluster node goes down, this does not cause the Message Queuing cluster group to fail over. This means that in such a case the Message Queuing resource will continue to work on the node, but HTTP messaging cannot be used. For more information on forcing failover of cluster groups when IIS goes down, see the Windows Server 2003 family Help file, or the IIS Help file.

# Message Queuing in Clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing in Clusters**
This section provides information about messaging over clusters, and how to administer message queuing in clusters. For details, see the following links:

- For details on deploying Message Queuing in a server cluster, see Message Queuing in server clusters.
- For information on implementing Message Queuing on a Network Load Balancing cluster, see Message Queuing in Network Load Balancing clusters.

# Message Queuing in server clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing in server clusters**
The Message Queuing service can be implemented in a server cluster, which appears to network clients as a single, highly available system. Such clusters are used to increase reliability and fault tolerance through failover as well as to achieve load balancing. Message Queuing server clusters can be created only on computers running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. For these clusters, the Message Queuing service is installed on every node in the cluster. These instances of the Message Queuing service are needed to support Message Queuing resources in the virtual servers. In addition, although they are unaware of clustering, they are needed, even in a clustered system, to serve the many applications and system components that run outside the context of any virtual server and call Message Queuing APIs.

**Cluster groups and virtual servers**
A cluster group is a collection of cluster resources with the following characteristics:

- Groups define the units of failover. That is, when one resource in a group fails and it is necessary to move the resource to an alternate node, all of the resources in the group are moved to the alternate node.

- A group is always owned by one node at any point in time. Likewise, a resource is always owned by a single group. These relationships ensure that all of a group's members reside on the same node.

To access a network application or resource in a nonclustered environment, network clients must connect to a physical server (that is, a specific computer on the network identified by a unique network name and Internet Protocol (IP) address). If that server fails, access to the application or resource is impossible. Through server clusters, Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition enable the creation of virtual servers. Unlike a physical server, a virtual server is not associated with a specific computer and can be failed over like a group. If the node hosting the virtual server fails, clients can still access its resources using the same server name. A virtual server is a group that contains a network name resource, IP address resources, other virtual servers, and other resources - including applications like Message Queuing, to be accessed by the clients of the virtual server.

When you form cluster groups for Message Queuing, you must create a virtual server. The Message Queuing resource is dependent on a Physical Disk resource, to store message and queue data, and a Network Name resource, so that remote clients can access it. This virtual server is created on each node of the cluster using standard cluster tools (Cluster Administrator is the standard GUI tool) or cluster-creating APIs. If you are using triggers, HTTP messaging, or external transactions on your cluster, requiring a Distributed Transaction Coordinator (DTC) resource, a single DTC resource is created only in one of the virtual servers. Then you create a Message Queuing resource using Cluster Administrator in some or all of the existing cluster groups. The first time that a Message Queuing resource on any virtual server is brought online, the cluster Network Name resource creates a pseudo-computer object, and the Message Queuing resource creates the Message Queuing objects under it in Active Directory. Each virtual server functions similarly to a physical computer, so a Message Queuing server running in the context of a virtual server provides services similar to a Message Queuing server running on a physical computer. In particular, queues can be created on a virtual server, and messages can be sent to them. Such queues are addressed using the *VirtualServerName\QueueName* syntax.

For more information on Cluster Administrator, see Using Cluster Administrator, in the Cluster Administrator Help file.

For more information on creating virtual servers for Message Queuing using Cluster Administrator and on creating a DTC resource in a server cluster, see Installing Message Queuing in a server cluster.

Note that when you select the Physical Disk resource for the Message Queuing cluster group, Message Queuing allocates its storage in the *MSMQ\STORAGE* folder on the shared disk. After storage has been allocated, you cannot modify the folder location.

Message Queuing clients can communicate with a standard Message Queuing server running on a node of a server cluster, or if Message Queuing applications are cluster-aware, they can run on a Message Queuing server running in the context of a virtual server.

In the active/active model, which is supported by all versions of Message Queuing following MSMQ 1.0, there can be multiple Message Queuing virtual servers running (active) on a single node. Thus, in a simplified example, if there are two nodes in a server cluster and Message Queuing is installed on both of them and if these two nodes host a total of three virtual servers,

any of these virtual servers can fail over to the other node.

In the event of a failover, the resources of a group on one node, initially the preferred node, are taken offline and then brought back online on another node. The data stored on the physical disk remains unchanged because only the ownership of the Physical Disk resource is transferred to the new node. Upon failback, the resources are moved back logically to the preferred node.

Because the Message Queuing Triggers service is cluster-aware and supports the active/active paradigm, when the Message Queuing service fails over to another node, the Triggers service will fail over along with it. For this to occur, you must create a Message Queuing Triggers resource with resource dependencies on the Message Queuing resource and the Network Name resource on the applicable node using Cluster Administrator. When failover occurs, the trigger and rule definitions, which are stored in the Windows registry, can then propagate between cluster nodes along with the other Message Queuing keys. After failover, the Triggers service can thus continue to process the incoming messages in each monitored queue and invoke the applicable stand-alone executable or COM component according to the rules defined.

Virtual servers are managed using standard snap-ins. The Users and Computers snap-in can be used to manage the Message Queuing resources within a virtual cluster just as it is used to manage Message Queuing computers in a network. You can also open the Computer Management snap-in from within a virtual server for local management of the Message Queuing resource.

In a server cluster, the Message Queuing servers installed on the nodes must all provide the same set of services to enable failover. The types of services provided by Message Queuing running in the context of a virtual server depend on the configuration of the Message Queuing servers installed on the host nodes. For example, if Message Queuing servers with routing services enabled are installed on the nodes of a server cluster, these services will also be available in the context of the virtual servers hosted on those nodes.

Note that the **Downlevel Client Support** component cannot run on a virtual server. However, computers requiring this component can query a remote Message Queuing server with this component, running on a domain controller.

**IP addressing with multiple network interface cards on a cluster node**
On the physical node of a cluster, there are usually two network interface cards with different IP addresses. One of these network interface cards is used only for internal cluster communication. To ensure that Message Queuing does not use the private IP address of an internal cluster Network Interface Card, which would result in messaging failure, Message Queuing maintains a list of all private IP addresses on a cluster node. When Message Queuing starts, it checks this list to make sure that the IP address of an internal network interface card is not selected for messaging. Alternatively, you can specify an IP address on the cluster node that must be used for messaging, instead of allowing Message Queuing to randomly select an IP address from those available.

The IP address used for messaging is derived by applying the following conditions:

- On a virtual server, the virtual server's IP address defined for the IP address resource is used.
- Else if the cluster node has only one IP address, that is used.
- Else if an IP address is specified in the registry, that is used. If the IP address specified cannot be found on the node, an event will be issued and the registry entry ignored.
- Else if a node has multiple IP addresses, the cluster API is used to make two lists - a first list of all private (not static) IP addresses, and a second list of all the node's IP addresses. These two lists are then compared, to select an address that is in the second list but not the first. An informational event is issued with the IP address chosen. If the only IP addresses available are those in the first list, one of those is used, and an event issued.

To specify an IP address, create a string value **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\ClusterBindIP**, in the usual IP address format. After editing the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

Note that after restarting a node computer, the Message Queuing service running on the node does not restart automatically, and you need to restart it manually. However, Message Queuing resources that were online do come back online

automatically.

**IP addressing for multicast messaging on a cluster node**
On a cluster node with multiple network interface cards, a problem will arise when the computer tries to send multicast messages by means of these multiple network interface cards. In effect, Message Queuing will randomly choose a network interface card for sending multicast messages. If the private network interface card is chosen, multicast recipients will not receive the message. To work around this issue, you can specify the source IP address to be used for sending multicast messages. To do this, create the string value **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\MulticastBindIP**, in the usual IP address format. After setting the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

Note that for multicast messaging on a cluster node, if no IP address is specified in the **MulticastBindIP**, then the IP address to be used will be derived from the procedure detailed previously in the section entitled **IP addressing with multiple network interface cards on a cluster node**.

**Memory management for Message Queuing resources in clusters**
If you have multiple Message Queuing resources in a server cluster, message activity may not function as expected unless you increase the system view space memory pool size of each node by 4 MB for each instance of the Message Queuing resource. This is recommended for cluster nodes with one or two Message Queuing resources and necessary for cluster nodes with three or more Message Queuing resources: To do this:

- Open Registry Editor using **regedit**.
- Open the registry key **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management**.
- Create a new string value called **SystemViewSize**.
- Calculate and specify this value as follows:
    - Use this formula: (16 + (the number of Message Queuing resources x 4)).
    - For example, the value for a cluster with three Message Queuing resources equals 28.
- Reboot each node.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

For more information on server clusters for Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition, see Server Clusters, in the Windows Help file.

# Message Queuing in Network Load Balancing clusters

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing in Network Load Balancing clusters**

Message Queuing services can be implemented in an Network Load Balancing cluster. Network Load Balancing clusters distribute client connections over multiple servers, providing scalability and high availability for client requests for services and applications, but they do not have failover capabilities. In its most common implementation, Network Load Balancing distributes incoming TCP/IP traffic between multiple Internet Information Services (IIS) servers, which comprise a Web farm. Network Load Balancing can combine up to 32 servers running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition into a single load-balancing cluster. Servers can be added without shutting down the cluster.

The heart of Network Load Balancing is the WLBS driver, which is loaded into each member server, or host, in the cluster. This driver includes the statistical mapping algorithm that the cluster hosts collectively use to determine which host handles each incoming request.

Under this type of clustering, if a host fails or goes offline, Network Load Balancing automatically reconfigures the cluster to redirect subsequent client requests to hosts that are still viable members of the cluster. Any client connections that were open when the host failed or went offline are ended. On retry, the client connection is routed to a viable host. The downtime for client connections is less than 10 seconds.

Network Load Balancing allows all computers in the cluster to be addressed by the same set of cluster Internet Protocol (IP) addresses, while also maintaining their existing, dedicated IPs. This feature transparently distributes client requests among the hosts in the cluster, using virtual Internet Protocol (IP) addresses. You must run IIS 5.0 or another TCP/IP service on each host, and the hosts must serve the same content so that any of them can handle any request. You can copy updated pages to local disks on the hosts, or you can use commercial file-replication software to perform updates. Network Load Balancing allows you the option of specifying that all connections from the same client IP address be handled by a particular server (unless, of course, that server fails). It also permits you to allocate all requests from a Class C address range to a single server.

When you set up a Web farm using Network Load Balancing, each server is in constant communication with all the others. They exchange performance statistics and divide the responsibilities of handling incoming requests. Every incoming request is seen by every server in the farm, and Network Load Balancing has its own algorithm to determine which server will handle each request.

When messages are sent over HTTP transport to a queue at a virtual URL address, a TCP session is established with one of the nodes in the cluster. Messages can be sent only to destinations specified by direct format names. In the case of express and recoverable messages, the receiver is not required to maintain any internal state, and Message Queuing does not guarantee exactly-once delivery through a Web farm, although a best-effort attempt is made by means of a lightweight nonpersistent duplicate removal mechanism. When transactional messages are sent over HTTP transport, in-order delivery is guaranteed by including an SRMP stream header entry that includes information for message sequencing. For more information, see Store and forward servers.

When a session between a client and a node is disconnected and the client is routed to a different node for the next session, the messages whose delivery was not acknowledged are resent by the client and accepted by the new node with the possible creation of duplicates.

Message Queuing applications can be deployed on the nodes of an Network Load Balancing cluster to receive and process messages sent to the cluster.

Similar Web farms can also be implemented using DNS round-robin distribution, and network address translation (NAT).

# Cross-Platform Messaging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Cross-Platform Messaging**

This section provides information about messaging between systems running Message Queuing and those running a different messaging software. These disparate systems communicate by means of a connector application. For details, see the following links:

- Foreign computers and sites
- MSMQ-MQSeries Bridge

# Foreign computers and sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Foreign computers and sites**

Message Queuing clients can communicate with foreign computers using a connector application. Foreign computers run operating systems that do not support Message Queuing or use other messaging systems. Connector applications run on Message Queuing servers and enable foreign computers to communicate with Message Queuing clients. A Message Queuing server running a connector application typically has two additional queues, called connector queues: one used for transactional messages and one used for nontransactional messages. For a definition of transactional messages, see Transactional messaging. When a Message Queuing client sends a message to a foreign computer, the message is first routed to a connector queue on the Message Queuing server and is then forwarded to the foreign computer.

Examples of connector applications are Microsoft MSMQ-MQSeries Bridge, which allows connectivity with computer platforms running IBM MQSeries.

Microsoft MSMQ-MQSeries Bridge extends the functionality of Message Queuing to provide seamless, transactional connectivity with IBM MQSeries Version 2.x and Version 5.x platforms. Microsoft MSMQ-MQSeries Bridge currently ships as part of Microsoft Host Integration Server 2000. For more information on Microsoft Host Integration Server 2000, refer to the Microsoft Host Integration Server Web site.(http://www.microsoft.com/hiserver/)

**Foreign sites**

To communicate with foreign computers, you must first create a foreign site, add the foreign computers to the foreign site, and create queues on the foreign computers. All of these are Message Queuing objects in Active Directory whose existence in the physical world is not essential. Then, you must create a routing link between the foreign site and a Windows Server 2003 family or Windows 2000 Message Queuing (non-foreign) site that contains a Message Queuing server running a connector application, define this Message Queuing server as a site gate for the routing link, and add the foreign site to the list of sites where this computer resides.

Foreign computers can be assigned to the same foreign site if the computers are all serviced by the same connector application. Connector applications run on Message Queuing servers and enable foreign computers to communicate with other Message Queuing computers in your network.. When a Message Queuing computer sends a message to a foreign computer, the message is routed to the Message Queuing server running the connector application in the foreign site because this server is also a site gate in the routing link connecting to the foreign site. When the server identifies the message destination as a queue on a foreign computer, it places it in a connector queue. The message is subsequently processed by the connector application, which communicates with the foreign computer.

You must create a routing link between the foreign site and each Windows Server 2003 family or Windows 2000 site that will communicate with the foreign site. The Message Queuing routing server that runs the connector application in the foreign site must also function as a site gate in each routing link connecting to the foreign site. Site gates are always associated with a particular routing link. Note that if the routing server running the connector application, and functioning as a site gate, is unavailable, site gates in other sites cannot route messages to the applicable connector queue for transmission to computers in the foreign site.

For information on how to create a foreign site, see Create foreign sites.

For information on how to add foreign computers to a foreign site and how to add a Message Queuing server running a connector application to a foreign site, see Add foreign computers to a site.

For information on how to create and configure a routing link, see Routing links.

# MSMQ-MQSeries Bridge

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**MSMQ-MQSeries Bridge**

Microsoft MSMQ-MQSeries Bridge is a connector application used to interface computers running Message Queuing applications and computers running IBM MQSeries applications. To send a message from a Message Queuing computer to a MQSeries computer, a destination queue on the foreign (MQSeries) computer must already exist. For more information on configuring Microsoft MSMQ-MQSeries Bridge and foreign computers running IBM MQSeries, see the documentation provided with Microsoft MSMQ-MQSeries Bridge.

Microsoft MSMQ-MQSeries Bridge currently ships as part of the Microsoft Host Integration Server 2000. For more information, refer to the Microsoft Host Integration Server Web site (http://www.microsoft.com/hiserver/).

# Administering Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Message Queuing**

This section provides conceptual information about the administrative tasks for Message Queuing:

- For an overview of the tools provided to administer your Message Queuing network, see Administration overview.
- For information about planning and deployment, installing Message Queuing, and upgrading computers running MSMQ 1.0 and MSMQ 2.0, see Planning, Installing, and Upgrading Message Queuing.
- For information on administering sites, configuring routing links, messaging through firewalls, and configuring DNS settings, see Administering a Message Queuing Network.
- For information on Message Queuing objects in Active Directory, see Administering Message Queuing in Active Directory.
- For information on assigning Message Queuing servers for routing, administering server cluster nodes, and joining a workgroup computer to a domain, see Administering Message Queuing Computers.
- To learn more about security tasks, see Administering Message Queuing Security.
- To learn about administering queues, see Administering Queues.
- For more on administering and managing distribution lists, see Administering Distribution Lists.
- For background information about message tasks, see Administering Messages.
- To learn more about defining and processing triggers, see Administering Triggers.
- For information about monitoring Message Queuing and performance tuning, see Monitoring and Testing Message Queuing.

# Administration overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administration overview**

You administer your Message Queuing network and computers primarily using snap-ins displayed in the Microsoft Management Console (MMC). For a few administrative tasks, you use the **Message Queuing Properties** dialog box, which can be opened from Computer Management. The following table shows the administrative tools used to manage Message Queuing.

| Administrative tool name | Type of tool | Type of tasks used for |
|---|---|---|
| Computer Management | MMC snap-in | Most workgroup-based tasks; managing queues and messages; some local tasks; managing user certificates and cryptographic keys |
| Active Directory Users and Computers | MMC snap-in | Most domain-based tasks; managing computers, queues, and messages |
| Active Directory Sites and Services | MMC snap-in | Some domain-based tasks; managing routing links, and foreign sites for cross-platform messaging. |

For general information about using MMC and snap-ins, see Microsoft Management Console.

MSMQ Explorer was the administrative tool used to administer MSMQ objects on MSMQ 1.0 computers, but it will not run on Windows 2000, Windows XP, or Windows Server 2003 family computers. For Windows XP and Windows Server 2003 family computers, Message Queuing is administered using the Computer Management, Active Directory Users and Computers, and Active Directory Sites and Services snap-ins in MMC consoles. This section does not discuss how to administer security for Message Queuing. For more information, see Message Queuing security overview.

**Using snap-ins to administer Message Queuing**

Three snap-ins are used to manage Message Queuing. The Computer Management snap-in gives you access to local queue and message information. The Active Directory Users and Computers snap-in and the Active Directory Sites and Services snap-in give you access to information in Active Directory for routing configurations, computers, queues, and other Message Queuing objects throughout your Windows Server 2003 family forest. For more information on the objects associated with Message Queuing, see Message Queuing and Active Directory.

Most Message Queuing objects appear in the console tree (usually the left pane) of the MMC console displaying the snap-ins. When you want to view the properties for a particular Message Queuing object, you can usually right-click the object in the console tree, and then click **Properties**. The details pane (usually the right pane) of the MMC console displaying the snap-ins typically shows the name, type, and properties (using columns) of Message Queuing objects.

Active Directory replication can delay the display of information updates, so changes you make using a snap-in do not appear until after replication takes place. For example, when you add a queue to a computer in site C from a computer in site B, you do not see the change in the applicable snap-in until the change has been replicated from site C to site B. You can press F5 after making a change to refresh the information displayed in the snap-in.

**Computer Management snap-in**

The Computer Management snap-in can be used to perform many of the daily administrative tasks involving queues and messages on computers. In fact, it is the only snap-in available to manage Message Queuing in a workgroup environment (not part of a Windows Server 2003 family or Windows 2000 domain).

You can use the Computer Management snap-in to perform the following tasks:

- Create and view private queues and set queue properties.
- View cached public queues (if the local computer has at one time belonged to a domain and had access to Active Directory).
- Pause and resume the operation of an outgoing queue.

- Pause and resume the operation of all outgoing queues for a computer.
- View message properties and purge outgoing messages.
- Manage queues and messages on other computers.

In addition, you can use the **Message Queuing Properties** dialog box, which can be opened from the Computer Management snap-in, to perform the following local administrative tasks for Message Queuing:

- Specify which local disk drives and folders on which to store message and log files.
- Register, remove, renew, and view user certificates.
- Renew cryptographic keys.
- Specify a new site to which messages will be forwarded for a mobile computer. This applies only to Message Queuing 3.0 computers that belong to a Windows NT 4.0 enterprise and are capable of connecting to MSMQ 1.0 controller servers to access the MQIS database.

Outgoing queues are visible only when using the Computer Management snap-in. They are not displayed in any other snap-in.

The Computer Management snap-in allows you to manage queues and messages on other computers (provided you have administrative permissions for the other computers). For more information on how to manage queues and messages on other computers, see Manage queues on other computers.

You can also manage the queues and messages for all computers in your workgroup (or domain) by creating an MMC console (.msc) file that displays all the applicable computers. For information about creating console files, see Creating consoles.

**Note**

- You manage Message Queuing in the context of a virtual server in a cluster using the Computer Management snap-in only. In this case, a cluster group object having the name of the Network Name resource of the virtual server is displayed. Message Queuing objects are displayed under this object.

**Active Directory Users and Computers snap-in**

You can use the Active Directory Users and Computers snap-in to perform the following domain-based administrative tasks for Message Queuing involving Active Directory:

- View all Message Queuing computers and set computer-specific properties.
- Create, view, delete, and find all public queues and set queue properties.
- Create, view, and delete local private queues and set queue properties.
- View message properties and purge messages.
- Send MQPing messages, test messages, and configure message route tracking.
- Create and delete queue aliases as well as view and change their properties.

The shortcut link used in the procedure topics (step 1) to open the Active Directory Users and Computers snap-in opens MMC in author mode. This snap-in must be initially opened in author mode so that you can select the proper view options for displaying all Message Queuing objects in Active Directory. You will note the subsequent step in the procedures:

"On the **View** menu, click **Users, Groups, and Computers as containers**, and then click **Advanced Features**."

You can save these changes so that these views are always enabled by default by creating your own .msc file for this snap-in. In such a case, the first time you open the .msc file that you previously created, on the **File** menu, click **Options**, and then select

one of the three user mode entries in **Console mode**. Now the console will subsequently open in the user mode selected with the correct view enabled. Opening a snap-in console in one of the user modes (rather than in author mode) is safer from an administrative standpoint because no one else can potentially change the behavior or the look of the console.

**Active Directory Sites and Services snap-in**

You can use the Active Directory Sites and Services snap-in to perform the following domain-based administrative tasks for Message Queuing involving Active Directory:

- Create and delete routing links as well as view and set their properties (including the site gates).
- Create foreign sites and foreign computers as well as view and set their properties.
- Set the default lifetime of messages on your network (known as the time-to-reach-queue setting).

The shortcut link used in the applicable procedure topics (step 1) to open the Active Directory Sites and Services snap-in opens MMC in author mode. This snap-in must be initially opened in author mode so that you can select the proper view option for displaying Message Queuing objects in Active Directory. You will note the subsequent step in the procedures:

"On the **View** menu, click **Show Services Node**."

Again, you can save these changes so that this view is always enabled by default by creating an .msc file for this snap-in in the manner described previously.

To use Message Queuing to send and receive messages, relevant Message Queuing applications must first be designed, developed, and deployed.

# Planning, Installing, and Upgrading Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning, Installing, and Upgrading Message Queuing**

This section discusses planning and deployment issues, installation options, and upgrade strategies. For more information, see:

- Planning for Message Queuing
- Installing Message Queuing
- Upgrading to Message Queuing

# Planning for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning for Message Queuing**

This section suggests ways to plan for and deploy Message Queuing in your organization. Planning and deployment options are included. The section on business scenarios provides simple overviews for deploying Message Queuing in different organizations. For details, see the following links:

- For an overview of planning Message Queuing deployment, see Planning overview.
- For information on licensing considerations for a Message Queuing network, see Licensing considerations.
- Message Queuing can be deployed in either a domain or a workgroup environment. In the context of Message Queuing, a domain environment includes domain controllers that provide a directory service such as Active Directory. For more information, see Deploying in a domain environment.
- A workgroup does not provide or have access to such a directory service, and can be run in an environment that is not part of a domain. For more information about workgroup deployment, see Deploying in workgroup mode.
- Message Queuing 3.0 supports the sending of messages over HTTP. For more information on deploying in an Internet environment, see Internet deployment considerations.
- For an overview of how different business situations can use Message Queuing, see Business scenarios.
- For information on how Message Queuing and Windows Firewall work together to secure your server from unsolicited incoming traffic, see Windows Firewall and Message Queuing

# Planning overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning overview**

When planning a Message Queuing deployment, it is important to consider performance requirements. After you have assessed these requirements, you can make informed decisions about your hardware requirements and upgrading strategies. Generally, performance of Message Queuing applications, like other applications, can be improved with the following strategies:

- Increasing the amount of system memory for each server.
- Upgrading the processor or adding additional processors.
- Increasing the number, speed, or size of the disks.
- Replacing disk drives and volume sets with striped drive arrays.
- Limiting the number of other services running on the computer by moving nonessential software to other computers. A server that runs additional services needs greater hardware resources than it would otherwise.

**Disk considerations**

Consider the following:

- **Number of disks**. Since Windows Server 2003 family operating systems and Message Queuing are able to perform many disk operations in parallel, using separate physical disks (as opposed to single disks with multiple partitions) will result in performance improvements for most Message Queuing applications. Applications that use recoverable or transactional messages will see the greatest improvement because these messages are constantly being written to disk and retrieved from disk.
- **Disk type**. Not all hard disks deliver equivalent performance. In particular, there are high-performance disks that use hardware striping and battery-protected write-through disk controllers that delay write operations until they can be performed most efficiently. These disks will significantly improve messaging performance, especially when sending or receiving recoverable or transactional messages. Note also that for the best messaging performance on Message Queuing servers, put the messaging (*.mq) files, message log files, and transaction log files on separate physical disks.
- **Disk size**. When deciding disk size for your computers, consider the space requirements for Message Queuing files, the type of messaging (recoverable, transactional or express), the total number of messages that are likely to accumulate on the server at any time, and the total size of those messages. It can be difficult to anticipate message storage requirements. However, if you use Message Queuing servers for session concentration within a site (in-routing and out-routing servers) or in routing links (site gates), you must allow for additional message storage space on those servers. Also, servers that support dependent clients are likely to need additional disk space.
- **Number of disk drives**. Adding disk drives ensures that disk access has a minimal impact on messaging performance. However, if your CPU (processor) usage is at or near 100%, adding disk drives does not improve messaging performance. To determine whether your computers are limited by disk access or by processing power, use System Monitor to track the **% Processor Time** counter (located in the Processor object) and the **Avg. Disk Queue Length** counter (located in the DiskLength object). If the sustained **% Processor Time** value is above 75% during the time messages are being sent, adding processing capacity may improve messaging performance. If the **Avg. Disk Queue Length** value for any drive is greater than 0.6 when messages are being sent, additional disks may improve messaging performance. For more information on monitoring Message Queuing performance, see Monitoring Message Queuing performance.

**Memory considerations**

Consider the following:

- **Storing messages**. To maximize messaging performance, there must be enough memory on a given computer to hold all of the messages that are expected to accumulate in its queues under normal operation. Messages may accumulate on the source computers, if destination computers are unreachable. On destination computers, messages will accumulate if receiving applications are not running, or are unable to keep up with the arrival rate of messages.

- **Calculating RAM requirements**. To calculate the amount of RAM required to hold all messages, you must consider message sizes. For example, when sending 20,000 messages that are approximately 1 kilobytes (KB) each with typical header sizes, allow at least 23 megabytes (MB) (20,000 × 1 KB + 20,000 × 150) of available RAM beyond normal system requirements. Note that this applies only to cases where all messages actually accumulate on a computer. If messages are normally retrieved (removed from queues) as quickly as they are delivered, significantly less RAM will be required.

**Rolling out Message Queuing**

A rollout process can consist of the following phases:

- **Setting administrative policy**. When setting out such a policy, consider how access control will be established in your organization, how administrative duties will be delegated, how work will be documented, and how backups and emergencies will be handled.

- **Conducting lab tests**. Lab testing helps you to determine the load that Message Queuing places on your servers, and tests your in-house Message Queuing applications. Before conducting such tests, ensure that your computers meet the minimum hardware requirements for running Message Queuing, and that your Message Queuing applications are functioning properly.

- **Conducting one or more pilot rollouts**. After Message Queuing has been tested in a lab, you can deploy in a limited environment. It is recommended that the pilot rollout be introduced on a limited scale, such as 15 to 50 users. You can then make any needed adjustments to your administrative policy and to your Message Queuing applications for the final rollout. If you make extensive changes to the final rollout plan, consider doing a second pilot rollout.

- **Conducting the final rollout**. After analyzing the results of the pilot rollouts, you are ready to finalize the plans for the full-scale rollout of Message Queuing in your organization. The final rollout plan is an extension of the pilot planning process, with the added steps of documenting, budgeting for, and carrying out the final logistics.

# Licensing considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Licensing considerations**

Message Queuing counts Windows Server 2003 family client access licenses (CALs). If no CALs are available, Message Queuing applications can fail to send messages and to open all queues. Message Queuing enforces the following rules for counting CALs:

- An independent client running on Windows XP Professional can have no more than 10 concurrent Message Queuing sessions and remote-read sessions with other independent clients running on Windows XP Professional.
- A dependent client does not count CALs, but its supporting server counts any sessions or queues opened on behalf of the dependent client. All Message Queuing sessions, remote-read sessions, and queues opened by dependent clients are counted. The number of dependent clients that can be supported is limited by the number of server CALs on the server.
- All sessions used by a Message Queuing computer are counted only once.

For more information on licensing for Windows Server 2003 family operating systems, see Licensing, in the Windows Help file.

# Deploying in a domain environment

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying in a domain environment**

During installation, if you choose to install Message Queuing with Active Directory Integration and the installation computer is part of a domain, Message Queuing objects are created in Active Directory. For more information about installation options, see Installation overview. For more information about Message Queuing objects in Active Directory, see Message Queuing and Active Directory.

An Active Directory domain includes one or more domain controllers that store directory information for the domain. The collection of all domains in a Windows Server 2003 network is called a forest, and one or more domains in the forest can be designated as a global catalog, with directory information for other domains in the forest, in addition to its own. Active Directory employs a multi-master model, so that any Windows Server 2003 family domain controller can read from or write to objects stored in Active Directory. For more information, see Introduction to Active Directory, in Active Directory Help.

**Accessing Active Directory**

In a domain environment, computers running Windows XP, or a Windows Server 2003 operating system, and Message Queuing can directly access Message Queuing objects in Active Directory. On the other hand, Windows 2000 computers running Message Queuing require either a Windows Server 2003 domain controller running the Downlevel Client Support Component to provide the Message Queuing Directory Service, or a Windows 2000 domain controller hosting a Message Queuing server in its site and its domain to access such objects in Active Directory. In addition to this requirement, a Windows NT 4.0, Windows 98, or Windows 95 computer running MSMQ 1.0 also requires that this domain controller be configured as a global catalog server.

**Note**

- When receiving a user's request to Active Directory, Active Directory Service Interfaces (ADSI) resolves the query by attempting to locate a domain controller in the user's domain. This can potentially be a problem for users who log on to remote computers in a different domain from their own. If the remote computer's domain is not connected to the user's domain, the Active Directory query will fail.

**Sites**

In a domain environment, a Message Queuing network can be divided into different Windows Server 2003 family *sites*, which are interconnected using *routing links*. Sites map the physical structure of your network, whereas domains generally map the logical structure of your organization, independently of each other. There may be multiple domains in a single site as well as multiple sites in a single domain. For more information, see Message Queuing and Active Directory. For more general information on sites in Windows Server 2003 family, see Sites overview, in the Active Directory Help file.

In the context of Message Queuing, a site can consist of the following:

- Windows Server 2003 domain controllers, which hold configuration and status information in the Active Directory and replicate such information between sites using site links. Active Directory employs what is called a multi-master model, which means that any Windows Server 2003 domain controller can read from or write to objects stored in Active Directory.

- Windows Server 2003 family computers, all of which use the same network protocol (typically IP). Any two computers in a site that use the same network protocol have direct connectivity with each other. Such connectivity also implies fast and cheap communication.

- Collections of associated subnets, each with a single IP subnet address.

When a Message Queuing client communicates with a Message Queuing server, it directs the request to a predetermined server in the same site, if one is available.

**Site considerations**

All sites are determined during the planning and installation of Windows Server 2003 family computers in your organization. There is not a separate site topology as there was in previous versions of Message Queuing. This simplifies your site planning.

However, it is recommended that you consider the factors listed in the following table.

| Site consideration | Requirement or suggestion |
|---|---|
| Communication link | The communication link between sites must be permanent. |
| Available network bandwidth | The network bandwidth must be able to support the volume of messages transmitted within the site. |
| Performance | The number of domain controllers in each site affects performance. Each additional domain controller in a site generates more network traffic for Active Directory replication throughout that site. You need to weigh the benefits of redundancy against the performance overhead of increased replication. |
| Performance and connectivity | Configuring a domain controller as a global catalog server in each site will enhance performance and reduce connectivity issues. |
| Organizational | Group together users who work in the same site to improve overall performance of the system, reduce network traffic, and reduce resource use. |

**Note**

- There is no longer a special definition of a site in the context of Message Queuing as there was for MSMQ 1.0. When upgrading from MSMQ 1.0, each MSMQ 1.0 site is mapped to a Windows Server 2003 family site, and for cross-platform messaging, each foreign connected network is mapped to a foreign site. If you are upgrading from MSMQ 1.0, see Upgrade overview for a list of changes.

**Offline mode**

A Message Queuing computer can also belong to a domain but be temporarily unable to communicate with a domain controller. This is known as *offline mode* and occurs when:

- The computer itself is offline.
- All the domain controllers in its site are offline.
- An attempt is made to access a remote computer and the remote computer is temporarily unable to query a domain controller for authentication.

In all these cases, the computer's configuration as a member of a domain is maintained in the registry, and normal domain operation resumes as soon as a domain controller becomes available. While in offline mode, messages can be sent directly by using *direct format names*. When other format names are used, the messages are stored on the local computer and are sent as soon as a domain controller becomes available. For more information, see "Format names" in Queue names.

**Managing computers in a domain under the Local User account**

Computers that are part of a domain can be managed under the Local User account. To do this, the Message Queuing Directory Service must be running on the domain controller, and you need to add the **EnableLocalUser** key (DWORD=1), to the registry of the local computer, at location
**HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Parameters\EnableLocalUser**

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

# Deploying in workgroup mode

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Deploying in workgroup mode**
For Message Queuing, any mode of operation that does not allow access to Active Directory is known as *workgroup mode*. Note that this is regardless of whether a computer belongs to a domain, and that computers that belong to a domain can operate in workgroup mode. Computers in workgroup mode require direct connectivity with a destination computer for messaging.

**Computers that belong to a domain**
If you are installing Message Queuing on a computer that is a member of a Windows Server 2003 or Windows 2000 domain, you can specify whether the computer will operate in domain mode, by installing the Active Directory Integration subcomponent, or in workgroup mode, by not installing the subcomponent. In the context of Message Queuing, workgroup mode can be defined as any mode of operation that does not allow access to a directory service, even if the applicable computer belongs to a domain.

The default installation setting is that the Active Directory Integration component is installed, and when your computer is part of a domain, Setup will attempt to contact a Windows Server 2003 or Windows 2000 Server domain controller in the local site or a nearby site. If successful, the computer will operate in domain mode, meaning that access to Active Directory will be enabled. If one of these domain controllers cannot be located, you will be prompted for the name of an MSMQ 1.0 PEC or PSC (in a Windows NT 4.0 enterprise) in the local site. If you do not supply such a name, and select **Next** in the setup process, Message Queuing will be installed in workgroup mode. In such a situation, where the Active Directory Integration subcomponent is installed but the computer is unable to access a domain controller, the next time you restart such a computer, or stop and restart the Message Queuing service, Message Queuing will automatically attempt to contact a domain controller in the local domain. If a domain controller is available and contact is successful, the computer will then operate in domain mode.

**Computers that do not belong to a domain**
For computers that are not part of a domain and have no access to Active Directory, during default setup they are installed as independent clients in workgroup mode. The Active Directory Integration subcomponent is still installed, and if the workgroup computer later joins a domain, this subcomponent is activated. Conversely, a Message Queuing computer can be part of a domain and then join a workgroup. Such a computer can later rejoin the same domain.

The following restrictions exist when using Message Queuing in workgroup mode:

- Computers in workgroup mode require direct connectivity with a destination computer, and only support direct message transmission. Messages sent by such computers cannot be routed.
- There is no access to Active Directory. As such, you can create and manage private queues only on a local computer. You can view the list of private queues on another computer, and the messages in them, using the Computer Management snap-in. For information on managing queues on remote computers, see Manage queues on other computers. You cannot view or manage public queues or any other information in Active Directory. You can, however, send messages to or retrieve messages from private queues if there is direct connectivity.
- Internal certificates cannot be used for sending authenticated messages; an external certificate must be used. For more information on user certificates, see Managing user certificates.
- Messages cannot be encrypted. For more information on encryption, see Encryption for Message Queuing.
- There is no support for dependent clients. For more information on restrictions on the deployment of dependent clients, see Dependent clients.
- Cross-platform messaging is not supported. For more information, see Cross-Platform Messaging.

**Joining a Windows NT 4.0 domain**
When a computer running Message Queuing in workgroup mode joins a Windows NT 4.0 domain, the installation subcomponent for Active Directory Integration is removed. After the computer has been joined to the domain and rebooted,

open the Control Panel, double-click **Add or Remove Programs**, click **Add/Remove Windows Components**, and in the Windows Components Wizard, select **Application Server**, click **Details**, select **Message Queuing**, click **Details**, and select **Active Directory integration**.

# Internet deployment considerations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Internet deployment considerations**

Message Queuing 3.0 has increased support for Internet messaging and includes the following features:

- HTTP as an optional transport protocol
- An XML-based SOAP extension that defines a reliable end-to-end messaging protocol
- Support for load-balancing, Web farms, and firewalls

If your network will be sending or receiving messages through the Internet, consider the following:

- **Network load balancing**. For increased scalability and availability, Message Queuing integrates with common network load-balancing mechanisms, namely, Network Load Balancing (NLB), NAT, and DNS round-robin. For more information, see Message Queuing in Network Load Balancing clusters.
- **Messaging through perimeter networks**. Most organizations connect to the Internet using a proxy server and a perimeter network protected by firewalls. Incoming messages pass through the firewall, and outgoing messages are sent through a proxy server. The proxy server is a mediator between the organization's intranet and the Internet world. It provides caching and decoupling. Message Queuing uses an HTTP proxy to connect to Web addresses for delivering HTTP messages. Message Queuing thus needs to know the name of the proxy server and the applicable port to which it will connect. At the same time, there may be a list of target names for which the proxy connection is bypassed; that is, Web addresses that do not need to be accessed through the proxy server. An attempt is made to establish a direct connection with such targets. All of the information regarding proxy servers is stored in registry keys. For more information, see Configuring firewalls for Message Queuing and Configuring Message Queuing with a proxy server.
- **Deploying Message Queuing in hardened MSMQ mode**. This new feature enhances the security of Message Queuing computers running on the Internet. Hardened MSMQ mode is intended to support scenarios that employ only HTTP (SRMP) messages. For more information, see Message Queuing in hardened MSMQ mode.

For information on Internet messaging, see Internet Messaging.

# Business scenarios

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Business scenarios**

The following scenarios show how different business situations could benefit from using Message Queuing. They also serve as representative examples of the different options available when you use Message Queuing.

Because the differences between using Message Queuing servers and clients affect implementation details, not actual business scenarios, the scenarios have been kept simple. It is recommended that application developers see the Message Queuing SDK for representative samples of Message Queuing applications.

**Floor automation scenario**

You can use Message Queuing to control the automated manufacturing of any product that is produced by a numerically controlled industrial machine that is, in turn, controlled through a computer. In the example in the accompanying figure, Message Queuing is used to collect work orders and manage the information flow for production.

The following Message Queuing features are critical to the success of floor automation:

- **Guaranteed message delivery**. Ensures that each message is delivered and helps ensure a reliable messaging system.
- **Message prioritization**. Efficiently routes messages. For example, although quality assurance (QA) messages need to be delivered eventually, they should not obstruct the efficient delivery of time-critical messages.
- **Connectionless messaging**. Enables all computers and machines to interact as a single system.
- **Multiple-platform support**. Integrates personal computers and legacy systems. For example, an accounting package can reside on an IBM mainframe MVS system and can communicate with Message Queuing applications residing on personal computers using Microsoft MSMQ-MQSeries Bridge. For more information, see Foreign computers and sites.
- **Performance**. Because messages can be delivered quickly, they can control real-time production processes, such as cooking temperature.
- **Asynchronous delivery**. Makes it possible for faster devices to continue processing without having to wait for slower devices to respond.

**Ticket sales scenario**

The accompanying figure shows how multiple clients can access a ticket sales Web server using the Internet. Web clients view HTML pages that show ticket availability, pricing, and seating diagrams.

A business selling tickets to events can use the following Message Queuing features to improve its system:

- **Internet connection**. Accepts orders over the Internet by using a Message Queuing application and COM components in conjunction with Active Server Pages (ASP) and Internet Information Services (IIS). This is done through Web forms, which provide security and multiple-platform support.

- **Connectionless messaging**. Account updating and ticket shipping, performed asynchronously.

- **Multiple-platform support**. Integrates personal computers and legacy systems. For example, the ticket sales server might be running on a UNIX computer. For more information, see Foreign computers and sites.

**Publish-and-subscribe scenario**

Message Queuing can be used to simplify the development of typical publish-and-subscribe programs, such as news wire services and financial data subscription services. Although a server program must continuously send updated data of a specified type to the client, the server does not have to resend the data if the client is offline or unavailable.

The accompanying figure shows a publish-and-subscribe scenario that keeps a mobile sales staff current on the status of available goods. A Message Queuing application can also be used to take orders, and the two systems can be integrated. However, to simplify the details of the example, this publish-and-subscribe scenario covers only the dissemination of information.

In this figure, mobile clients retrieve data in the field. Regional servers retrieve data from the main server only for the types of information to which the clients subscribe. Each client then receives only information it subscribes to receive. This reduces both intersite communication and mobile communication costs.

In this scenario, the regional servers and the data center are located in different sites. Messages are routed between the data center and the sites along routing links in which the main server in the data center and the regional servers are configured to be site gates.

The following Message Queuing features are critical to the success of traditional publish-and-subscribe programs:

- **Connectionless messaging and message prioritization**. Places the burden of message delivery on Message Queuing. You do not have to deal with information that expires (which, therefore, is no longer useful) or with information that cannot be delivered in a timely fashion.

- **Security**. Ensures that the information is delivered to the correct client, and ensures that services are not used without payment.

**Banking scenario**

Financial transactions require both security and transaction-based programming. Automated teller machine (ATM) transactions also require connectionless messaging. In the accompanying figure, each ATM has its own local database. Even if the local, regional, or headquarters database is temporarily offline, the ATM can still process transactions.

In this scenario, the regional data centers, each of which has direct connections to multiple local data centers that communicate directly with several ATMs, are located in different sites. Messages are routed between the headquarters data center and the sites along routing links, in which the main server in the headquarters data center and the servers in the regional data centers are configured to be site gates.

This banking scenario uses these Message Queuing features:

- **Connectionless messaging**. For communication between ATMs and regional centers.
- **Transactional messaging**. For sending messages that occur synchronously with the updating of the financial databases. Messages are delivered only once.
- **Security**. For ensuring the integrity of the system. Would-be thieves cannot impersonate an ATM, and transactions cannot be monitored by persons attempting to steal account numbers and personal identification numbers.

**Stock brokerage scenario**

In the example shown here, customers communicate by telephone with traders who make trade requests on their behalf. The trade server performs the following tasks in the following order:

1. Queries the account server to verify that the transaction can be completed.
2. Verifies the transaction with the risk-management server.
3. Places the trade request with the stock exchange server.

The stock exchange server makes the stock transaction and then asynchronously updates the customer account and risk-management server.

This stock transaction scenario uses these Message Queuing features:

- **Security**. For message authentication, encryption, and access auditing to ensure a secure environment.
- **Multiple-platform support**. Integrates personal computers and legacy systems. For more information, see Foreign computers and sites.

- **Transactions (exactly once delivery)**. For guaranteed message delivery, ensuring accurate accounting.
- **Connectionless messaging**. For updating accounts and making risk assessments asynchronously.

# Windows Firewall and Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Firewall and Message Queuing**

Windows Firewall monitors and restricts information that travels between your computer and a network or the Internet. Windows Firewall drops all incoming traffic that has not been sent in response to a request of the computer (solicited traffic) or specified as traffic from a program or port that has been added to the exceptions list. This behavior of Windows Firewall provides a level of protection from malicious users and programs that use unsolicited incoming traffic to attack computers. By default, Windows Firewall is disabled for Windows Server 2003 Service Pack 1 (SP1).

When Windows Firewall is enabled, there is more protection for Windows computers, however, it can impair some types of communication and affect applications such as Message Queuing. To help overcome this, Windows Server 2003 SP1 allows administrators to define an exceptions list of applications by specifying the path to the file name of each application.

**Configuring Windows Firewall for Message Queuing**

In Windows Server 2003 Service Pack 1 (SP1), Windows Firewall is disabled by default for all connections including LAN (wired and wireless), dial-up, and virtual private network (VPN) connections. New connections also have Windows Firewall disabled by default. Windows Firewall is enabled by default only when it is explicitly enabled by using Network Setup Wizard or Internet Connection Wizard or if Windows Firewall/Internet Connection Service is enabled when you apply Windows Server 2003 Service Pack 1 (SP1).

By default, when you install Message Queuing or upgrade Message Queuing, Setup automatically adds Message Queuing to the exceptions list in Windows Firewall. You can remove Message Queuing from the exceptions list by running the following command:

**netsh firewall delete allowedprogram program=** *%windir%\system32\mqsvc.exe* **profile** *=all*

By default, when installing or upgrading to Windows Server 2003 SP1, the Downlevel Client Support component (mqdssvc.exe) is added to the exceptions list. This service is separate from the Message Queuing service (mqsvc.exe) and is not installed by default. To remove mqdssvc.exe from the exceptions list, run the following command:

**netsh firewall delete allowedprogram program=** *%windir%\system32\mqdssvc.exe* **profile** *=all*

To add Message Queuing to the exceptions list, run the following command:

**netsh firewall add allowedprogram program=** *%windir%\system32\mqsvc.exe* **name=** *msmq* **mode=** *enable* **scope=** *all* **profile** *=all*

To add Message Queuing Downlevel Client Support component (mqdssvc.exe) to the exceptions list, run the following command:

**netsh firewall add allowedprogram program=** *%windir%\system32\mqdssvc.exe* **name=** *mqds* **mode=** *enable* **scope=** *all* **profile** *=all*

To view the exceptions list, run the following command:

**netsh firewall show allowedprogram ENABLE**

When running Message Queuing with Windows Firewall enabled, in order to view public queues on remote computers by using Active Directory Users and Computers, it might be necessary to add Remote Administration to the exceptions list.

**netsh firewall set service type=** *remoteadmin* **mode=** *enable* **scope=** *all*

When installing MSMQ HTTP Support, setup automatically installs Internet Information Services (IIS), which is a World Wide Web Publishing service, and creates an IIS extension for Message Queuing (called MSMQ). Refer to the IIS documentation for information about configuring IIS for Windows Firewall.

You can also use the Security Configuration Wizard included with Windows Server 2003 SP1 to add and remove Message Queuing to and from the exceptions list. For more information, seeSecurity Configuration Wizard Overview.

For computers running Windows Server 2003 SP1 that are joined to a domain, you can also configure Windows Firewall settings by using Active Directory, and the Windows Firewall settings in Computer Configuration Group Policy of Windows 2000 or Windows Server 2003. The domain policy will override the local Windows Firewall settings.

# Installing Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing Message Queuing**

This section explains the requirements for installing Message Queuing software on computers running Windows Server 2003 family operating systems. It also explains how to install new Message Queuing software remotely, using a script. For details, see the following links:

- For general installation information, see Installation overview.
- For information on installation requirements and restrictions, see Installation requirements and restrictions.
- For information on permissions required to install Message Queuing components, see Installation permissions.
- To help you select which Message Queuing subcomponents to install, see Choosing installation subcomponents.
- For information on integrating Message Queuing with Active Directory, see Active Directory Integration subcomponent.
- For information on installing Message Queuing servers, independent clients, and dependent clients, see Installing Message Queuing Computers.
- For a guide to installing Message Queuing triggers, see Installing Message Queuing triggers.
- For advice on installing Message Queuing in a server cluster configuration on Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition computers, see Installing Message Queuing in a server cluster.
- For information about using Windows unattended setup feature to install Message Queuing software, see Unattended setup.
- For help with uninstalling Message Queuing software components, see Uninstalling Message Queuing.

# Installation overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installation overview**

Message Queuing is not installed by default during installation of Windows Server 2003 family operating systems, but the files needed to install it and its subcomponents are copied to the computer during this process. When you install Message Queuing, an additional 6.7 megabytes (MB) of space is required for Message Queuing folders. You install Message Queuing on a computer by adding it as a Windows component after installation of the operating system is complete. The Message Queuing component can be found in **Add or Remove Programs**, **Add/Remove Windows Components**, **Application Server**, **Message Queuing**.

To configure Message Queuing, you choose the Message Queuing subcomponents you require by selecting **Message Queuing**, clicking **Details**, and then selecting or clearing the applicable check boxes.

The Message Queuing subcomponent tree has the following form:

Message Queuing

├Common

│ ├Core

│ └Local Storage

├Active Directory Integration

├Triggers

├MSMQ HTTP Support

├Routing Support

└Downlevel Client Support

For more detailed information on these components, see Choosing installation subcomponents.

Message Queuing can be installed in two modes:

- **Active Directory mode**. If you install Message Queuing with Active Directory Integration and the installation computer is part of a domain, Message Queuing objects are created in Active Directory. This mode supports direct message transmission, and messaging using path names. For more information on these types of messaging, see Queue names. For more information on Active Directory domain mode, see Deploying in a domain environment.

- **Workgroup mode**. Any mode of operation that does not allow access to Active Directory is known as workgroup mode, regardless of whether a computer belongs to a domain. Computers in this mode require direct connectivity with a destination computer, and only support direct message transmission. Messages sent by such computers cannot be routed. For more information, see Deploying in workgroup mode.

Note that during a default installation, the Active Directory Integration subcomponent is installed. If the computer is in the workgroup mode, the presence of this subcomponent allows for the possibility that the computer might later join a domain. In that case, the computer will try to integrate with Active Directory and attempt to create a Message Queuing object in Active Directory, each time the Message Queuing service is started. For more information, see Active Directory Integration subcomponent.

By choosing the subcomponents you require, you can decide on Message Queuing functionality for your Windows Server 2003 family computer, as follows:

- **Dependent client**. Dependent clients require the Local Storage subcomponent of the Common component to be selected. Dependent clients rely on a supporting server for all their messaging functions and cannot use new Message Queuing 3.0 features. It is recommended that you install independent clients, rather than dependent clients, where possible.

- **Independent client**. These clients can operate in workgroup mode or Active Directory domain mode. Computers configured as independent clients run the Message Queuing service, host queues, send and receive messages, operate while disconnected from the network, access Active Directory directly, and can act as a supporting server for dependent clients. However, for an independent client in workgroup mode, direct connectivity is required to send messages, and the computer cannot act as a supporting server for dependent clients. To differentiate between independent clients and Message Queuing servers:

    - Independent clients do not provide the message routing capabilities of a Message Queuing server with the Routing component enabled.

    - Independent clients do not have the Downlevel Client Support component enabled, and cannot provide Active Directory access for MSMQ 1.0 clients running on Windows NT 4.0, Windows 98, or Windows 95 computers, or Message Queuing 2.0 clients running on Windows 2000 computers.

**Default installation settings**

A default installation installs the Common (Core and Local Storage) and Active Directory Integration components. Installing the Active Directory Integration component means that if your computer is part of a domain, and has access to Active Directory, your computer will operate in domain mode following installation. If your computer is in workgroup mode, or in a domain but without Active Directory access, the Active Directory Integration component attempts to access a domain controller, and work in domain mode each time the Message Queuing service is restarted. This allows you to join your workgroup computer to a domain and work in domain mode at any time following installation.

If you are installing Message Queuing on a computer that is a member of a Windows Server 2003 family domain or Windows 2000 domain, you can still specify whether the computer will operate in domain mode (by ensuring that Active Directory Integration subcomponent is selected) or in workgroup mode (by canceling the selection of the Active Directory Integration subcomponent).

During any installation or upgrade, there are certain requirements and restrictions that apply and must be met before you can install Message Queuing. For more information, see Installation requirements and restrictions. For more information on installation permissions, see Installation permissions.

**Unattended setup**

Windows unattended setup feature can be used to install Message Queuing software remotely. For more information, see Unattended setup.

# Installation requirements and restrictions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installation requirements and restrictions**

**Installation requirements**
Regardless of whether you are performing a new installation of Message Queuing or upgrading from previous versions, the following requirements must be met before you can successfully install Message Queuing on a computer running a Windows Server 2003 family operating system:

- You must be logged on with the proper administrative permissions for the computer on which you want to install or upgrade Message Queuing. For more information on the permissions required for installation, see Installation permissions.

- It is recommended that you have network connectivity if you want to install or upgrade Message Queuing on a computer that is part of a Windows Server 2003 family or Windows 2000 domain. However, Message Queuing can be installed offline.

- To support MSMQ 1.0 clients on Windows NT 4.0, Windows 98, or Windows 95 computers, and MSMQ 2.0 clients on Windows 2000 computers in a Windows Server 2003 domain, you must install the Message Queuing Downlevel Client Support component on a Windows Server 2003 domain controller or install Message Queuing 2.0 on a Windows 2000 domain controller in the local domain.

- If a domain controller in the local site or in a nearby site cannot be accessed or does not exist, the installation process can continue. In this case, if the Active Directory Integration subcomponent is not selected, Message Queuing will be installed in workgroup mode, even if the computer on which Message Queuing is being installed belongs to a domain. If the Active Directory component is selected, the installation process continues, and Message Queuing will attempt to create the Active Directory object every time the Message Queuing service is restarted.

**Installation restrictions**
To successfully install or upgrade Message Queuing, the following restrictions must be observed:

- Do not install Message Queuing simultaneously on multiple Windows Server 2003 family domain controllers. In Active Directory, creating an object with the same name at the same time on multiple domain controllers may result in objects' names being changed. This can happen because it takes a certain amount of time for changes to be replicated among domain controllers.

- Do not manually create Message Queuing objects (such as the msmq object, for example) in Active Directory before you install or upgrade Message Queuing.

In addition, the following restrictions apply to specific subcomponent configurations:

- A dependent client cannot be installed in workgroup mode. Thus, the Core subcomponent cannot be installed without the Local Storage subcomponent in workgroup mode.

- After Message Queuing is installed, the Local Storage subcomponent cannot be added or removed.

- The domain controller that an independent client will attempt to contact during installation cannot be defined in advance in attended setup. If you want to specify a pre-Windows Server 2003 family domain controller, you must run Setup in unattended mode and include a **ControllerServer** entry in the [msmq] section.

- No additional subcomponents can be installed on a dependent client. If you want to add a subcomponent, you must first uninstall Message Queuing and install it again as an independent client.

- The Downlevel Client Support component cannot be installed if the computer does not belong to a domain.
- The Downlevel Client Support component cannot be installed if no domain controller is available, as in *offline mode*.
- The Routing Support component cannot be installed if the computer does not belong to a domain.
- The Routing Support component cannot be installed if no domain controller is available, as in *offline mode*.

Finally, there may be certain restrictions on creating queues on computers that are specified during Message Queuing Setup. For more information, see Access control for Message Queuing.

**Installing Message Queuing using a Windows NT 4.0 user account**
When you install Message Queuing on a computer running Windows Server 2003 family and you are logged on using a Windows NT 4.0 domain user account, it is recommended that you have at least one Message Queuing server running on a Windows Server 2003 family domain controller that is in the same domain in which you are installing. Otherwise, you will be prompted to enter the name of the primary site controller (PSC) in a Windows NT 4.0 domain during setup.

**Installing MSMQ 1.0 in a Windows Server 2003 family domain**
The following applies if you are installing MSMQ 1.0 on a computer running Windows NT 4.0, Windows 98, or Windows 95 in a Windows Server 2003 family domain:

When prompted for the name of a PSC during setup, you must enter the name of a domain controller instead. This Windows Server 2003 family domain controller must be running the Message Queuing directory service (Downlevel Client Support), must be configured as a global catalog server, and must be in the same site and the same domain in which you are installing MSMQ 1.0.

If you plan to install MSMQ 1.0 on computers running Windows NT 4.0 in a new Windows Server 2003 family domain, you select the Downlevel Client Support subcomponent during installation of the first domain controller in the new domain. If you are installing MSMQ 1.0 on computers running Windows NT 4.0 in an existing Windows Server 2003 family domain, you verify that the Everyone group has been added to the "Pre-Windows Server 2003 family Compatible Access" group for the domain. To do this, open Active Directory Users and Computers. In the console tree, double-click **Builtin**, right-click **Pre-Windows Server 2003 family Compatible Access**, click **Properties**, and on the **Members** page, check to see if the Everyone group is listed. If not, click **Add**, and then select **Everyone**.

Also, dependent clients running Windows NT 4.0 must have Windows NT 4.0 Service Pack 4 (SP4) or higher installed. SP4 or higher is required for transactional messaging.

In addition, for computers running Windows 98 or Windows 95, you must be granted the Create Computer Objects permission for the Computers container object in Active Directory, as the computer object for such computers does not exist in Active Directory.

To allow users to install MSMQ 1.0 in a Windows Server 2003 family domain, you must use the Delegation of Control Wizard to grant specific permissions to all users in the domain. For more information, see Set installation permissions to enable upgrade from MSMQ 1.0.

# Installation permissions

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installation permissions**

The following table shows the administrative permissions required to install different Message Queuing software components and to create various Message Queuing computers. By default, logging on using an account with these permissions allows the applicable Message Queuing objects to be created in Active Directory during Message Queuing installation.

| Message Queuing computer | Permission level required |
|---|---|
| Message Queuing server on a domain controller | domain administrative permissions (or member of the Domain Admins group) |
| Message Queuing server on a nondomain controller with Routing Support | enterprise administrative permissions (or member of the Enterprise Admins group). |
| Message Queuing server on a nondomain controller without Routing Support | local administrative permissions (or member of the local Administrators group) |
| Independent client | local administrative permissions (or member of the local Administrators group) |
| Dependent client | local administrative permissions (or member of the local Administrators group) |

For more information on administrative groups for Windows Server 2003 family, see Default groups, in the Active Directory Help file.

**Notes**

- When installing a Message Queuing server on a nondomain controller with routing enabled, domain administrative permissions are sufficient, provided Setup can contact a Windows Server 2003 or Windows 2000 domain controller and provided you are granted the specific permissions for objects listed in the table that follows.

- When installing Message Queuing in a server cluster, the user account under which the cluster service is running must be granted permissions to create computer objects and Message Queuing objects. This can be done only on a Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. See the following table for specific permissions needed to create specific objects.

If you do not want to grant users such general or wide-ranging permissions to install Message Queuing, you can grant permissions to create those objects specifically required to create different Message Queuing computers. The following table lists the specific child objects in Active Directory that you must be granted permission to create for Message Queuing installation to complete.

| Message Queuing computer | Specific permissions required | For which object |
|---|---|---|
| Message Queuing server (on a domain controller or on a nondomain controller with routing enabled) | Create MSMQ Configuration Objects | applicable domain controller object located in Active Directory Users and Computers |
| Message Queuing server (on a domain controller or on a nondomain controller with routing enabled) | Create All Child Objects | Servers container object located in Active Directory Sites and Services |
| Message Queuing server (on a nondomain controller with no routing) | Create MSMQ Configuration Objects | applicable computer object located in Active Directory Users and Computers |

| | | |
|---|---|---|
| Independent client | Create MSMQ Configuration Objects | applicable computer object located in Active Directory Users and Computers |
| Dependent client | none | not applicable |

You can grant these specific permissions to specific users or to all users in a domain using the Delegation of Control Wizard.

For more information on Message Queuing objects, where they are created, and where they are located in Active Directory, see Message Queuing and Active Directory.

For more information on permissions for objects, see Access control for Message Queuing.

For an example of how to grant permissions using the Delegation of Control Wizard, see Set installation permissions to enable upgrade from MSMQ 1.0.

**Notes**

- To install Message Queuing, you may also need the Delete MSMQ Configuration Objects permission, because if Setup finds an msmq (MSMQ Configuration) object in Active Directory, it must delete it before creating a new one.

- To uninstall Message Queuing, you must be granted the Delete MSMQ Configuration Objects permission.

# Choosing installation subcomponents

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Choosing installation subcomponents**

The following table lists the subcomponents of Message Queuing, the 32-bit Windows Server 2003 family operating systems on which they can be installed, their dependencies on other subcomponents, and their names in the .inf file.

| Component or subcomponent name | Description and setup steps | Suitable platforms | Depends on | Name in the .inf file |
|---|---|---|---|---|
| Message Queuing | Parent for all subcomponents | All Windows Server 2003 family operating systems except Windows XP Home Edition | DTC | msmq |
| Common | Performs common setup tasks, parent for the Core and Local Storage subcomponents | All Windows Server 2003 family operating systems. | none | msmq_Common |
| Core | Performs the most fundamental setup operations, creates and sets registry keys, and provides dependent client functionality | All Windows Server 2003 family operating systems. | none | msmq_Core |
| Local Storage | Creates and installs the Message Queuing service and provides independent client functionality | All Windows Server 2003 family operating systems. | Core | msmq_LocalStorage |
| Active Directory Integration | Creates an msmq object and (if needed) an MSMQ Setting object in Active Directory and thereby provides integration with Active Directory whenever the computer belongs to a domain | All Windows Server 2003 family operating systems. | Local storage | msmq_ADIntegrated |
| Triggers | Installs the Message Queuing Triggers service | All Windows Server 2003 family operating systems. | Local storage | msmq_TriggersService |
| MSMQ HTTP Support | Creates an IIS extension for Message Queuing (called MSMQ) | All Windows Server 2003 family operating systems. | Local storage, IIS (the World Wide Web Publishing service) | msmq_HTTPSupport |
| Routing Support | Creates an MSMQ Setting object in Active Directory and provides Message Queuing routing server functionality | Windows Server 2003 family operating systems. | Active Directory Integration | msmq_RoutingSupport |
| Downlevel Client Support | Installs the Message Queuing directory service on a domain controller | All Windows Server 2003 family operating systems. | Active Directory Integration | msmq_MQDSService |

The Message Queuing subcomponent tree has the following form:

Message Queuing

├ Common

│ ├ Core

│ └Local Storage

├Active Directory Integration

├Triggers

├MSMQ HTTP Support

├Routing Support

└Downlevel Client Support

**Note**

- On 64-bit platforms, the Core and Local Storage subcomponents are combined in a single subcomponent, called Common, which in this case, provides independent client functionality.

**Default options**

When you select Message Queuing in the Windows Components Wizard on computers running on platforms from the Windows Server 2003 family, the following subcomponents are selected by default:

- Common (consisting of Local Storage and Core)
- Local Storage
- Active Directory Integration

This means that, by default, an independent client capable of integrating with Active Directory (whenever the computer belongs to a domain) will be installed on computers running Windows Server 2003 family operating systems.

If a computer belongs to a workgroup, the Active Directory Integration subcomponent is selected by default. In workgroup mode, the presence of this subcomponent means that the computer will allow for the possibility that it joined a domain and will try to integrate with Active Directory each time the Message Queuing service is started (that is, it will attempt to create an msmq object in Active Directory, and so on). As long as the computer remains in workgroup mode, no msmq object is created in Active Directory, only direct messages can be sent, and only private queues can be created or deleted.

**Computers running on 64-bit platforms**

A dependent client cannot be installed on a computer running on a 64-bit Windows Server 2003 family platform. Therefore, we can simplify the list of Message Queuing subcomponents for 64-bit computers by combining the Core and Local Storage subcomponents into a single Common subcomponent, and we do not need two levels of Message Queuing subcomponents. The subcomponent tree for 64-bit computers has the following form:

Message Queuing

├Common

├Active Directory Integration

├Triggers

├MSMQ HTTP Support

├Routing Support

└Downlevel Client Support

The Routing Support and Downlevel Client Support subcomponents are available only on platforms from the Windows Server 2003 family. Furthermore, Downlevel Client Support can be installed only on a domain controller. If only the Core subcomponent is selected, an independent client will be installed.

The following table shows the subcomponent dependencies for 64-bit computers.

| Subcomponent name | Depends on | Comment |
|---|---|---|

| | | |
|---|---|---|
| Message Queuing | DTC | parent |
| Core | none | none |
| Active Directory Integration | Core | none |
| Triggers | Core | none |
| MSMQ HTTP Support | Core, IIS (the World Wide Web Publishing service) | none |
| Routing Support | Active Directory Integration | only on servers |
| Downlevel Client Support | Active Directory Integration | only on servers |

**Registry keys**

A registry key is created in **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\MSMQ\Setup** for each subcomponent installed, and its value is set equal to 0x1. It indicates that the applicable subcomponent was installed successfully on the computer. The absence of a key means that the subcomponent was not installed. The following list gives the names of these registry keys:

- msmq_Core
- msmq_LocalStorage
- msmq_ADIntegrated
- msmq_TriggersService
- msmq_HTTPSupport
- msmq_RoutingSupport
- msmq_MQDSService

# Active Directory Integration subcomponent

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Active Directory Integration subcomponent**
During a default installation, the Active Directory Integration subcomponent is installed, regardless of whether your computer is a member of a domain.

If you are installing Message Queuing on a computer that is a member of a Windows Server 2003 or Windows 2000 domain, you can specify whether the computer will operate in domain mode, by installing the Active Directory Integration subcomponent, or in workgroup mode, by not installing the subcomponent. In the context of Message Queuing, workgroup mode can be defined as any mode of operation that does not allow access to a directory service, even if the applicable computer belongs to a domain. The workgroup mode of operation requires direct connectivity to send messages.

If you are installing Message Queuing on a computer that belongs to a domain and you select the Active Directory Integration subcomponent (as in the default configuration), Setup will attempt to contact a Windows Server 2003 or Windows 2000 Server domain controller in the local site or a nearby site. If successful, the computer will operate in domain mode, meaning that access to Active Directory will be enabled and an msmq object will be created in Active Directory. Note that a Windows Server 2003 or Windows 2000 Serverdomain controller can only be found automatically. If one of these domain controllers cannot be located, you will be prompted for the name of an MSMQ 1.0 PEC or PSC (in a Windows NT 4.0 enterprise) in the local site. If you do not supply such a name, and select **Next**, Message Queuing will be installed in workgroup mode. In such a situation, where your computer belongs to a domain and has the Active Directory Integration subcomponent installed, but is temporarily unable to access a domain controller, the computer will work in workgroup mode. However, the next time you restart such a computer, or stop and restart the Message Queuing service, Message Queuing will automatically attempt to contact a domain controller in the local domain. If a domain controller is available and contact is successful, the computer will then operate in domain mode.

If your computer does not belong to a domain, default installation of the Active Directory Integration subcomponent allows for the possibility that the computer might later join a domain.

For more information on the characteristics of workgroup mode, domain mode, and offline mode, see Deploying in a domain environment, and Deploying in workgroup mode.

For information on security permissions required by Message Queuing with the Active Directory Integration component on a computer that belongs to a domain, see Installation permissions.

.

# Installing Message Queuing Computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing Message Queuing Computers**

This section provides information about installing different types of Message Queuing computers, and the platforms that support them. For details, see the following links:

- For a summary of what types of Message Queuing computers can be installed on different Windows Server 2003 family computers, see Installation platforms for Message Queuing computers.
- For information on installing Message Queuing servers, and the necessary requirements, see Installing Message Queuing servers.
- For information on installing Message Queuing on a domain controller, see Installing on a domain controller.
- For details of requirements for installing independent clients, see Installing independent clients.
- To learn about installing dependent clients with a supporting server, see Installing dependent clients.

Note that for the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed on it. The term *Message Queuing client* can refer to either an *independent client* or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed. Such computers are referred to as having independent client functionality or dependent client functionality.

# Installation platforms for Message Queuing computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installation platforms for Message Queuing computers**

The following table shows which types of Message Queuing computers can be created on which Windows Server 2003 family operating systems.

| Type of Message Queuing computer | Windows Server 2003 family operating systems |
|---|---|
| Message Queuing server | All Windows Server 2003 family operating systems |
| Independent client | All Windows Server 2003 family operating systems |
| Dependent client | All 32-bit Windows Server 2003 family operating systems |

**Notes**

- For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed. The term *Message Queuing client* can refer to either an *independent client* or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed, and such computers are referred to as having independent client functionality or dependent client functionality.

- A dependent client cannot be installed on a computer operating in workgroup mode or on a 64-bit computer.

# Installing Message Queuing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing Message Queuing servers**

This topic covers the installation of Message Queuing server software on computers running on platforms from the Windows Server 2003 family that do not have previous versions of Message Queuing installed.

For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed. The term *Message Queuing client* can refer to either an *independent client* or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed, and such computers are referred to as having independent client functionality or dependent client functionality.

Before installing a Message Queuing server on a Windows Server 2003 family computer in a particular site, verify that there is at least one Windows Server 2003 or Windows 2000 domain controller trusted for delegation in the local site or in a nearby site. To reduce replication traffic, configure a Windows Server 2003 or Windows 2000 domain controller in each site as a global catalog server. During setup, an attempt is made to automatically detect the nearest Windows Server 2003 or Windows 2000 domain controller in the local site or in a nearby site. If a suitable domain controller cannot be found, Setup assumes that you are installing a Message Queuing client in a Windows NT 4.0 environment and prompts you for the name of a controller server (PEC or PSC) before Setup can continue.

If a Windows Server 2003 or Windows 2000 domain controller is not available, you can also start the installation again and install Message Queuing without the Active Directory Integration subcomponent. If this option is chosen, only private queues can be created and managed, direct connectivity is needed to send messages, and the computer will never try to access Active Directory. In the context of Message Queuing, any mode of operation that does not allow access to a directory service is called workgroup mode, even if the applicable computer belongs to a domain.

Alternatively, Message Queuing can be installed on a computer that belongs to a workgroup and has not joined a domain. In this case, Setup will install Message Queuing in workgroup mode. In this mode of operation, only private queues can be created and managed, and direct connectivity is needed to send messages. However, in this case, the Active Directory Integration subcomponent will be installed, but the computer will not be able to access Active Directory and will continue to operate in workgroup mode until it joins a domain. After the computer joins a domain, the next time you restart it, or stop and restart the Message Queuing service, Message Queuing will automatically attempt to access Active Directory through a domain controller in the local domain and create an msmq object.

Similarly, if a Message Queuing server is taken offline or if all the domain controllers from its domain in the local and nearby sites are offline, the computer will not have access to Active Directory and will operate in offline mode. As in workgroup mode, only private queues can be created and managed and direct connectivity is needed to send messages. Each time the computer is restarted, Message Queuing will attempt to locate its domain controller. If successful, Message Queuing will return to the domain mode of operation, which enables access to Active Directory.

Before you can install a Message Queuing server, the following requirements must first be met:

- You must install a Windows Server 2003 family platform from the server family.
- To install a Message Queuing server on a Windows Server 2003 family domain controller, you must be logged on with domain administrative permissions or belong to the Domain Admins group.
- To install a Message Queuing server with routing services on a nondomain controller, you must be logged on with enterprise administrative permissions or belong to the Enterprise Admins group.
- To install Message Queuing, you may also need the Delete MSMQ Configuration Objects permission, because if Setup finds an msmq (MSMQ Configuration) object in Active Directory, it must delete the object before creating a new one.
- To uninstall Message Queuing, you must be granted the Delete MSMQ Configuration Object permission.

For more information on the administrative permissions required for installation, see Installation permissions.

**Installing additional Message Queuing servers**

In a domain environment, when Message Queuing servers are installed on additional Windows Server 2003 family computers in the same site, Setup automatically attempts to locate a Windows Server 2003 domain controller, or Windows 2000 domain controller, in the local or a nearby site. If one cannot be located, Setup assumes that you are installing a Message Queuing client in a Windows NT 4.0 environment and prompts you for the name of a controller server (PEC or PSC) before Setup can continue.

For information on installing Message Queuing servers on additional Windows 2000 computers in the same site, see the version of this topic in the online Help file for Message Queuing in a Windows 2000 computer.

If you are installing a Message Queuing server with routing services in a mixed-mode domain environment, you must specify the name of a Windows Server 2003 domain controller running the Message Queuing directory service (Downlevel Client Support) or a Windows 2000 domain controller hosting a Message Queuing server in the same site (not the name of an MSMQ 1.0 PSC) if prompted during setup.

You can also choose to install a Message Queuing server without routing on a nondomain controller in a workgroup environment (or any other environment that does not provide a directory service such as Active Directory). In this case, direct connectivity is required to send messages.

# Installing on a domain controller

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing on a domain controller**

If Message Queuing is being installed only on Windows Server 2003 family computers in a particular site, there is no need to install Message Queuing on a domain controller in that site because Message Queuing clients on Windows Server 2003 family computers can access Active Directory directly. However, if you intend to install Message Queuing on a Windows 2000 computer in a site, you must install Message Queuing with Downlevel Client Support on a Windows Server 2003 domain controller in the site, or install a Message Queuing server on a Windows 2000 domain controller in the site, or promote the Windows 2000 computer on which you want to install a Message Queuing server to a domain controller. In addition, even in a pure Windows Server 2003 family enterprise, enabling routing services for Message Queuing servers running on domain controllers may degrade performance. It is therefore preferable to install such Message Queuing servers on nondomain controllers. If you need to install Message Queuing on a domain controller (because you want to run an application over Message Queuing), it is recommended that you install a Message Queuing server without routing enabled (a server with independent client functionality).

To create a server that will provide access to Active Directory for Message Queuing 1.0 clients on Windows 95, Windows 98, Windows Millennium Edition, Windows NT 4.0 computers, or Message Queuing 2.0 clients running on Windows 2000 computers, promote the computer to a Windows Server 2003 domain controller. For information on how to promote a computer to a Windows Server 2003 family domain controller, see the Active Directory Help topic on installing on a domain controller.

Furthermore, before you can install MSMQ 1.0 on clients running on Windows NT 4.0, Windows 98, or Windows 95 computers, in a Windows Server 2003 domain, there must be at least one domain controller running the Message Queuing directory service (Downlevel Client Support component) or Message Queuing 2.0 that is configured as a global catalog server in the local site from the domain of each computer on which you want to install MSMQ 1.0. For information on how to configure a domain controller as a global catalog server, see Configure a domain controller as a global catalog server. For more information on the global catalog in Active Directory, see The role of the global catalog. Note that the Message Queuing Downlevel Client Support service must run under the default LocalSystem account.

For each applicable domain controller, also verify that it is trusted for delegation before installing Message Queuing. This property is enabled by default. If this property is disabled, the Message Queuing service cannot run. For information on how to verify that this property is enabled, see Make a domain controller trusted for delegation.

If you install a Message Queuing server with Downlevel Client Support on a domain controller and security has not been weakened in your forest to support MSMQ 1.0 clients or Message Queuing 2.0 clients logged on with local user accounts, Setup prompts you about whether or not to weaken security. This mode of operation is optional. However, to effectively support computers running MSMQ 1.0 and computers running Message Queuing 2.0 that are logged on using a local user account, security for Active Directory needs to be weakened. Nevertheless, dependent clients cannot run under a local user account, and any computer that sends queries about Message Queuing objects to Active Directory on a domain controller directly, rather than through the Message Queuing directory service, will not be able to access Active Directory when it logs on using a local user account even if the security for Active Directory is weakened. For more information, see Enabling weakened security.

For information on how to install a Message Queuing server after all requirements are met, see Install Message Queuing servers.

**Important**

- When you make a change from a computer running a Windows Server 2003 operating system against directory service objects belonging to computers running Windows 95, Windows 98, Windows NT 4.0, or Windows 2000, these earlier computers are unable to receive notification about the change from the Windows Server 2003 family computer. To resolve this, Active Directory detects by default that the object belongs to an earlier computer and attempts to make the change without accessing Active Directory directly. To override this default behavior:
    - For a single computer, set the DisableDownlevelNotifications key in the registry.
    - For an enterprise-wide system, set the PROPID_E_CSP_NAME attribute in the msmq enterprise object.

- Each Windows Server 2003 family site containing MSMQ 1.0 clients running on Windows NT 4.0, Windows 98, or Windows 95 computers must contain at least one Windows Server 2003 domain controller that is running the Message Queuing directory service (Downlevel Client Support) and is configured as a global catalog server or at least one Windows 2000 domain controller that is running Message Queuing and is configured as a global catalog server from the domain of each such client. This is required to enable such clients to communicate with Message Queuing servers. For information on how to configure a computer as a global catalog server, see Configure a domain controller as a global catalog server.

# Installing independent clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing independent clients**

This topic covers the installation of Message Queuing servers with independent client functionality on computers. Computers configured as independent clients can operate in workgroup mode or Active Directory domain mode. These computers run the Message Queuing service, host queues, send and receive messages, operate while disconnected from the network, access Active Directory directly, and can act as a supporting server for dependent clients. However, for an independent client in workgroup mode, direct connectivity is required to send messages, and the computer cannot act as a supporting server for dependent clients. For more information, see Independent clients.

For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed. The term *Message Queuing client* can refer to either an *independent client* or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed, and such computers are referred to as having independent client functionality or dependent client functionality.

Before installing a Message Queuing server with independent client functionality, note the following:

- To install Message Queuing in domain mode, you must have network connectivity. During a default installation, the Active Directory Integration subcomponent is installed, and Setup will automatically attempt to contact a Windows Server 2003 or Windows 2000 domain controller. If this attempt is successful, Message Queuing is installed in domain mode. If such a domain controller cannot be found, you will be prompted to enter the name of an MSMQ 1.0 PEC or PSC in the local site (for a Windows NT 4.0 enterprise). If you do not enter a name, Message Queuing will automatically be installed in workgroup mode. In the context of Message Queuing, any mode of operation that does not allow access to a directory service is called workgroup mode, even if the applicable computer belongs to a domain. The workgroup mode of operation requires direct connectivity to send messages.

- During a default installation, the Active Directory Integration component is installed. If your computer is in a domain, but without Active Directory access, this component will attempt to access a domain controller and work in domain mode each time the computer, or the Message Queuing service, is restarted. If your computer is not part of a domain and is in workgroup mode, installing this component provides you with the option of joining the computer to a domain at a later time.

- You can also install your Message Queuing server with independent client functionality in workgroup mode by canceling the selection of the Active Directory Integration component that is selected as part of the default installation settings.

- You must be logged on with local administrative permissions (as a member of the local Administrators group). For more information on the permissions required for installation, see Installation permissions.

- If you are installing a Message Queuing server with independent client functionality on a Windows Server 2003 family computer in a Windows NT 4.0 enterprise, and you want to specify an MSMQ 1.0 PEC during installation, you can only do this from unattended setup. For more information, see Unattended setup.

- To install Message Queuing, you may also need the Delete MSMQ Configuration Objects permission, because if Setup finds an msmq (MSMQ Configuration) object in Active Directory, it must delete the object before creating a new one.

- To uninstall Message Queuing, you must be granted the Delete MSMQ Configuration Object permission.

- A Message Queuing server configured with independent client functionality does not have the Routing subcomponent enabled. In addition, the Downlevel Client Support component is not enabled, and independent clients cannot provide Active Directory access for MSMQ 1.0 clients running on Windows NT 4.0, Windows 98, or Windows 95 computers, or Message Queuing 2.0 clients running on Windows 2000 computers.

For instructions on how to install an independent client after all requirements are met, see Install independent clients.

# Installing dependent clients

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing dependent clients**

This topic describes the installation of Message Queuing servers with dependent client functionality. It is recommended that you install independent clients wherever possible.

For the purposes of this documentation, the term *Message Queuing server* refers to a Windows Server 2003 family computer that has Message Queuing installed. The term *Message Queuing client* can refer to either an *independent client*, or a *dependent client*. Both of these terms are used to describe Message Queuing servers that have particular Message Queuing components installed, and such computers are referred to as having independent client functionality, or dependent client functionality.

Before you can install Message Queuing with dependent client functionality, the following requirements must first be met:

- You must have network connectivity and be able to contact a supporting server.
- Dependent clients cannot be installed on 64-bit computers, or on Windows Server 2003 family computers operating in workgroup mode.
- You must be logged on with local administrative permissions as a member of the local Administrators group. For more information on the permissions required for installation, see Installation permissions.
- You must have a Windows Server 2003 family computer installed with at least independent client functionality, to act as a supporting server. This computer must be configured to support dependent clients.
- Note that computers configured as independent clients cannot provide Active Directory access for MSMQ 1.0 clients. These clients require Message Queuing servers running on a domain controller to act as a supporting server.

**Supporting servers for dependent clients.**

A dependent client requires server support for all its messaging functionality. The Message Queuing server that supports a dependent client (by storing queues and messages) is referred to as the supporting server. Note that following installation, Message Queuing servers are not configured to support dependent clients. In addition, to enable a Windows Server 2003 family computer to act as the supporting server for dependent clients, you must change the security configuration of the Microsoft Distributed Transaction Coordinator (DTC) to enable network DTC. For instructions on enabling dependent client support and changing the DTC configuration, see Enable a supporting server.

During setup of a dependent client, you must specify the name of such a Message Queuing server in the same site or in a nearby site. If no name is specified, setup cannot continue. Dependent clients and their supporting servers do not have to be in the same site. However, because all communication with the dependent client goes through the supporting Message Queuing server, if the communication link to the supporting server is slow or expensive, all dependent client communication will also be slow or expensive.

For information on how to install a dependent client after all installation requirements have been met, see Install dependent clients.

# Installing Message Queuing triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing Message Queuing triggers**

Message Queuing Triggers is an integral part of Message Queuing and can be installed during Message Queuing Setup by selecting the Triggers subcomponent. Triggers and rules are defined and managed in the Computer Management snap-in. Diagnostic data generated by the Message Queuing Triggers service are recorded in the Application Log and can be viewed using Event Viewer.

The support for Message Queuing Triggers can be installed by Message Queuing Setup during the installation of a Message Queuing server or independent client on computers running platforms from the Windows Server 2003 family. Message Queuing Triggers cannot be installed on a dependent client.

To install Message Queuing Triggers, select the Triggers subcomponent of Message Queuing during the installation of a Message Queuing server or an independent client. If the check box for this subcomponent is selected, the Triggers service is installed automatically and started. If this check box is not selected, the Triggers service can be installed later by running **Add or Remove Programs** and selecting **Triggers** in the Windows Components Wizard.

An answer file for unattended setup can contain an **msmq_TriggersService = ON** entry, which corresponds to selecting the **Triggers** check box on the **Message Queuing** page of the Windows Components Wizard.

Setup requires the presence of four files for the Triggers service in the \Windows\System32 folder: mqtrig.dll, mqtgsvc.exe, mqgentr.dll, and mqtgclus.dll.

By default, the Message Queuing Triggers service runs under the Network Service account. Services that are running under this account interact with the network using the credentials of the computer account, and this account has the same level of access to resources and objects as members of the Users group accounts. For heightened security, you can change the default Triggers service account to a more secure setting; for example, the Local Service account, which limits access to the local computer. You can also specify a less secure account for the Triggers service; for example, the Local System account, allowing access to the entire domain. Note that the Triggers service running under the Network Service account does not interact with the desktop. If this functionality is required, you can configure the Triggers service to run under the Local System account, and enable interaction with the desktop in Computer Management.

Message Queuing Triggers installs with a set of default configuration values that are stored in the registry. These values can be changed later using the Computer Management snap-in. For more information on how to change the default configuration, see Change default configuration values for triggers.

Message Queuing Triggers is cluster-aware and supports the active/active model. When the Message Queuing service fails over to another node, the Triggers service can fail over along with it. For this to occur, you must create a Message Queuing Triggers resource with resource dependencies on the Message Queuing resource and the Cluster Name resource on the applicable node using Cluster Administrator, and you must bring it online. The trigger and rule definitions for the cluster resource are stored in the local Windows registry. The Message Queuing Triggers resource is checkpointed with this registry key and the subkeys under it so that when the resource is moved to a new node (during failover, for example), the required keys propagate to the local registry on the new node. After failover, the Triggers service can thus continue to process the incoming messages in each monitored queue and invoke the applicable stand-alone executable or COM component according to the rules defined. For more information on server clusters and the active/active model, see Distributing Message Queuing in a network. For more information on creating and configuring Message Queuing Triggers resources in a virtual server, see Configure trigger resources for server clusters.

# Installing Message Queuing in a server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Installing Message Queuing in a server cluster**

This section applies only to users running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition in a server cluster configuration. Installing Message Queuing in a server cluster will provide active/active queue failover in case of computer failure or malfunction.

Installing the required instances of the Message Queuing service on each node of a server cluster before creating and configuring a Message Queuing resource is similar to installing Message Queuing on any other server. However, there are several additional requirements and considerations to keep in mind when installing Message Queuing in a server cluster, including the following:

- Install Message Queuing with the same set of subcomponents on all nodes in a server cluster. For example, if you install a Message Queuing server with Routing Support on one node, install Message Queuing servers with Routing Support on the other nodes as well.
- Create one Message Queuing resource for each cluster group, using Cluster Administrator. To open Cluster Administrator, click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Cluster Administrator**.
- If you intend to use triggers, HTTP/HTTPS messaging, or external transactions on your cluster, before creating a Message Queuing resource in any cluster group hosted on a computer in a server cluster, do the following:
    - Cluster Microsoft Distributed Transaction Coordinator (DTC). This must be done using Cluster Administrator, and not by running comclust.exe. DTC is installed by default on Windows Server 2003 family operating systems.
    - Configure the DTC, create a DTC resource, and bring it online. Note that only one DTC resource is created for an entire server cluster. For more information on creating a DTC resource, see Checklist: Installing a Distributed Transaction Coordinator resource, in the Server Clusters Help file. For instructions on bringing a DTC resource online, see Bring a resource online, in the Server Clusters Help file.
    - After the DTC resource is online, install Message Queuing on each cluster node.
- After the preceding tasks are completed, you can create Message Queuing resources on any virtual server in the cluster. When you create a Message Queuing resource in a cluster group, configure it with a Network Name resource and a Disk resource using Cluster Administrator. For instructions on configuring Message Queuing and Message Queuing Triggers resources for server clusters, see Configure Message Queuing resources for server clusters, and Configure trigger resources for server clusters.

**Notes**

- It is recommended that Message Queuing be installed on the physical computer before creating a Message Queuing resource.
- You must not create more than one Message Queuing resource in a single cluster group, because the behavior of such multiple resources is undefined.
- To uninstall Message Queuing on a computer that is part of a server cluster, the Message Queuing virtual server must be deleted from the node before uninstalling Message Queuing on the physical node computer.
- On a cluster, the Message Queuing service start configuration is set to manual. Thus, after restarting a node computer, the Message Queuing service running on the node does not restart automatically. However, Message Queuing resources that were online do come back online automatically.
- For more information on configuring resources using Cluster Administrator, see Server Cluster Resources, in the Server

Clusters Help file.

- For information on upgrading Message Queuing in a server cluster, see Upgrading Message Queuing in a server cluster.
- For instructions on how to start the Message Queuing service, see Start or stop services for Message Queuing.

# Unattended setup

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Unattended setup**

You can use Windows unattended setup to install Message Queuing software by remotely using an answer file. It is recommended that this file be located either in the Message Queuing installation folder on the source computer from which you are running unattended setup or in the Windows system folder (typically C:\Windows) on the target computer on which you are installing Message Queuing.

For more information on unattended setup for Windows Server 2003 family, see Planning for unattended Setup in the Windows Help file.

During Message Queuing unattended setup, no text or dialog boxes are displayed. Errors are logged to the Msmqinst.log file located in the Windows system folder (typically C:\Windows) of the target computer.

Because the name of an online Message Queuing server is required for some installation types, it is easiest to create and run separate unattended setup scripts for computers in each Windows Server 2003 family or Windows 2000 site. You can use a single script file for multiple sites, but if you do so, you must create separate file entries for each computer that is not in the specified (default) site.

To run Message Queuing unattended setup, type the following command at the command prompt in the Windows system folder:

**sysocmgr.exe /i:sysoc.inf /u:** *path and file name of answer file*

**Answer file entries**

The answer file specifies various installation settings. The applicable settings for Message Queuing are described below.

Setup looks in the [Components] section to determine what to do for each of the Message Queuing subcomponents. In this section **ON** means to install the subcomponent, and **OFF** means to uninstall it, while the absence of an entry means that the state of the subcomponent will not be changed. The keys appearing in entries in this section are as follows:

**msmq_Core**

An **msmq_Core = ON** entry calls for installation of the Core subcomponent, which performs the most fundamental setup operations: creates and sets registry keys, and provides dependent client functionality. It is mandatory if you want to install Message Queuing. To install a dependent client, you must specify a supporting server. The supporting server can be any Message Queuing server operating in domain mode with at least independent client functionality, preferably in the local site, but also in a nearby site. Specify its name using the **SupportingServer** key in the [msmq] section. No additional subcomponents can be installed on a dependent client. To perform an unattended uninstallation of Message Queuing software, include the entry **msmq_Core = OFF**. All message and log files are removed when Message Queuing is uninstalled. However, no Message Queuing files are removed from the \Windows\System32 and \Windows\System32\Drivers folders.

**msmq_LocalStorage**

An **msmq_LocalStorage = ON** entry calls for installation of the Local Storage subcomponent, which installs the Message Queuing service and provides independent client functionality. This entry is mandatory if you are installing any additional subcomponent. Local Storage cannot be installed without the Core subcomponent. Thus, if you are installing Local Storage, there is no need to include an **msmq_Core = ON** entry. This subcomponent will be installed automatically. After the Local Storage subcomponent is installed, it cannot be removed without completely uninstalling Message Queuing.

**msmq_ADIntegrated**

The entry **msmq_ADIntegrated = ON** calls for installation of the Active Directory Integration subcomponent, which creates an msmq object and (if needed) an MSMQ Setting object in Active Directory and thereby provides integration with Active Directory whenever the computer belongs to a domain. If you want to use a specific pre-Windows 2000 domain controller, you must specify it using the **ControllerServer** key in the [msmq] section. Active Directory Integration cannot be installed without the Core and Local Storage subcomponents. Thus, if you are installing Active Directory Integration, there is no need to include **msmq_Core = ON** and **msmq_LocalStorage = ON** entries. The applicable subcomponents will be installed automatically.

You can include an **msmq_ADIntegrated = ON** entry if you are installing Message Queuing in a workgroup environment or any environment that does not have access to Active Directory. In this case, the **ControllerServer** entry is ignored and the

computer will never attempt to connect to a domain controller to access Active Directory. Such a computer requires direct connectivity to other computers to send and receive messages. This entry is applicable only if you are installing a configuration with independent client functionality on a nondomain controller.

**msmq_TriggersService**

This key specifies whether the Message Queuing Triggers service will be installed. If you include an **msmq_TriggersService = ON** entry, it will be installed. Conversely, if you include an **msmq_TriggersService = OFF** entry, it will be removed. Setting this key equal to **ON** is equivalent to selecting the Triggers subcomponent during the installation of Message Queuing with independent client functionality. Thus, if you are installing Triggers, there is no need to include **msmq_Core = ON** and **msmq_LocalStorage = ON** entries. These subcomponents will be installed automatically.

**msmq_HTTPSupport**

This key specifies whether MSMQ HTTP Support, which installs Internet Information Services (IIS) and creates an IIS extension for Message Queuing (MSMQ), will be installed. If the answer file includes an **msmq_HTTPSupport = ON** entry, an IIS extension will be created. Conversely, if you include an **msmq_HTTPSupport = OFF** entry, the extension will be removed. MSMQ HTTP Support cannot be installed without the Core and Local Storage subcomponents. Thus, if you are installing MSMQ HTTP Support, there is no need to include **msmq_Core = ON** and **msmq_LocalStorage = ON** entries. The applicable subcomponents will be installed automatically.

**msmq_RoutingSupport**

The entry **msmq_RoutingSupport = ON** calls for installation of the Routing Support subcomponent, which creates an MSMQ Setting object in Active Directory and provides routing services. This key can be used only when you are installing Message Queuing on computers running on platforms from the Windows Server 2003 family. The Routing Support subcomponent can only be installed on computers that have access to Active Directory. Routing Support cannot be installed without the Core, Local Storage, and Active Directory Integration subcomponents. Thus, if you are installing Routing Support, there is no need to include **msmq_Core = ON**, **msmq_LocalStorage = ON**, and **msmq_ADIntegrated = ON** entries. The applicable subcomponents will be installed automatically. Routing Support can be uninstalled by including an **msmq_RoutingSupport = OFF** entry.

**msmq_MQDSService**

Include a **msmq_MQDSService = ON** entry if you need to install the Message Queuing directory service on a domain controller to provide access to Message Queuing objects in Active Directory for downlevel clients. Setting this key equal to **ON** is equivalent to selecting the Downlevel Client Support subcomponent during the installation of Message Queuing on a domain controller. This key is relevant only to platforms from the Windows Server 2003 family. To install Downlevel Client Support, Message Queuing must be integrated with Active Directory.

The keys appearing in entries in the [msmq] section are as follows:

**ControllerServer**

This key specifies the NetBIOS or DNS name of the MSMQ 1.0 site controller hosting a Message Queuing server that the computer will try to contact during Setup. Specifying a Windows 2000 domain controller or a Windows Server 2003 domain controller will generate an error. This key is applicable only to an independent client or a routing server being installed on a domain computer and only when **msmq_ADIntegrated** is set equal to ON. It is optional, but if it is not included in the answer file, Setup will try to find a suitable domain controller automatically through AD.lib. If an entry is specified, unattended setup will use the entry and will not attempt to find the computer automatically. If it fails, however, unattended setup will not continue.

Do not include an entry with this key if you are installing Message Queuing on a domain controller.

**SupportingServer**

This key is set equal to the NetBIOS or DNS name of a Message Queuing server that will be used to support the dependent client being installed. This entry is required when you are creating a dependent client.

**SupportLocalAccountsOrNT4**

A **SupportLocalAccountsOrNT4 = TRUE** entry provides support for computers running MSMQ 1.0 and computers running Message Queuing 2.0 that are logged on using a local user account. This entry enables weakened security for Active Directory on a domain controller, which is then replicated to all other domain controllers in every domain in your forest. Thus, it must be included only for the first instance of Message Queuing with Downlevel Client Support on a domain controller in your forest, and Downlevel Client Support must be installed on all domain controllers. Then, computers requiring this support will be able

to query Active Directory and view the properties of Message Queuing objects. Otherwise, such computers will not be able to query Active Directory about Message Queuing objects. This key is optional, and if it is set to **FALSE**, weakened security is removed.

For the security implications of weakening Active Directory security, see Enabling weakened security.

### Notes

- Dependent clients cannot run under a local user account.

- Any computer that sends queries about Message Queuing objects to Active Directory on a domain controller directly, rather than through the Message Queuing directory service, will not be able to access Active Directory when it logs on using a local user account even if weakened security for Active Directory is enabled.

### Site

Include a line with this key if you are installing a Message Queuing routing server. Setup may not be able to automatically resolve the proper site if subnets in your network are not configured correctly. In such a case, this entry becomes mandatory. Set the key equal to the name of the default Active Directory site containing the domain controller with which this server will communicate.

#### Sample answer file

You can use the following sample answer file as a template. Use a text editor to appropriately edit the entries.

### Note

- Unattended setup ignores any file entries that begin with a semicolon (**;**). You can use these to place comments in your answer file.

```
[Version]
Signature = "$Windows NT$"

[Global]
FreshMode = Custom
MaintenanceMode = RemoveAll
UpgradeMode = UpgradeOnly

[Components]
msmq_Core = ON | OFF
msmq_LocalStorage = ON | OFF
msmq_ADIntegrated = ON | OFF
msmq_TriggersService = ON | OFF
msmq_HTTPSupport = ON | OFF
msmq_RoutingSupport = ON | OFF
msmq_MQDSService = ON | OFF

[Msmq]
ControllerServer = MyDomainController
SupportingServer = MyDomainControllerOrRoutingServer
SupportLocalAccountsOrNT4 = FALSE | TRUE
Site = DefaultFirstSiteName
```

Be sure to test your unattended setup script before deployment.

# Uninstalling Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Uninstalling Message Queuing**
To uninstall Message Queuing software from a computer, it is recommended that you first be granted the Delete MSMQ Configuration Object permission. If you do not have this permission, you can still uninstall Message Queuing, but this object will not be deleted from Active Directory. For more information on installation permissions, see Installation permissions.

**Running Message Queuing Setup**
You uninstall Message Queuing using **Add or Remove Programs** in Control Panel. When you uninstall Message Queuing from a computer, Message Queuing Setup removes all of the queues (including private queues) and messages for that computer from Active Directory and from the local computer. However, no Message Queuing files are removed from the \Windows\System32 and \Windows\System32\Drivers folders.

When you uninstall a Message Queuing server, all the applicable computer objects (the MSMQ Configuration and MSMQ Settings objects) are also deleted, and the name of the server is removed from the message routing lists of clients using that server.

For information on how to uninstall Message Queuing software, see Uninstall Message Queuing.

You can also uninstall certain individual Message Queuing subcomponents by running **Add or Remove Programs** and clearing the check boxes for the applicable subcomponents in the Windows Components Wizard. For more information on the Message Queuing subcomponents, see Choosing installation subcomponents.

**Removing Message Queuing objects from Active Directory**
If you cannot uninstall Message Queuing software from a computer, such as during a hardware malfunction or if you no longer have physical access to a computer, you can remove Message Queuing objects for the computer from Active Directory. When you remove the Message Queuing objects from Active Directory, all queues and messages on the local computer are also removed.

For more information on Message Queuing objects, where they are created, and where they are located in Active Directory, see Message Queuing and Active Directory.

For information on how to remove objects for Message Queuing in Active Directory, see Remove Message Queuing objects from Active Directory.

### Note

- You must not delete the MsmqServices object unless you are removing Message Queuing from every computer in your organization. This object is the "enterprise" object for Message Queuing.

# Upgrading to Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrading to Message Queuing**

This section explains the requirements for upgrading earlier versions of Message Queuing software (MSMQ 1.0 and MSMQ 2.0) on computers that are being upgraded to Windows Server 2003 family operating systems from Windows NT Server 4.0 or Windows 2000 Server. For details, see the following links:

- For an overview of upgrading, see Upgrade overview.
- For information on upgrading on clusters, see Upgrading Message Queuing in a server cluster.

# Upgrade overview

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrade overview**
This topic provides an overview of upgrading from MSMQ 1.0 on Windows NT Server 4.0 computers, and from Message Queuing 2.0, which runs on Windows 2000, to Message Queuing 3.0.

**Upgrading from MSMQ 2.0 on Windows 2000 computers**
MSMQ 2.0, running on a Windows 2000 computer will automatically be updated to Message Queuing 3.0 during the upgrade to a Windows Server 2003 family operating system.

**Upgrading from MSMQ 1.0 on Windows NT 4.0 computers**
For computers running Windows NT Server 4.0, the Message Queuing software is also automatically upgraded to Message Queuing 3.0, with the exception of MSMQ 1.0 controller servers. Message Queuing is upgraded for controller servers using the Message Queuing migration tool. The upgrade entails upgrading MSMQ 1.0 controller servers, and migrating all the information stored in the MQIS database to Active Directory. After the upgrade, PECs will be upgraded to a Windows Server 2003 family operating system, promoted to domain controllers, and running Message Queuing 3.0. Other MSMQ 1.0 controller servers will be upgraded to Windows Server 2003 family computers, running as Message Queuing 3.0 routing servers.

Note that *mixed-mode operation* is not permitted in Message Queuing 3.0. In other words, a configuration of MSMQ 1.0 controller servers running on Windows NT 4.0 computers, together with Message Queuing domain controllers in a Windows Server 2003 domain environment, is not supported.

For more information on this upgrade scenario, see the white paper at Microsoft Message Queuing(http://www.microsoft.com/).

# Upgrading Message Queuing in a server cluster

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Upgrading Message Queuing in a server cluster**
This topic applies only to Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition users who need to upgrade an existing server cluster that is running an earlier version of Message Queuing software. For more information on how Message Queuing functions in a server cluster, see Distributing Message Queuing in a network.

**Upgrading from Windows 2000 on a cluster containing Message Queuing resources**
When upgrading Message Queuing resources from a Windows 2000 cluster, do the following:

- Confirm that your computer hardware configuration is compatible with Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition.
- Take all Message Queuing resources in the cluster offline using Cluster Administrator.
- Upgrade all of the cluster nodes to Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. Before upgrading, use Cluster Administrator to remove resources that are not supported by these operating systems.
- Bring the Network Name resources back online, ensure that the Distributed Transaction Coordinator (DTC) is online, and then bring the Message Queuing resources online. Note that DTC is required if you want to use external transactions, triggers, or HTTP messaging with Message Queuing applications on your cluster.

For instructions on managing cluster resources, see Manage Resources, in the Server Clusters Help file.

Note that during a rolling upgrade of a cluster, Windows Server 2003 family computers do not support failover of the Message Queuing service from Windows Server 2003, Standard Edition nodes to Windows 2000 nodes.

For more information on creating and configuring Message Queuing Triggers resources in a virtual server, see Configure trigger resources for server clusters.

**Upgrading MSMQ 1.0 in a server cluster**
You can also upgrade from Windows NT Server 4.0 to Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition on a cluster that contains DTC and Message Queuing resources. There is a Knowledge Base (KB) article available with detailed instructions for this upgrade scenario. To search for this KB article, see Searching the Knowledge Base (http://www.microsoft.com/)

# Administering a Message Queuing Network

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering a Message Queuing Network**
This section provides conceptual information about common tasks for administering a Message Queuing network. Instructions for completing individual tasks can be found in the How To... section in this online Help file. For details about administering Message Queuing networks, see the following links:

- For information on moving Windows Server 2003 family computers between sites, see Moving mobile computers between sites.
- To learn about messaging between different kinds of messaging systems, see Configuring cross-platform messaging.
- For information on adding and removing sites from a server list, see Adding or removing sites from a server list.
- For information on routing links, see Configuring routing links.
- To learn about configuring your company's firewall to allow Message Queuing messages through, see Configuring firewalls for Message Queuing.
- To learn about configuring DNS settings so that Message Queuing can resolve computer names correctly, see Configuring Message Queuing with a proxy server.

# Moving mobile computers between sites

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Moving mobile computers between sites**

Windows Server 2003 family computers can be moved to other Windows Server 2003 family sites. When you move a computer to a new site, Message Queuing automatically detects the domain controllers in its new site and uses them for information services. It then updates the directory service with the new site in which the computer resides. After the new site is established, all messages that were sent to the computer while it was disconnected are automatically rerouted from the previous site to the new site. Whenever the computer connects at the new site, its messages are routed directly to it at that site. If the computer is a Message Queuing routing server, it automatically recovers its full functionality in the new site.

A Windows Server 2003 family computer that uses an MSMQ 1.0 site controller as an information server is not capable of automatically revealing its new site. In this case, you can provide the name of the new site either before disconnecting the computer from the network or after reconnecting to the network. Selecting a new site enables your computer to connect to the closest controller server and thus optimizes access to the MQIS database. If you specify the new site before disconnecting from the network, messages sent to the computer while it is disconnected are routed directly to the new site while the computer is en route. If the computer's new site is not specified, Message Queuing will attempt to use a site controller in its former site. Any message sent to that computer will be routed to its previous site. This applies only to Message Queuing independent clients and Message Queuing servers without routing enabled. Message Queuing servers that have routing enabled (provide routing services to clients) are not supported in an environment of MSMQ 1.0 site controllers.

For information on how to specify a new site for mobile computers, see Specify a new site for mobile computers.

# Configuring cross-platform messaging

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring cross-platform messaging**

For cross-platform messaging to communicate with foreign computers, you must first create a foreign site, add the foreign computers to the foreign site, and create queues on the foreign computers. All of these entities are Message Queuing objects in Active Directory. Then you must create a routing link between the foreign site and a Windows Server 2003 site that contains a Message Queuing server running a connector application, define this Message Queuing server as a site gate for the routing link, and add the foreign site to the list of sites where this computer resides.

Note that for Windows Server 2003 family computers running a connector application, after adding the foreign site to the list of sites, the foreign site will not appear in the list until you restart the Message Queuing service on the domain controller of the domain to which the Message Queuing server running the connector application belongs.

Foreign computers can be assigned to the same foreign site if the computers are all serviced by the same connector application. Connector applications run on Message Queuing servers and enable foreign computers to communicate with other Message Queuing computers in your network. A common Message Queuing connector application is Microsoft MSMQ-MQSeries Bridge. When a Message Queuing computer sends a message to a foreign computer, the message is routed to the Message Queuing server running the connector application in the foreign site because this server is also a site gate in the routing link connecting to the foreign site. When the server identifies the message destination as a queue on a foreign computer, it places it in a connector queue. The message is subsequently processed by the connector application, which communicates with the foreign computer.

You must create a routing link between the foreign site and each Windows Server 2003 family or Windows 2000 site that will communicate with the foreign site. The Message Queuing routing server that runs the connector application in the foreign site must also function as a site gate in each routing link connecting to the foreign site. Site gates are always associated with a particular routing link. Note that if the routing server running the connector application, and functioning as a site gate, is unavailable, site gates in other sites cannot route messages to the applicable connector queue for transmission to computers in the foreign site.

For information on how to create a foreign site, see Create foreign sites.

For information on how to add foreign computers to a foreign site and how to add a Message Queuing server running a connector application to a foreign site, see Add foreign computers to a site.

For information on how to create and configure a routing link, see Routing links.

# Adding or removing sites from a server list

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Adding and removing sites from a server list**

In most cases, Message Queuing determines the sites in which servers reside automatically. Message Queuing also offers procedures for manually adding and removing sites from the list of sites where a Message Queuing server with routing enabled, which is also known as a routing server, resides. Any routing server that resides in a specific site can be configured as an in-routing or out-routing server for computers that reside in that site. Such routing servers can be also configured as site gates in routing links to that site. A routing server can reside in multiple sites, and it can be configured as an in-routing server, an out-routing server, or a site gate independently in each site in which it resides.

For information on how to add sites to the list of sites where a Message Queuing server with routing enabled resides, see Add sites to a Message Queuing server's list of sites.

For information on how to remove sites from the list of sites where a Message Queuing server with routing enabled resides, see Remove sites from a Message Queuing server's list of sites.

To learn more about sites and subnets, see Sites overview, in the Active Directory Help file.

# Configuring routing links

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring routing links**

Message Queuing uses *routing links* to route messages between sites. When a new Windows Server 2003 site is created, you must also create a corresponding routing link to guarantee that messages can always be sent to other sites. However, you will not be prompted to create a routing link when a new site is created. Create multiple routing links to provide load balancing and redundancy. For more information, see Routing links.

For general information on routing, see Message Queuing routing overview. For instructions on creating a routing link, see Create routing links.

By default, users in the Enterprise Admins group and Domain Admins group can create or modify routing links. For information on how to set permissions for routing links, see Set permissions for routing link objects.

You can change routing-link costs where alternative routes are possible and you want to enforce one route over another route using link costs. You can assign costs that reflect the differences in bandwidth or communications costs between the different links. Costs can range from 1 to 999999.

For example, two sites in one city, called A and B, are connected by a high-speed link, and an overseas site, called C, is connected to site B by a low-speed link. In this case, you can define the cost between A and B as 1, and the cost between B and C as 2. For information on how to change routing-link costs, see Change the cost for a routing link.

A routing link may use Message Queuing servers with routing enabled, called *site gates*, to route messages between two sites. A routing link can have any number of site gates or no site gate, and each site gate can be in either or both of the sites connected by it. If a routing link is associated with a pair of site gates, one in each site, only those servers are used to transfer messages on the routing link on behalf of clients. It is recommended that all sites in your organization be interconnected using routing links.

After a routing link has been created, you can double-click on the link and change the link's description.

For information on how to change the Message Queuing servers used for a routing link, see Change the site gates for a routing link.

# Configuring firewalls for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring firewalls for Message Queuing**
The following sections describe configurations for messaging through firewalls.

**HTTP messaging through firewalls**
The use of HTTP as a transport enables MSMQ to leverage existing firewall support, without the need for Message Queuing-specific firewall configurations, and it is recommended that HTTP be used for messaging through firewalls. For more information on HTTP messaging, see HTTP/HTTPS messages.

**Messaging through firewalls using the Message Queuing protocol**
To send messages across firewalls using the native Message Queuing protocol, specific configuration settings are required to allow Message Queuing computers located on either side of the firewall to communicate with each other. Note that for best security practice, it is recommended that HTTP messaging be used as a solution for messaging through firewalls. These specific configuration settings include allowing Message Queuing computers located on an external network to be able to connect to Message Queuing computers on your internal network over the Internet. This is achieved by opening the following service ports on your firewall.

| | |
|---|---|
| TCP | 1801 |
| RPC | 135, 2101, 2103, 2105 |
| UDP | 3527, 1801 |

**Important**

- If Message Queuing computers located on an external network require access to Active Directory, it is strongly recommended that you set up a virtual private network (VPN) connection with the Point-to-Point Tunneling Protocol (PPTP). Otherwise, your network security could be compromised. For more information on VPN connections and PPTP, see the Point-to-Point Tunneling Protocol (PPTP) in the Windows Help file.

**Notes**

- With direct format names, only the TCP port needs to be opened. This provides for two-way sending, but only local reading. If you need to read from remote queues, or if you need to query Active Directory for information regarding public queues or other Message Queuing objects, you must also open the RPC ports.

- RPC ports 2103 and 2105 can be incremented by 11 if the initial choice of an RPC port is in use when the Message Queuing service starts. Message Queuing queries RPC port 135 to discover the 2*xxx*-series ports.

- Before establishing a connection with another Message Queuing computer, Message Queuing sends a ping message on UDP port 3527 to verify that the other computer responds, and only then does it attempt to establish a connection. If you do not want to open this port on the firewall, you can disable this feature by setting registry key value **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\msmq\parameters\UsePing** to zero. This might incur some performance cost as ping verification is disabled. After setting the registry, restart the Message Queuing service for the changes to take effect.

  **Caution**

  - Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

The following firewall configurations allow you three different operating modes for remote Message Queuing computers located on external networks.

**Sending messages only**
For remote clients to be able to send messages, you must allow these clients access to TCP port 1801 on your firewall.

In this configuration, remote clients cannot access Active Directory nor will messages be routed by Message Queuing servers through your internal network. This means that remote clients must be able to directly connect to the destination computer on your internal network over this port. Remote clients can then send messages using a direct format name for the destination queue.

This does not apply to dependent clients.

**Sending messages with Active Directory access**
In addition to opening TCP port 1801, allowing access to RPC ports 135 and 2101 permits remote clients access to Active Directory. RPC port 135 is used for handshaking between a remote client and a Message Queuing server. Message Queuing servers also use RPC port 2101 for communicating with each other.

Assuming that multicast network packets are allowed to pass through your firewall, allowing access to UDP port 1801 also permits remote clients to send a broadcast message to automatically determine their site.

This does not apply to dependent clients.

**Sending and receiving messages with Active Directory access**
In addition to opening TCP port 1801 and RPC ports 135 and 2101, allowing access to RPC ports 2103 and 2105 also permits remote clients to access queues and retrieve messages on Message Queuing computers located on your internal network.

Access to RPC ports 2103 and 2105 also allows remote dependent clients to send and receive messages using their supporting server on your network.

# Configuring Message Queuing with a proxy server

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring Message Queuing with a proxy server**
Most organizations connect to the Internet using a proxy server for dispatching outgoing messages and a perimeter network protected by firewalls for routing incoming messages. A proxy server acts as a liaison between the intranet and the Internet. It creates a protected channel for passing information between the private network and the Internet and provides caching. Message Queuing uses an HTTP proxy to connect to URL addresses for delivering HTTP messages. Message Queuing thus needs to know the name of the proxy server and the applicable port to which it must connect. At the same time, there may be a list of target names for which the proxy connection is bypassed; that is, URL addresses that do not need to be accessed through the proxy server. An attempt is made to establish a direct connection with such targets. A Message Queuing application can only send messages over HTTP through a proxy server. No other type of Message Queuing messages can be sent. All of the information regarding proxy servers is stored in registry keys, at **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\Internet Settings**. After setting the registry, restart the Message Queuing service for the changes to take effect.

**Caution**

- Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.

You can use the Proxy Configuration utility to configure a proxy server. To configure a proxy server, type the following command at the command prompt:

```
Proxycfg.exe -p ProxyServerName:PortNumber BypassedTargets
```

Note that wildcards can be used to define a list of bypassed targets.

The proxy server configuration is read whenever an outgoing queue is created to send messages to a new URL, so you do not need to stop and restart the Message Queuing service for new proxy settings to take affect. However, if you change the proxy server configuration using the Proxy Configuration utility and you want an active outgoing queue to use the new settings, you must pause and resume that outgoing queue.

# Administering Message Queuing in Active Directory

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Message Queuing in Active Directory**

This section provides information about Message Queuing objects found in Active Directory, and their location. For details, see the following links:

- For information about each Message Queuing object in Active Directory, see Message Queuing objects.
- For details of where each Message Queuing object is located in the Active Directory snap-ins, see Message Queuing object locations.

# Message Queuing objects

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing objects**
This topic provides an overview of all Message Queuing objects in Active Directory. For more detailed information on Message Queuing objects, see the Active Directory topic in the Microsoft Platform Software Development Kit (SDK). To open the Active Directory Start Page in the Platform SDK section of the MSDN Library, in **Contents**, click **Active Directory**.

**MsmqServices object**
An MsmqServices object is created when the first domain controller of your forest is configured. There can be only one MsmqServices object in a forest. The MsmqServices object is of the MSMQ-Enterprise class type. The MsmqServices object contains organization-wide configuration information for Message Queuing.

**Routing link object**
A routing link object with a user-defined name is created for each routing link that you create between two Message Queuing sites and contains connectivity information. Routing link objects are of the MSMQ-Routing-Link class type.

**MSMQ Settings object**
An MSMQ Settings object is created for each Message Queuing server that is installed on a Windows Server 2003 family domain controller and for each Message Queuing server with routing services. The MSMQ Settings object contains configuration information, such as what Message Queuing-specific services the server provides. The MSMQ Settings object is of the MSMQ-Settings class type.

**Message Queuing object**
An msmq object is created for each independent client and for each Message Queuing server, and it contains configuration information for the local computer. The msmq object is of the MSMQ-Configuration class type. The msmq object is the parent object of the queue objects under it. The msmq object is also known as the MSMQ Configuration object, for example, in names of specific permissions for this object and in the Delegation of Control Wizard.

**Queue object**
A queue object with a user-defined name is created for each queue and contains information associated with the particular queue. Queue objects are of the MSMQ-Queue class type. Each queue object contains a Queue messages folder and a Journal messages folder.

**Distribution list object**
Distribution lists are essentially distribution group objects in Active Directory. They can contain explicit references only to destinations published in Active Directory; that is, to public queues, queue aliases, and other distribution lists, but not to private and URL-named queues. Queue aliases are published in Active Directory and can point to any queue, including private and URL-named queues. Thus, queue aliases pointing to private and URL-named queues can be included in a distribution list.

**Queue alias object**
A queue alias object with a user-defined name is created for each queue alias and contains information associated with the particular queue alias, such as the string comprising the alias and the format name to which the alias points. Queue alias objects are of the MSMQ-Custom-Recipient class type. For more information on queue aliases, see Queue aliases.

**Distribution group object**
Distribution lists are essentially distribution group objects in Active Directory. They can contain explicit references only to destinations published in Active Directory; that is, to public queues, queue aliases, and other distribution lists, but not to private and URL-named queues. Queue aliases are published in Active Directory and can point to any queue, including private and URL-named queues. Thus, queue aliases pointing to private and URL-named queues can be included in a distribution list.

A distribution group object with a user-defined name is created for each distribution list published in Active Directory and contains information associated with the particular distribution list, such as the elements comprising the distribution list, which can be public queues, queue aliases, and other distribution lists. Distribution group objects are of the Group class type. For more information on distribution lists, see Distribution lists.

# Message Queuing object locations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Message Queuing object locations**

This table describes where Message Queuing objects are located in Active Directory.

| Object name | Location |
|---|---|
| MsmqServices object | The MsmqServices object is displayed in the console tree (usually the left pane) of the Active Directory Sites and Services snap-in in the following location:<br>• Active Directory Sites and Services<br>• Services<br>• MsmqServices |
| Routing link object | Routing link objects are located under the MsmqServices object in the details pane of the Active Directory Sites and Services snap-in:<br>• Active Directory Sites and Services<br>• Services<br>• MsmqServices<br>• Routing link object |
| MSMQ Settings object | The MSMQ Settings object is displayed in the details pane (usually the right pane) of the Active Directory Sites and Services snap-in when the applicable server object is selected. Server objects are found in the following location:<br>• Active Directory Sites and Services<br>• Sites<br>• *YourSiteObject*<br>• Servers<br>• *YourServerObject* |

| | |
|---|---|
| msmq object | The msmq object and child container objects are displayed in the console tree of the Active Directory Users and Computers snap-in in the following location:<br>• Active Directory Users and Computers<br>• *YourDomainObject*<br>• *YourOrganizationalUnitObject* (such as Computers or Domain Controllers)<br>• *YourComputerObject*<br>• **msmq**<br>• *YourQueueFolder* (such as Private Queues and System Queues)<br>• *YourQueueObject*<br>• Queue messages Journal messages |
| Queue object | Queue objects are located under the msmq object of the computer on which they reside (except for dependent clients, whose Queue objects are located under the msmq object of the supporting server). |
| Queue alias object | Queue alias objects are displayed in the console tree of the Active Directory Users and Computers snap-in in the following location:<br>• Active Directory Users and Computers<br>• *YourDomainObject*<br>• *YourContainer* (such as Computers or Domain Controllers)<br>• *YourQueueAliasObject* |
| Distribution group object | Distribution group objects are displayed in the console tree of the Active Directory Users and Computers snap-in in the following location:<br>• Active Directory Users and Computers<br>• *YourDomainObject*<br>• Users<br>• *YourDistributionGroupObject* |

# Administering Message Queuing Computers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Message Queuing Computers**
This section provides conceptual information about common administration tasks for Message Queuing computers. Instructions for completing individual tasks can be found in the How To... section in this online Help file. For details about administering Message Queueing computers, see the following links:

- To learn about administering server cluster nodes, see Administering server cluster nodes.
- For information on assigning Message Queuing servers as in-routing and out-routing servers, see Assigning in-routing and out-routing servers.
- For information on joining workgroup computers to a domain, see Joining a domain from a workgroup.
- For information on configuring DNS settings so that Message Queuing can resolve computer names, see Configuring DNS settings for Message Queuing.

# Administering server cluster nodes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering server cluster nodes**

You administer Message Queuing running in a server cluster node the same way as you would a standard Message Queuing server, using the same snap-ins.

In addition, you can also locally administer Message Queuing running in the context of a virtual server in a cluster by using the Computer Management snap-in. A virtual server is a cluster group that contains a Disk resource and a Network Name resource. A virtual server functions similarly to a server running on a physical computer, so a Message Queuing server running in the context of a virtual server provides services similar to the services provided by a Message Queuing server running on a physical computer.

To administer Message Queuing running in the context of a virtual server, the associated node on which the virtual server is running must be online and available. For information on how to create a Generic Application resource for managing a Message Queuing cluster resource from a local Computer Management snap-in, see Configure Message Queuing resources for server clusters.

# Assigning in-routing and out-routing servers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Assigning in-routing and out-routing servers**

Message Queuing servers, called in-routing servers or out-routing servers, can be used to route messages within a site. Each independent client (or Message Queuing server without routing enabled) can be configured to use up to three in-routing servers and out-routing servers to route messages on its behalf.

It is recommended that in-routing and out-routing servers be used for mobile clients that are mostly disconnected from the network or connect to the network through a remote access server.

The same Message Queuing server can serve as both an in-routing server and out-routing server. However, all such servers must be located in the original site of the client (the site the client was installed in). When a mobile client moves to another site, these in-routing and out-routing servers are not used for message routing until the client returns to its original site.

For redundancy, it is recommended that you configure clients to use more than one in-routing or out-routing server.

For information on how to specify or change the in-routing or out-routing servers that a client can use, see Change in-routing or out-routing servers.

# Joining a domain from a workgroup

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Joining a domain from a workgroup**

Message Queuing can be used in an environment that is not part of a Windows Server 2003 domain, such as a computer that is part of a Windows Server 2003 family operating system workgroup, or a Windows 2000 workgroup. If Message Queuing is run on a computer that is part of a workgroup, that computer can later join a domain. Conversely, a Message Queuing computer can be part of a domain, and then join a workgroup. Such a computer can then rejoin the same or a new domain at a later time. A Message Queuing computer running on Windows Server 2003 family operating systems can join any new Windows Server 2003 family or Windows 2000 domain. For a Message Queuing computer running on a Windows Server 2003 family computer to be able to join a new domain, a domain controller must be available in its site. It is also advisable that the domain controller be configured as a global catalog server. In addition, Message Queuing computers can join only Windows Server 2003 and Windows 2000 domains. For information on how to join a domain from a workgroup, see Join a domain from a workgroup.

In Windows Server 2003, directory service functionality is configured by the user. When a Message Queuing computer has been configured with directory service functionality, this functionality will be provided whenever that computer is promoted to a domain controller.

**Caution**

- When you join a Message Queuing computer in workgroup mode to a domain, or move a Message Queuing computer to a different forest, all messages in outgoing transactional queues on the computer will be discarded, or placed in the dead-letter queue if negative source journaling is enabled.

**Joining a Windows NT 4.0 domain**

When a computer running Message Queuing in workgroup mode joins a Windows NT 4.0 domain, the installation subcomponent for Active Directory Integration is removed. After the computer has been joined to the domain and rebooted, open the Control Panel, double-click **Add or Remove Programs**, click **Add/Remove Windows Components**, and in the Windows Components Wizard, select **Application Server**, click **Details**, select **Message Queuing**, click **Details**, and select **Active Directory integration**.

For information on the operating restrictions of running Message Queuing in a nondomain environment, see Deploying in workgroup mode.

# Configuring DNS settings for Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configuring DNS settings for Message Queuing**

If you are operating in an environment that requires the resolution of DNS domain names, such as an environment in which queries are sent to Active Directory, the DNS settings (for example, the DNS server addresses) must be configured properly on each computer for Message Queuing to resolve computer names correctly.

It is recommended that you verify that each computer is set with a fully qualified DNS name. Otherwise, some Message Queuing operations may fail. This property is typically set automatically by the Net Logon service on each computer in a Windows Server 2003 domain. To check this property, open Active Directory Users and Computers. In the console tree, right-click the applicable computer object, click **Properties**, and on the **General** page, inspect **DNS Name**.

For information on how to configure DNS properties for Message Queuing, see Set DNS properties for Message Queuing.

# Administering Message Queuing Security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Message Queuing Security**

This section provides background information about security tasks for Message Queuing. Instructions for completing individual tasks can be found in the How To... section in this online Help file. For details about administering security, see the following links:

- For background information about the Message Queuing service and the Local System account, see Managing the Message Queuing service account.
- To learn about weakened security for Active Directory, and when to enable it, see Enabling weakened security.
- For information about message authentication, see Managing message authentication.
- To learn about authentication for Message Queuing using user certificates, see Managing user certificates.
- For information about server authentication, see Managing server authentication.
- For details of how HTTP/HTTPS messages are authenticated, see Authenticating HTTP/HTTPS messages.
- For information about IIS security, see Resolving IIS Anonymous Access settings.

# Managing the Message Queuing service account

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing the Message Queuing service account**
Services run in their own security context. To establish a security context, a service needs to log on to the system. The Message Queuing service runs by default under the LocalSystem account, and you can change this default account if necessary.

The Message Queuing Downlevel Client Support service is installed on Message Queuing servers that provide Active Directory Integration to Windows 95, Windows 98, and Windows NT 4.0 computers running MSMQ 1.0, and Windows 2000 computers running MSMQ 2.0. This service must run under the default LocalSystem account.

The following are features of the LocalSystem account:

- The LocalSystem account is a member of the local Administrators group.
- The LocalSystem account already has the required rights to run as a service.
- The LocalSystem account already has the Generate Security Audits privilege.

The default LocalSystem account is a member of the Authenticated Users group, and is granted the Read permission for all Message Queuing objects in Active Directory. This permission allows these users to read the attributes of Message Queuing objects in Active Directory, but does not control the rights of users to receive (and remove) messages from queues. Change the account that the Message Queuing service runs under only if you do not want to grant the Read permission to all members of the Authenticated Users group. In this case, to run the Message Queuing service under a specific user account, you need to do the following:

- Grant the Read permission for all Message Queuing objects in Active Directory to the user account.
- Add the user account to the local Administrators group.

If you must provide greater functionality you may consider granting the user account the following privileges:

- Log on as a service
- Act as part of the operating system
- Replace a process level token
- Increase quotas
- Generate security audits

In addition, if you use a local user account to run Message Queuing applications on Windows 2000 independent clients, such clients cannot authenticate Message Queuing servers that run on domain controllers. Such domain controllers provide access to Active Directory. If authenticating those Message Queuing servers is a requirement, you must use a domain user account instead.

For information on how to change the account the Message Queuing service runs under, see Change the Message Queuing service account.

**Triggers service security**
By default, the Message Queuing Triggers service runs under the Network Service account. Services that are running under this account interact with the network using the credentials of the computer account, and this account has the same level of access to resources and objects as members of the Users group accounts. For heightened security, you can change the default Triggers service account to a more secure setting; for example, the Local Service account, which limits access to the local computer. You can also specify a less secure account for the Triggers service; for example, the LocalSystem account, allowing

access to the entire domain. The account used must be able to access the queues with which triggers are associated. Specifically, the account must be granted the **Log On As A Service** permission as well as the **Peek Message** permission for all applicable queues. If the message processing type of a trigger is "retrieval" or "transactional retrieval," the user must be granted the **Receive Message** permission for that queue. If you change the security settings for a queue to enable a trigger to monitor it, you must stop and start Triggers to update the service's configuration before the trigger will start to work. Note that executable files invoked by triggers are invoked with the same security privileges as those assigned to the Triggers service.

# Enabling weakened security

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Enabling weakened security**

Message Queuing servers running on Windows Server 2003 domain controllers, or Windows 2000 domain controllers can operate using weakened security for Active Directory. If you install Message Queuing with the Message Queuing Downlevel Client Support component on a domain controller, a dialog will appear, asking you if you want to enable or disable weakened security. Enable weakened security if any of the following operating configurations apply to your organization:

- A domain environment where users running MSMQ 1.0 (on Windows NT 4.0, Windows 98, or Windows 95) access the Message Queuing Downlevel Client Support service on Windows Server 2003 domain controllers, and Windows 2000 domain controllers for directory services. This applies even if such users are logged on with Windows Server 2003 or Windows 2000 domain accounts.

- A Windows Server 2003 family domain, or Windows 2000 domain, where users running Message Queuing (on Windows Server 2003 family operating systems, Windows XP, or Windows 2000) are logged on with Windows NT 4.0 domain accounts.

- An environment where Message Queuing 2.0 users are logged on with local user accounts. Note that:

    - Dependent clients cannot run under a local user account.

    - Any computer that sends queries about Message Queuing objects to Active Directory on a domain controller directly, rather than through a Message Queuing server, will not be able to access Message Queuing objects in Active Directory when it logs on with a local user account, even if the security for Active Directory is weakened.

If weakened security is enabled, a Message Queuing server running on a Windows Server 2003 domain controller or a Windows 2000 domain controller will access Active Directory within its own security context. This access will be under the LocalSystem account on the applicable domain controller. You can view the properties of Active Directory objects, including msmq (MSMQ configuration) objects and queue objects. You can also check security settings for operating systems requiring the Downlevel Client Support service or Windows XP clients. You cannot bypass any security restrictions on creating objects or setting object security.

For users running MSMQ 1.0, when the MSMQ service starts an RPC call to a Message Queuing server running on a Windows Server 2003 domain controller, the call is impersonated as an anonymous logon in the default security context. To allow such an anonymous user access to Active Directory, domain security is weakened by not impersonating this call. Consequently, all queries for Message Queuing objects in Active Directory are accepted by Windows Server 2003 Message Queuing servers. This means only that the properties of Message Queuing objects can be viewed. It does not mean that messages can be retrieved (removed) from public queues.

You can also check how Message Queuing is configured and modify this setting after installation using ADSI Edit. For information on how to do this, see Weaken security using ADSI Edit.

It is also possible to support MSMQ 1.0 users (and other configurations discussed) without weakening security. In this case, you must grant the Everyone group the List Content permission on all computer objects in each domain. This, however, greatly compromises the domain security.

# Managing message authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing message authentication**

*Message authentication*, which confirms that a message has not been tampered with and can be used to verify the identity of the sender of a message to the receiver, is implemented using certificates. Messages are authenticated asynchronously without the sender and the receiver communicating with one another.

The use of message authentication is optional. Message Queuing applications are not required to use authentication when sending or receiving messages. It should be noted that the use of message authentication slows the transfer of messages. When used, Message Queuing applications that send or receive authenticated messages must use the cryptographic service provider installed by default with Windows Server 2003 family operating systems, and which is needed for both message authentication and encryption. For more information on message encryption, see Encryption for Message Queuing.

For more information on authentication for Windows Server 2003 family, see Authentication, in Windows help.

For more information on certificates for Windows Server 2003 family, see Certificates overview in Windows help.

In addition to confirming that no tampering has been done to a message, message authentication can be used to verify the identity of the user who sent the message. Authentication is done at the request of the sending application, which indicates that a message is to be authenticated by setting its authentication level.

An authenticated message is sent with a *digital signature* and a *certificate*. Digital signatures are created and validated using public-key (asymmetric) encryption. In Message Queuing, the sender uses the private key to create a digital signature, and the receiver uses the public key in the certificate attached to the message to validate the digital signature.

Because Message Queuing is an asynchronous messaging system, the source computer and the destination computer are not assumed to be online and connected at the same time.

The sender of a message cannot always be authenticated. For example, before you can authenticate the sender of a message sent between computers in the same forest with access to Active Directory, a user certificate must be registered in Active Directory. Registering a certificate in Active Directory associates the certificate with the owner's security ID (SID). You can also use the internal user certificate created on the local computer during setup, which is automatically registered the first time you log on to the computer.

Then, when an authenticated message is sent, a Message Queuing application on the source computer creates a digital signature for the message, attaches the digital signature, the SID, and the applicable certificate to the message, and sends the message. The Message Queuing service on the destination computer validates the digital signature and then queries the applicable directory service to see whether the SID/certificate pair is registered. If the SID/certificate pair is registered, the message is considered authenticated and is placed in the destination queue.

When the sending application indicates that a message is to be authenticated by setting its authentication level, the Message Queuing runtime code does the following:

1. Retrieves the applicable certificate. By default the internal certificate is retrieved. However an external certificate is used if one is provided on the sender certificate property. For more information, see Managing user certificates.

2. Obtains the private signing key for the certificate used. For Windows Server 2003 family computers, certificates are stored in certificate stores. Certificates can also be found in a public certificate store, but Message Queuing will not accept these. In the case of external certificates, Message Queuing searches for the private key in the personal certificate store (the external certificate must be registered there). For internal certificates, Message Queuing locates the private key internally.

3. Computes a hash value from a fixed limited portion of the message using a hash algorithm. The default hash algorithm is the Secure Hash Algorithm (SHA).

4. Encrypts the hash value using private key obtained in step 2 to create a digital signature.

5. Attaches the digital signature, the security ID (SID), the name of the hash algorithm, and a digital certificate containing the

public cryptographic key for the source computer to the message.

On the destination computer, the Message Queuing service does the following:

1. Computes a hash value from a fixed limited portion of the message using the same hash algorithm as the source computer.

2. Decrypts the digital signature attached to the message using the public cryptographic key from the digital certificate to obtain a second hash value.

3. Compares the two hash values to confirm that the message was not tampered with during delivery.

4. If the values match, locates the user certificate in Active Directory and verifies that the user who registered the certificate matches the sender (the SID) listed on the message. If the hash values do not match, the message is discarded, and a negative acknowledgment is returned to the sending application, if such an acknowledgment was requested.

In this case, the digital signature uniquely identifies the user who sent the message as well as the message itself. Because no user can digitally sign a message with another user's identity, no user can deny having sent a message if it contains a validated digital signature that can be identified with a specific sender.

You can also send authenticated messages to connector applications. The intermediary Message Queuing server (running the connector application) can validate authenticated messages.

You can specify whether or not a queue accepts only authenticated messages. For more information, see Allow only authenticated messages on queues.

**Authentication in workgroup mode**
When authenticating messages when the receiving computer is in workgroup mode, you cannot work with user certificates registered in Active Directory to map the certificate to the respective user security ID (SID). Instead, do the following:

On the sender computer:

- The user gets an external certificate from a CA that is trusted by both the sender and the receiver, particularly the receiver.

- Set Message Queuing to use this certificate when sending the message (use **MQGetSecurityContextEx**).

- Message Queuing finds the private key and attaches the signature, but does not add the SID (use **MQMSG_SENDERID_TYPE_NONE**).

On the receiver computer, the procedure is the same as that described above for an Active Directory computer, except that:

- The Message Queuing service does not attempt to locate the certificate in Active Directory.

- The user must verify the certificate by verifying the certificate chain (use **CertGetCertificateChain** and **CertVerifyCertificateChainPolicy**).

For more information on internal certificates, see Managing user certificates.

For more information on cryptographic keys used by Message Queuing, see "Cryptographic keys" in Encryption for Message Queuing.

# Managing user certificates

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing user certificates**

There are two types of user certificates, or public-key certificates, that Message Queuing can use: *internal certificates* and *external certificates*. An internal certificate is automatically created during Message Queuing Setup for the user installing Message Queuing. External user certificates contain information that is supplied by a certification authority (CA). Unless stated otherwise, the information in this section applies to both types of user certificates.

You manage user certificates for a Message Queuing computer using the **Message Queuing Properties** dialog box in Computer Management. For information on how to view all user certificates that are registered in Active Directory, see View certificates for Message Queuing. All certificates have a validity period. After the end of the validity period, the certificate is no longer considered an acceptable or usable credential. Also, if Message Queuing is installed on a computer operating in a workgroup, and then the computer joins a domain, you must manually renew the internal certificate. For information on how to renew internal user certificates, see Renew certificates for Message Queuing.

User certificates can be stored in Active Directory. If you reinstall Windows Server 2003 family on a computer (rather than upgrade an existing installation), you must delete the user's previous (now obsolete) certificate. For information on how to delete a user certificate, see Remove certificates for Message Queuing. Next, you must register the new certificate manually. For information on how to register a user certificate, see Register certificates for Message Queuing.

**Notes**

- If permissions are used to control access to queues, user certificates must be registered in Active Directory so that Message Queuing can map the certificate to the respective SID of the user. Although it is possible to send unauthenticated messages to queues that restrict access, doing so could compromise security as the content of such messages could be tampered with or read while en route.

- In the case of a cluster, a user profile, which is needed to store a user certificate in the registry, will not be created for a user account that is used only for a cluster service until it logs onto a node of the cluster at least once. After a user profile is created, the user must manually register a user certificate for Message Queuing.

- Active Directory sets a multi-valued attribute limit of approximately 800 user certificates for a specific user account. This limit is usually exceeded when obsolete user certificates have not been deleted from Active Directory. If multiple certificates exist for a user account, only the latest is used, and obsolete certificates can be deleted. For instructions, see Remove certificates for Message Queuing.

**External certificates**

External user certificates contain information that is supplied by a certification authority (CA), rather than the SID, for verifying a sender's identity. The information in an external certificate is guaranteed by the CA that created the certificate. The Message Queuing service on the destination computer still validates the digital signature when a message is received but does not validate the external certificate itself. It is the responsibility of the receiving application to validate an external certificate before acting on the message. For more information on certification authorities, see Certification Authorities.

An external certificate can be registered in Active Directory and then used to authenticate the sender's SID when authenticated messages are sent to other computers in the same forest, precisely as in the case of an internal certificate, but with a possibly higher level of security.

If you register an external certificate in Active Directory and thereby associate an SID with the certificate, you can send messages to queues that restrict access. This is because the Message Queuing service verifies the sender's SID. Registering an external certificate thus provides an additional, although optional, measure of authentication, which can be used by the receiving application.

External certificates are required for sending authenticated messages to environments other than Windows Server 2003 family or Windows 2000. Other reasons you may want to use an external certificate include the following:

- You want to control who can send authenticated messages by controlling the use of certificates. Internal certificates are created automatically during the installation of Message Queuing and can be used by everyone.

- You want to send messages to someone who does not have access to Active Directory.
- You belong to a workgroup, as opposed to a domain.

In cases where SIDs cannot be used to authenticate the sender, as in the case of a message sent between computers operating in workgroup mode, an external certificate can be used for message authentication. In such cases, when an authenticated message is sent, the Message Queuing service on the source computer creates a digital signature for the message, attaches the digital signature and the applicable external certificate to the message, and sends the message. The Message Queuing service on the destination computer validates the digital signature.

More specifically, on the source computer, the Message Queuing service does the following:

1. Computes a hash value from a fixed limited portion of the message using a hash algorithm.
2. Encrypts the hash value using the sender's private cryptographic key to create a digital signature.
3. Attaches the digital signature, the name of the hash algorithm, and a digital certificate containing the sender's public cryptographic key to the message.

On the destination computer, the Message Queuing service does the following:

1. Computes a hash value from a fixed limited portion of the message using the same hash algorithm as the source computer.
2. Decrypts the digital signature attached to the message using the public cryptographic key from the digital certificate to obtain a second hash value.
3. Compares the two hash values to confirm that the message was not tampered with during delivery.
4. If the values match, validates the external certificate (this step is optional).

One way to obtain an external certificate is to use Internet Explorer 5.0 or later to request a certificate from a certification authority. For example, you can contact one of the following representative CA vendors:

- AT&T
- InternetMCI Mail
- Keywitness Canada
- VeriSign Commercial Software Publishers

In general, you can obtain different levels of external certificates. Some external certificates do not prove your identity. They prove only that you are the same person each time you send a message. This is sufficient for subscription-based applications. Other levels of external certificates prove that you are who you claim to be.

# Managing server authentication

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing server authentication**

Server authentication is used by clients to authenticate queries sent to domain controllers and Message Queuing servers. A client can verify that the query results have not been tampered with and that the results were returned by the correct domain controller or Message Queuing server. The method used for server authentication depends on the version of Message Queuing (and hence the operating system) running on the server and the client. The following table shows the method used for each situation.

| Client | Server | Server authentication method |
|---|---|---|
| Message Queuing client running on Windows Server 2003 family | Windows Server 2003 or Windows 2000 domain controller | Kerberos V5 |
| Message Queuing client running on Windows 2000 | Message Queuing server running on Windows Server 2003 family or Windows 2000 | Kerberos V5 |
| Message Queuing client on Windows 2000 | MSMQ 1.0 controller server running on Windows NT 4.0 | Server certificate |
| MSMQ 1.0 client running on Windows NT 4.0, Windows 98, or Windows 95 | Message Queuing server running on Windows Server 2003 family or Windows 2000 | Server certificate |

**Using server certificates**

Server certificates are used to authenticate some Message Queuing servers. You need to create and register a server certificate for the following:

- Message Queuing servers that reply to Active Directory queries from MSMQ 1.0 clients running on Windows NT 4.0, Windows 98, or Windows 95.
- MSMQ 1.0 controller servers running on Windows NT 4.0 that reply to queries from Message Queuing clients on Windows 2000 computers.

Note that Message Queuing clients running on Windows Server 2003 family or Windows 2000 use Kerberos V5 to authenticate Windows Server 2003 family or Windows 2000 Servers, and do not require server certificates.

For information on how to create a server certificate, see Create server certificates for Message Queuing. For information on how to change an existing server certificate, see Change server certificates for Message Queuing.

Server certificates used to authenticate Message Queuing servers must be installed separately from any user (client) certificates that may be installed for message authentication. However, if properly configured, the same certificate can be used by Message Queuing to authenticate servers and by Internet Information Services (IIS) for secure Web (HTTPS) communication.

# Authenticating HTTP/HTTPS messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Authenticating HTTP/HTTPS messages**

When messages sent over HTTP/HTTPS transport are authenticated, the sender attaches an XML digital signature and a user certificate, which contains the user's name, the user's public key, and the signature of the issuer. A user can obtain an external user certificate from a certification authority (CA), such as VeriSign or Microsoft Certificate Services, or use the internal user certificate that is created and registered on the local computer during setup and then first time that a user logs on to the computer. If an external user certificate is used, the user must register that certificate in Active Directory in the local forest using the Message Queuing UI.

When messages are sent over HTTPS transport, additional security requirements must be satisfied before an SSL session is established between the sender and the recipient. For more information, see HTTPS authentication.

When a message requiring authentication is sent within the same forest, the recipient decrypts the digital signature, and tries to locate the user certificate in Active Directory according to its GUID. If the user certificate is not found in Active Directory, Message Queuing tests the certificate to ascertain whether it is self-signed (an internal user certificate). If it is found in Active Directory, the message is inserted into the queue and marked as authenticated. However, if the user certificate is not found in Active Directory and it is not self-signed, the sender is regarded as an anonymous user and is allowed to access the destination queue accordingly.

When messages are sent over HTTP/HTTPS transport between different forests, the recipient cannot search for the certificate in Active Directory in the sender's forest. To overcome this problem and use the same user certificate to authenticate messages sent between different forests, perform the following steps:

1. Export the sender's user certificate to a file.
2. Send the file to the recipient's forest.
3. In the recipient's forest, create a pseudo-user to represent the sender or the sender's group.
4. Import the certificate to the pseudo-user's personal certificate store.
5. Log on as the pseudo-user.
6. Use the Message Queuing UI to register the certificate in Active Directory to the pseudo-user.
7. Grant the pseudo-user permissions to write to Message Queuing queues.

The recipient can now authenticate messages sent between forests by querying Active Directory in the local forest as in the case of messages sent over HTTP/HTTPS transport within a single forest.

For information about how to register a user certificate, see Register certificates for Message Queuing.

# Resolving IIS Anonymous Access settings

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Resolving IIS Anonymous Access settings**

By default, Internet Information Services (IIS) impersonates a special IIS local user account. Since this account is local to the IIS computer (unless it is a domain controller), it cannot be authenticated by other computers in the network and is treated as an anonymous user.

Active Server Page (ASP) applications and scripts run under IIS, and by default impersonate the IIS local user for any Message Queuing operations, including queries to Active Directory. Since anonymous users no longer belong to the Everyone group in Windows Server 2003 family, these queries fail, and ASP applications and scripts cannot locate, create, and delete queues. In addition, an anonymous user cannot open a queue for remote read, and you cannot read messages from queues that do not belong to the IIS computer using ASP.

You can resolve this issue in either of the following ways:

- **Using a domain user account instead of the IIS local user account for Anonymous Access**. The account must have the required permissions for the Message Queuing operation, for example access to Active Directory.

- **Disable Anonymous Access**. Trust the IIS computer for delegation to allow multiple hops in communicating with a domain controller. Note that this option will not resolve remote read limitations.

For instruction, see Change the security settings for Internet Information Services.

# Administering Queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Queues**

This section provides information about managing and configuring queues for Message Queuing. You can use the Computer Management snap-in or the Active Directory Users and Computers snap-in to administer queues. For more information, see Administration overview. Instructions for completing individual tasks can be found in the How To... section in this online Help file. For details about administering queues, see:

- Managing queues
- Managing queue properties
- Setting queue quotas
- Enabling target journaling

# Managing queues

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing queues**
The Computer Management snap-in or the Active Directory Users and Computers snap-in is used to manage and administer queues. For more information, see Administration overview.

**Creating queues**
There may be certain restrictions on creating queues on computers that are determined during Message Queuing Setup. For more information, see Access control for Message Queuing.

For information on how to create, delete, or find a queue, see Create queues, Delete queues, and Find queues.

**Viewing queues**
The operation of viewing the contents of a queue from the same computer on which the queue is located is called *local* reading. The operation of accessing the contents of a queue from a computer other than the one on which the queue is located is called *remote* reading.

You can view the contents of only those queues that you have sufficient permissions to open. Therefore, there can be public queues whose contents are not visible in the snap-ins. For more information, see Access control for Message Queuing.

By default, any user with the *Get Properties* permission for the msmq object can view the queue status of local outgoing queues. To limit this default, you can do either of the following:

- Change users' *Get Properties* permissions for the msmq object.
- In the registry, add the dword **RestrictAdminAPI** with a registry value of 1, under HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Msmq\Parameters. This restricts the ability to view the queue status of active outgoing queues to local administrators, regardless of security permissions for the msmq object.

  **Caution**

  - Incorrectly editing the registry may severely damage your system. It is recommended that you back up any valuable data on the computer before making changes to the registry.
- After setting the registry, restart the Message Queuing service for the changes to take effect.

**Viewing internal private queues and outgoing queues**
There are certain internal private queues that are used exclusively for internal operation, and the Active Directory Users and Computers and Computer Management snap-ins do not display any internal private queues. For more information, see Internal private queues and outgoing queues.

Outgoing queues on a computer are used to store messages temporarily before the messages are sent to their destinations. Outgoing queues are visible only when using the Computer Management snap-in. However, transactional messages in outgoing queues cannot be viewed from Computer Management.

**Pausing and resuming queues**
You can pause and then later resume the operation of a local outgoing queue, thereby deferring the sending of messages from that queue to the corresponding destination queue. This way, you can send all pending messages to a destination queue at a later time. For information on how to pause or resume an outgoing queue, see Pause or resume an outgoing queue.

You can also take Message Queuing offline from the network. When you take Message Queuing offline from the network, you pause the operation of all outgoing queues on the local computer. This is useful when you communicate over a slow, expensive connection and want to defer sending messages in all outgoing queues on the computer to a later time. For information on how to take Message Queuing offline from the network for a computer, see Take outgoing queues offline.

**Managing queues with triggers**
When you delete a queue, the triggers associated with that queue are not deleted. If you later re-create a queue of the same name, any existing triggers will be used by this queue. However, this re-created queue will not be monitored by the Message

Queuing Triggers service until the computer is restarted, or the associated triggers disabled and then enabled again. For instructions on setting the enabled or disabled property for a trigger, see View or change properties of triggers and rules for triggers.

# Managing queue properties

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing queue properties**

The Computer Management snap-in or the Active Directory Users and Computers snap-in is used to administer queues. For more information, see Administration overview.

Messages are sent to public queues based on the sum of each message's priority value and the destination queue's priority, or base priority, value. Messages with the highest numerical total are sent first. Messages are sent first by base priority, and then by message priority. Private queues do not support base priority, so messages are sent only according to message priority.

For information on how to change the base priority for a queue, see Change the base priority of queues.

The queue type ID specifies the type of service provided by the queue. The queue type ID must be a valid GUID in the form {*dddddddd-dddd-dddd-dddd-dddddddddddd*}, where *d* is a hexadecimal text digit. It can be used to search for queues of a specific type. After you have located queues by type ID, you can use the name retrieved to open or delete the queue. The use of the queue type ID is optional.

For information on how to change the queue type ID, see Change queue type IDs.

Each queue can have a label, which is a string with a maximum length of 124 Unicode characters that can be used to identify the queue. For example, queues that accept messages sent by a specific application may all have the label "Messages from my application." For information on how to change the queue label, see Change queue labels.

You can specify whether a queue accepts encrypted messages, unencrypted messages, or both by selecting the privacy level for the queue. If the queue privacy level is set to **None**, the queue accepts only unencrypted messages. If the queue privacy level is set to **Body**, the queue accepts only encrypted messages. If the queue privacy level is set to **Optional**, the queue accepts both unencrypted and encrypted messages. You can check whether a message sent to the queue was encrypted or unencrypted by using Active Directory Users and Computers (or programmatically by checking the PROPID_M_PRIV_LEVEL message property).

For information on how to set the privacy level for a queue, see Change the privacy level for queues.

You can also specify whether a queue accepts only authenticated messages. For more information on how to set this option, see Allow only authenticated messages on queues. For general information on message encryption, see Encryption for Message Queuing.

# Setting queue quotas

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting queue quotas**

The Computer Management snap-in or the Active Directory Users and Computers snap-in is used to administer queues. For more information, see Administration overview.

Queue quotas specify the cumulative limit for messages stored in a particular queue. When the message quota for a destination queue is reached, new incoming messages are discarded, and a negative acknowledgment message indicating that the destination queue is full is generated. Messages can be placed in the queue only after one or more messages are removed (read) from the queue.

Queue quotas can be set only for Message Queuing servers and independent clients. Queue quotas set on Message Queuing servers that support dependent clients apply both to the server and to all its dependent clients.

For background information on quotas, see "Quotas for messages" in Message storage.

For information on how to set a queue quota for normal messages, see Set the message storage size for queues.

For information on how to set a queue quota for journal messages, see Set the journal storage size for queues.

# Enabling target journaling

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Enabling target journaling**

Target journaling is configured on a queue basis. If it is enabled, a copy of each incoming message is placed in the applicable queue journal when a message is removed (read) from the destination queue.

For information on how to enable target journaling for a queue, see Enable or disable target journaling.

# Administering Distribution Lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Distribution Lists**

A distribution list is a set of one or more distribution lists, or target queues, which can be used to do the following:

- Send transactional and nontransactional messages to multiple destinations.
- Specify one or more administration queues for sending application-generated acknowledgment messages, when acknowledgment messages are requested.
- Specify one or more response queues for sending application-generated response messages, when response messages are requested.

For details about administering distribution lists, see the following links:

- To learn about creating distribution lists, and setting properties and security permissions, see Creating and managing distribution lists.
- To learn about managing queues, queue aliases, and other distribution list members of a distribution list, see, Managing distribution list elements.

# Creating and managing distribution lists

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating and managing distribution lists**

Distribution lists are public lists that are published as distribution group objects in Active Directory. You can use Active Directory Users and Computers to create and delete distribution lists as distribution group objects, and to view their properties. For more information on performing these tasks, see Create distribution lists, Delete distribution lists, and View, add, or delete elements in a distribution list. For more conceptual information on distribution lists, see Distribution lists.

When you create a distribution list (group) in Active Directory, you are prompted to specify the minimal information needed to establish the object in Active Directory. Each distribution list (group) has many more properties (attributes) that can be viewed and set, as follows.

| Property | Details |
|---|---|
| Group name | Name of distribution list object |
| Description | Description of distribution list object |
| Group scope | Distribution lists can be domain-scoped, global, or universal |
| Group type | The type of group for this object is *distribution* |
| Distribution list (group) elements (members) | Elements that make up the distribution group |
| Folders containing the members in Active Directory | Location of group elements |
| Distribution lists (groups) of which the applicable distribution list (group) is a member | If the distribution list is in turn the member of another distribution list |
| Administrative permissions | Security for the distribution list |

**Setting distribution list scope**

Distribution lists can be specified as "Global", "Domain-scope" or "Universal":

- Domain-scope distribution lists can only contain queues and distribution lists from the local domain as members, and cannot be moved to another domain.
- Distribution lists with global scope can include queues and distribution lists from the local domain, and queues and global distribution lists from other domains in the forest. They can be moved to another domain.
- Distribution lists with universal scope can include other groups and accounts from any domain in the domain tree or forest and can be granted permissions in any domain in the domain tree or forest.

**Setting distribution list security**

Because distribution lists are objects in Active Directory, security attributes can be attached to control access to them. A security descriptor is assigned to each queue and distribution list. This security descriptor lists the users and groups that are granted or denied access to the queue or distribution list, and the following specific permissions are associated with distribution lists:

- **Send To** permission allows a group or user to send messages to the applicable distribution list. By default, this permission is granted to everyone.
- **Add/Remove Self as Member** permission for a public queue or queue alias allows a group or user to add or remove the applicable public queue or queue alias as a member in a distribution list. All users are granted this permission by default.

- **Add/Remove Self as Member** permission for a distribution list allows a group or user to add or remove the applicable distribution list as a member in another distribution list. Only the owner of a distribution list has the Add/Remove Self as Member permission for it.

For more information on distribution list security, see Distribution lists.

Distribution lists can be referenced programmatically through distribution list format names. For more information on using distribution list format names and their syntax, refer to the Message Queuing Software Development Kit (SDK).

# Managing distribution list elements

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing distribution list elements**

Distribution lists are public lists that are published as distribution group objects in Active Directory. You can use Active Directory Users and Computers to add and delete members of a distribution list. For more information, see View, add, or delete elements in a distribution list. For more conceptual information on distribution lists, see Distribution lists.

The explicit members of a distribution list must be destinations published in Active Directory, including:

- Public queues. For more information on public queues, see Public and private queues.
- Queue aliases. For more information on queue aliases, see Queue aliases.
- Other distribution lists.

You cannot explicitly use private queues or URL-named queues as members of your distribution lists, but they can be included in a distribution list, and referenced indirectly by using queue aliases. For instructions, see Create queue aliases.

You can also identify all distribution lists for a given element, and remove a distribution list, queue, or queue alias from one or more distribution lists if required. For instructions, see Get a list of distribution lists containing a given element.

# Administering Messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Messages**

This section provides information about configuring and managing messages. Instructions for completing individual tasks can be found in the How To... section in this online Help file. For details about administering messages, see the following links:

- For information on message lookup and purging messages, see Managing messages.
- For information on sending test messages and tracking message routes, see Tracking messages and routes.
- To learn more about backing up messages, see Backing up and restoring messages.
- To learn about setting queue quotas and computer quotas for messages, see Setting message quotas.
- For information about storing messages on multiple disks, see Storing message files on multiple disks.
- To learn about sending transactional messages to multiple destinations, see Sending transactional messages to multiple destinations.

# Managing messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Managing messages**

A message body can contain text or binary information. If a message body contains text information, this information is displayed. If a message body contains binary information, hexadecimal data is displayed along with its text translation. Message bodies can be viewed on the **Body** dialog box for the message.

To retrieve messages from a queue, you must first be granted the Receive Messages permission for the queue. It is not sufficient to have the Read permission granted for the queue. For information on how to set permissions for queues, see Access control for Message Queuing.

**Message lookup**

Applications can be written to peek at or retrieve a specific message without navigating through the queue to find the message. This functionality is based on a 64-bit lookup identifier that is assigned to each message when it is placed in a destination queue. The lookup identifier of a message is unique within the queue and is always greater than the lookup identifier of the preceding message and less than the lookup identifier of the next message. Note that this functionality is designed to help you look at specific messages you have received. It is not a random search mechanism.

Both messages sent by applications and messages sent by Message Queuing have a lookup identifier. The local queue manager generates the lookup identifier and sets the lookup identifier properties of the message (**PROPID_M_LOOKUPID** and **MSMQMessage.LookupId**) whenever it places a message in a queue. Message Queuing generates a lookup identifier for messages placed in user- and application-generated queues, such as destination queues, administration queues, response queues, and report queues, as well as for copies of messages placed in system-generated journals, dead-letter queues, and connector queues. If a message is sent to several destination queues, or if a copy of a message is stored in a computer journal or queue journal, each copy of the message will be assigned its own lookup identifier when it is placed in its respective queue.

Message Queuing has an API function and methods of the **MSMQQueue** object that enable applications to perform the following tasks programmatically without using cursors:

- Peeking at the first message in the queue.
- Peeking at the message preceding the message specified by the message lookup identifier supplied.
- Peeking at the message specified by the message lookup identifier supplied.
- Peeking at the message immediately following the message specified by the message lookup identifier supplied.
- Peeking at the last message in the queue.
- Retrieving the first message in the queue.
- Retrieving the message preceding the message specified by the message lookup identifier supplied.
- Retrieving the message specified by the message lookup identifier supplied.
- Retrieving the message immediately following the message specified by the message lookup identifier supplied.
- Retrieving the last message in the queue.

When API function calls are made to peek at or retrieve messages, messages can be processed asynchronously, synchronously, or within a transaction. However, the method calls process the messages synchronously.

A receiving application can use the lookup identifier of a message to go directly to that message and then continue navigating the queue from that point toward the front or the end of the queue. Lookup identifiers differ from cursors in this respect. When cursors are used, the application must start at the front of the queue and navigate towards the end of the queue.

**Purging messages**

You can purge all messages in any queue, including outgoing queues. The only exception to this is system queues. Note that you cannot purge individual messages in a queue. For instructions on purging all messages in a queue, see Purge all messages in a queue.

# Tracking messages and routes

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Tracking messages and routes**
You can track the passage of messages from a source computer to a target queue by sending test messages. You can also track the route taken in your network by test messages or all messages sent from the source computer to test queues on remote computers by enabling the message route tracking feature. Neither of these features is enabled by default following Message Queuing installation. For instructions on enabling these features, see Enable route tracking and test messages.

**Sending a test message**
You can send a test message from an independent client or a Message Queuing server to a test queue on any other independent client or Message Queuing server within the same Windows forest. To do so, after you have enabled test messages, you must first create a test queue, or change the type ID of an existing queue, so that you can send test messages to the test queue on the destination computer. For more information, see Sending test messages.

Report messages, which track the routes of messages through your network, are always sent to the report queue specified by the source computer for test messages if message tracking is enabled on the source computer.

For information on how to send a test message, see Send test messages.

**Message route tracking**
You can use the message route tracking feature to track the route that messages take through your network. When all the conditions for route tracking are satisfied, a report message is sent to the report queue for the source computer when the message leaves its source computer, when it arrives at its destination computer, and whenever the message arrives at or leaves a Message Queuing server with routing enabled.

After message route tracking is enabled, there are two basic requirements for its use. First, you must enable message route tracking and create or specify a report queue for the source computer. Second, the route tracking flag (property) in the message must be set programmatically by the sending application. In addition, only messages sent to a remote computer are tracked, and messages sent over HTTP/HTTPS transport as well as messages sent to multiple destinations using IP multicast, distribution lists, or multiple-element format names cannot be tracked in the current version of Message Queuing.

For information on message route tracking, see Track message routing. For information on setting properties programmatically, refer to the Message Queuing Software Development Kit (SDK).

Only one queue can be specified in the header of a message as the report queue for that message. If a route-tracked message with a report queue specified in its header subsequently passes through a Message Queuing server with routing enabled that also has message route tracking enabled, Message Queuing sends a conflict report message to the report queue for that server when the message leaves it.

For example, consider three computers, called A, B, and C, where message route tracking is enabled for computer A. In this example, the Message Queuing application on computer A sends a message to computer C through out-routing server B. If the report queue for computer A is called QA, a report message is sent to QA when the following events occur:

- The message leaves computer A.
- The message arrives at out-routing server B.
- The message leaves out-routing server B.
- The message arrives at computer C.

If out-routing server B is also configured with message route tracking enabled, with report messages being sent to QB, this queue receives a conflict report message when the message leaves out-routing server B. The original source queue QA, however, continues to receive the regular tracking messages.

In a second example, computer A does not have message route tracking enabled, but route tracking is enabled on computers B and C. In this case, the message starts reporting its movements when it leaves out-routing server B. A total of two report messages are sent to QB (when the message leaves computer B and when the message arrives at computer C), but no conflict

report messages are sent.

In a third example, neither computer A nor computer B has message route tracking enabled, but route tracking is enabled on computer C. In this case, no report messages are sent before the message reaches the destination computer, but one report message is sent to QC when the message arrives at its destination. No conflict report messages are sent.

Report messages consist of a label and a body. The label has the following format:

```
gggg:dddd:hh sent from <computer> to <address> at <time>
```

```
gggg:dddd:hh received by <computer> to <address> at <time>
```

where *gggg* is the first four hexadecimal digits of the globally unique identifier (GUID) of the source queue, *dddd* is the internal message identifier, and *hh* is the hop count.

The internal message identifier is the message sequence number, which is part of the entire message identifier. The message identifier is not used in its entirety because it is too big to be easily read. It is a 16-byte source GUID and a 4-byte sequence number.

When conflict report messages are sent, the labels contain the string "Report Message Conflict."

The body of a regular report message contains the ID of the message, the target queue, the destination of the next hop (if any), and the hop count in an XML format. For example, the body of the report message sent to QA when the message leaves the out-routing server in the first example will have the following form:

```
<MESSAGE ID>message_ID</MESSAGE ID>
```

```
<TARGET QUEUE>format_name_of_target_queue_on_computer_C</TARGET QUEUE>
```

```
<NEXT HOP>IP_address_of_computer_C</NEXT HOP>
```

```
<HOP COUNT>1</HOP COUNT>
```

The body of a conflict report message contains has an additional line containing the original source queue. For example, the body of the "Report Message Conflict" message sent to QB when the report message just described is sent to QA in the first example will have the following form:

```
<ORIGINAL QUEUE>format_name_of_QA</ORIGINAL QUEUE>
```

```
<MESSAGE ID>message_ID</MESSAGE ID>
```

```
<TARGET QUEUE>format_name_of_target_queue_on_computer_C</TARGET QUEUE>
```

```
<NEXT HOP>IP_address_of_computer_C</NEXT HOP>
```

# Backing up and restoring messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use the message backup and restore command-line utility, Mqbkup, provided with Message Queuing to protect message storage files, log files, transaction log files, and registry settings against computer failure.

**Backing up and restoring messages**

You must first create a folder to use for backup before using the utility. You run the utility from a command prompt by typing **mqbkup**.

The syntax of the utility is:

**mqbkup {-b** *folderpath* **| -r** *folderpath* **| -y | -c** *resource name* **| -?}**

where:

**-b** *folderpath* backs up the files to the specified folder,

**-r** *folderpath* restores the files from the specified folder,

**-y** don't prompt (Yes to all questions).

**-c** cluster resource; please specify the MSMQ resource name.

**-?** displays help for the utility.

Before restoring messages, you must close Control Panel and all Message Queuing applications.

Certificate and cryptographic key information is not backed up using this utility.

| **Warning** |
| --- |
| When you run mqbkup, run wbadmin to backup any public queue information. |

After a restore operation, you must register a new user certificate. For information on how to register a certificate, see Register certificates for Message Queuing.

This utility stops and restarts the Message Queuing service.

# Setting message quotas

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Setting message quotas**
Message storage limits can be set by configuring the following:

**Set computer quota**
This quota specifies the cumulative limit for all messages stored in destination queues, outgoing queues, and queue journals on a computer. After a computer quota is reached, no messages can be delivered to any queue or journal on the computer. The computer quotas can be set for Message Queuing servers and independent clients. Following a new installation of Message Queuing, or an upgrade from Windows 2000, the default limit for these storage sizes is 8 gigabytes (GB). For more information, see Message storage. Computer quotas are set separately to limit message storage size and journal size. When you set the journal storage size limit for a computer, you automatically set equal quotas for the computer journal (the Journal messages queue), the dead-letter queue, and the transactional dead-letter queue. For instructions on setting the message storage limit for a computer, see Set the message storage size for computers. For instructions on setting the journal storage size for computers, see Set the journal storage size for computers.

**Set queue quota**
This quota specifies the cumulative storage size (number of bytes) available for all messages stored in a particular queue, whereas a computer quota limits the total storage available for all messages in destination queues, outgoing queues, and queue journals on the computer. When a queue quota is reached, messages can no longer be sent to the queue until one or more messages are retrieved (removed from the queue by a Message Queuing application). Queue quotas can be set for all queues. Queue quotas for journal queues and other queues are set separately. For instructions on setting the quotas for regular messages, see Set the message storage size for queues. For instructions on setting the journal storage size for a queue, see Set the journal storage size for queues.

# Storing message files on multiple disks

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Storing message files on multiple disks**

Independent clients and Message Queuing servers can improve their messaging performance by storing the various files used to implement messaging across several physical disks. Message Queuing can use three different disks to implement message functions. For the best messaging performance on Message Queuing servers, put the messaging (*.mq) files, message log files, and transaction log files on separate physical disks.

For information on how to store messaging files on multiple disks, see Store messages on multiple disk drives.

# Sending transactional messages to multiple destinations

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sending transactional messages to multiple destinations**
Both distribution lists and multiple-element format names have support for transactional messaging. When a message is sent to a distribution list or a multiple-element format name within a transaction, a copy of the message is sent to each applicable outgoing queue. Failure in sending the message to any of these outgoing queues will abort the entire transaction. A distribution list or a multiple-element format name may reference a mixture of transactional and nontransactional target queues. When a transactional message is sent to such a mixture of targets, the message is allowed to be sent to all the transactional and nontransactional target queues on the local or a remote computer. However, when the message reaches a nontransactional queue, it is rejected and transferred to the transactional dead-letter queue on the computer hosting the nontransactional queue for storage, and a negative acknowledgement message indicating that a transactional message was sent to a nontransactional queue is sent to the administration queue specified in the original message.

**Exactly-once and in-order delivery**
Message Queuing guarantees that transactional messages will be delivery in-order and only once. The Exactly-Once In-Order Delivery (EOD) protocol is an end-to-end protocol, guaranteeing that messages are not duplicated or delivered out-of-order. To achieve this, the sender attaches information to each message that allows the receiver to eliminate duplicate and out-of-order messages. All messages that have order relation between them are said to be in the same *message stream*. Each message in a stream carries a sequence number, identifying the message in the stream, and a previous number identifying the preceding message in the same message stream. The first message in a stream always carries a previous number equal to zero.

Each receiver filters the newly arriving messages and accepts only those messages that arrive in-order and are not duplicates. To implement this, the receiver uses the sequence numbers and previous numbers attached to the messages. The receiver needs to keep track of the sequence number of the last message accepted in each message stream, there is no need to keep message history or a larger database. The receiver acknowledges by sending the sequence number of the last message accepted back to the sender. This lets the sender know that the receiver accepted all messages up to the acknowledged message.

**Sending messages**
The sender tags each message with a monotonically increasing sequence number and links it to the previous message using the previous number. When there is no previous message in the message stream the sender places a zero in the previous number field. This ensures that the receiver will accept the message. A message that is discarded at the sender side (for example, when the time to receive the message before time-out has elapsed) is removed from the message stream, and the next message is linked to the message preceding the removed message.

The sender needs to keep resending the same messages until an "order-acknowledgment" arrives from the receiver. The acknowledgment carries a sequence number indicating that all messages up to that number have safely arrived in-order and exactly-once at the target. The sender can thus safely discard all messages up-to and including the indicated sequence number.

To overcome crash scenarios where the receiver cannot recover its database (last accepted message sequence number for a given message stream), the sender must assign the first message in the queue a previous number of zero. On the other hand, after a sequence number has been attached to a message, it must never be changed.

**Receiving Messages**
The receiver keeps track of the last accepted message sequence number for each message stream. It uses this number to filter out arriving messages and accept only those that arrive in-order and are not duplicates. The receiver initiates this last number with a zero for each new message stream. The simplest algorithm the receiver must implement looks like the following:

```
if(message.sequence <= last_accepted_sequence)
{
    Reject Message
}

if(message.previous > last_accepted_sequence)
{
    Reject Message
}
```

```
Accept Message

last_accepted_sequence = message.sequence;
```

When a new message stream has been created, the receiver occasionally sends an "order-acknowledgment" containing the last accepted sequence number. This acknowledgment signals the sender that the target has accepted all messages in the message stream up to the indicated sequence number. The receiver keeps sending these acknowledgments for active message streams; that is, message streams for which messages continue to arrive even if these messages are not accepted.

The receiver sends these "order-acknowledgments" to the acknowledgment return address indicated by the incoming message. All messages within the same message stream must have the same acknowledgment return address.

It is recommended that the quality of service for acknowledgment messages be as lightweight as possible because the receiver maintains the state to regenerate the acknowledgment persistently (last sequence number).

For more information on sending messages within transactions, see Transactional messaging.

For information on sending transactional messages to distribution lists, see Distribution lists.

For information on sending transactional messages to multiple-element format names, see Multiple-element format names.

# Administering Triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering Triggers**

This section provides conceptual information about administering Message Queuing triggers. Instructions for completing individual tasks can be found in the How To... section in this online Help file. For details about Message Queuing triggers, see the following links:

- To learn about defining message processing types for triggers, see Defining message processing types.
- For information on how trigger messages are processed, see Processing trigger messages.
- To learn about creating triggers, see Creating triggers.
- To learn about default trigger values, see Modifying default trigger values.
- For an example, see Implementing triggers.

# Defining message processing types

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Defining message processing types**

A message processing type is defined for each trigger. The available message processing types are peeking, retrieval, and transactional retrieval.

When peeking is selected as the message processing type for a given trigger and the Message Queuing Triggers service is running, it peeks at each message arriving at the monitored queue, tests it for the conditions of all the rules associated with the queue, and performs all the applicable actions, but does not remove it from the queue.

When retrieval is selected as the message processing type, the Message Queuing Triggers service peeks at each message arriving at the monitored queue, tests it for the conditions of all the rules associated with the queue, and invokes all the applicable actions. If at least one condition is satisfied, and no invoked action fails, the message is removed from the queue.

The transactional retrieval type of message processing is similar to the retrieval type, but in this case the message is returned to the queue if any of the operations involved in retrieving the message cannot be completed and the retrieval transaction is aborted.

When messages arrive at a monitored queue, Message Queuing does not limit access to these messages to the Message Queuing Triggers service. Thus, it is possible for another Message Queuing application to open the queue and remove messages before the Message Queuing Triggers service manages to process those messages.

# Processing trigger messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Processing trigger messages**

The Message Queuing Triggers service starts to process the messages in the queue as soon as the service starts running. The service starts at the beginning of the queue and processes all the messages in the queue. After processing all the existing messages, the service waits at the end of the queue for a new message. If the service is stopped and restarted, it will process all messages remaining in the queue again.

**Processing messages having the same priority**

When all the messages sent to a monitored queue have the same priority, new messages are always placed at the end of the queue. After processing all the existing messages in the queue, the Message Queuing Triggers service will activate the trigger each time a new message arrives at the end of the queue. The illustration below shows a queue with four messages and portrays a trigger with the peeking type of message processing. The Message Queuing Triggers service already peeked at message 1, message 2, message 3, and message 4 and will continue to peek at messages as they arrive at the end of the queue.

**Processing messages having different priorities**

When messages with different priorities arrive in a queue, a new message can be placed anywhere in the queue. For example, when a high-priority message is placed somewhere in the queue, the Message Queuing Triggers service processes the new message next regardless of where it is placed in the queue and then continues to process all the low-priority messages that are in the queue.

In the next illustration, which also portrays a trigger with the peeking type of message processing, the Message Queuing Triggers service makes one pass through the queue peeking at message 1, message 2, message 3, and message 4. Then, when message 5, a new message of priority 1, arrives at the queue, it is placed between message 2 and message 3. The service goes back and peeks at message 5 and then continues to peek at message 3 and message 4 again.

Note that in this case, the trigger is activated twice for message 3 and twice for message 4. You can avoid messages being read more than once by using a transactional queue (where all messages have a priority of 0). For more information on transactional queues, see Transactional messaging.

**Processing messages within transactions**

When a message is retrieved from within a transaction, Message Queuing does not roll back the cursor if the transaction is aborted. For example, given a queue with two messages, message 1 and message 2, if you remove message 1 from within a transaction, Message Queuing will move the cursor to message 2. However, if the transaction is aborted for any reason, message 1 is inserted back into the queue, but the cursor remains at message 2.

For the peeking type of message processing in a queue containing one message when a COM component invoked by a trigger rule receives the message invoking it and the same COM component is configured to be part of an external transaction, if any operation in the transaction cannot be completed, the transaction is aborted and the message is returned to the queue. Then, if the trigger is serialized, the Triggers service waits until the process performed by the COM component ends (aborts) before starting to process a message again. In this case, the queue cursor moves on to wait for the next message, and the trigger does not invoke the COM component again for the same message. However, if the trigger is not serialized, as soon as the Triggers service finishes peeking at the message, it sends a request to peek at the next message and waits for a message to appear in

the queue. Therefore, when the transactional COM component is invoked, there is already a pending peeking operation in the system. When the message is returned to the empty queue in the aborted transaction, it arrives at the queue in the position to which the queue cursor is pointing. In this case, the returned message is processed again, the COM component is invoked for the same message, and a perpetual loop exists until a new message arrives or all the operations in the transaction can be completed.

**Sample implementation of Message Queuing Triggers**

Suppose you create a new trigger named PrivateTrigger, which is associated with the private queue MyComputer\MyQueue and has two rules attached to it: MyRule1 and MyRule2.

Each of these rules defines a condition (such as "Message label contains marketing") and an action to be taken when the condition is true (such as "open MSPaint.exe" with the parameter Message label).

When a message arrives at MyComputer\MyQueue, the Message Queuing Triggers service is notified. Next, for the trigger, PrivateTrigger, defined for that queue, the rules MyRule1 and MyRule2, which are attached to that trigger, are applied. Last, Microsoft Paint is opened if all the conditions for those rules are satisfied (are true).

For more information about implementing the Message Queuing Triggers service, see Installing Message Queuing triggers.

# Creating triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Creating triggers**

Triggers are created on the local computer in Triggers under the Message Queuing Triggers folder in the console tree of the Computer Management snap-in or in Triggers under any queue that is already monitoring a trigger by right-clicking **Triggers**, pointing to **New**, and then clicking **Trigger**. In the latter case, the queue selected automatically becomes the *monitored queue*. On the first page of the **New Trigger** dialog box, you must type a name for the new trigger in **Trigger name**. The *monitored queue* can be a user-defined queue registered in Active Directory, whose path name must be typed in **Queue path name**, or one of the automatically created queues on the local computer, which is selected by clicking the applicable button. Regardless of where the creation of a trigger is initiated, every trigger created on the local computer is displayed in the Computer Management snap-in under **Triggers** and under the applicable monitored queue. You then select the *message processing type*, and finally you indicate whether the trigger will be *enabled* and whether it will be *serialized*. For more information on the message processing type, enabled triggers, and serialized triggers, see Triggers overview.

By default, the Message Queuing Triggers service runs under the Network Service account. For heightened security, you can change the default Triggers service account to a more secure setting. You can also specify a less secure account for the Triggers service. The account used must be able to access the queues with which triggers are associated. Note that executable files invoked by triggers are invoked with the same security privileges as those assigned to the Triggers service. If your rule invokes a COM component, make sure that it can be successfully invoked from the security context used by the Triggers service, is properly registered, and has suitable dependencies. For more information, see Triggers overview.

You can attach an existing rule to the new trigger by selecting a rule and then associating it with the trigger. The order in which the rules are tested (their priorities) can be specified. For more information, see Create triggers.

Before creating a trigger, verify that the account under which the Message Queuing Triggers service is running has been granted the **Peek Message** permission for all existing queues that will be associated with triggers. For more information, see Set permissions for computer and queue objects.

**Managing triggers and queues**

When you delete a queue, the triggers associated with that queue are not deleted. If you later re-create a queue of the same name, any existing triggers will be used by this queue. However, this re-created queue will not be monitored by the Message Queuing Triggers service until the computer is restarted, or the associated triggers disabled and then enabled again. For instructions on setting the enabled or disabled property for a trigger, see View or change properties of triggers and rules for triggers.

# Modifying default trigger values

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Modifying default trigger values**

The Message Queuing Triggers service has a set of default configuration values. You can modify these values after the service is installed by using the Computer Management snap-in.

Configuration information as well as the trigger and rule definitions are stored in the local registry.

You can modify any of the following configuration settings:

- **Initial number of threads**. The default value is 5.
- **Maximum number of threads**. The default value is 20.
- **Default message body size**. The default value is 2048. This parameter is the size of the buffer that Message Queuing Triggers allocates for an incoming message. It is recommended that the value of this setting be sufficient for a buffer that can accommodate 90% of all messages that are expected to arrive at the monitored queue. An excessively low value will force the service to reallocate this buffer for every message that arrives with a larger message body. An excessively high value will waste resources.

When you change a configuration setting, you will need to stop and restart the service before the new setting will take effect. For more information on how to change configuration settings, see Change default configuration values for triggers.

# Implementing triggers

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Implementing triggers**

Suppose you create a new trigger named PrivateTrigger, which is associated with the private queue MyComputer\MyQueue and has two rules attached to it: MyRule1 and MyRule2.

Each of these rules defines a condition (such as "Message label contains marketing") and an action to be taken when the condition is true (such as "open MSPaint.exe" with the parameter Message label).

When a message arrives at MyComputer\MyQueue, the Message Queuing Triggers service is notified. Next, for the trigger, PrivateTrigger, defined for that queue, the rules MyRule1 and MyRule2, which are attached to that trigger, are applied. Last, Microsoft Paint is opened if all the conditions for those rules are satisfied (are true).

For more information about implementing the Message Queuing Triggers service, see Installing Message Queuing triggers.

# Monitoring and Testing Message Queuing

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring and Testing Message Queuing**

This section provides information on monitoring Message Queuing, so that you can tune performance and identify issues. For details, see the following links:

- Monitoring events
- Monitoring Message Queuing performance
- Monitoring transactional messages
- Monitoring connectivity
- Sending test messages

# Monitoring events

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring events**

You can monitor Message Queuing events using Event Viewer.

Message Queuing logs information about its operation to the Windows Server 2003 family event logs. Message Queuing events are located in the Source column under "MSMQ." Most events are written to the Application Log. Security-related events are written to the security log, and service-related events are written to the system log.

For information on how to view Message Queuing events, see View Message Queuing events.

For more information on Event Viewer, see Event Viewer.

There are three types of application events for Message Queuing in the Windows Server 2003 family Application Log, as follows:

- **Informational events**. Infrequent, significant events that describe successful operations.
- **Warnings**. Not necessarily significant events, but indicative of potential problems.
- **Errors**. Events generated for significant problems.

Some application events are not logged at each occurrence. For example, if a Message Queuing server cannot establish a session with the destination computer, an event is logged for the first failure only and another event is logged after the session is established.

There are two types of security-related events for Message Queuing in the security log, as follows:

- **Success Audit**. Generated when selected objects are successfully accessed.
- **Failure Audit**. Generated when access to a selected object is denied.

For more information on access auditing, see Auditing Message Queuing objects.

# Monitoring Message Queuing performance

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring performance**
You can monitor the performance of Message Queuing by using the performance counters provided. You can view these performance counters using System Monitor. The default performance counters are grouped under the following objects:

- MSMQ Service
- MSMQ Queue
- MSMQ Session
- MSMQ Incoming HTTP Traffic
- MSMQ Outgoing HTTP Session
- MSMQ Incoming Multicast Session
- MSMQ Outgoing Multicast Session

For instructions on tracking counters, see Track Message Queuing service counters, and Track Message Queuing queue counters.

For more information about System Monitor, see System Monitor overview.

**Notes**

- Performance counters are not available when multiple instances of Message Queuing are running in a server cluster.
- Only the MSMQ Service and MSMQ Queue objects are always visible.

**MSMQ Service performance object**
The MSMQ Service performance object is provided on Message Queuing servers and independent clients. The MSMQ service object contains performance counters that you can use to monitor Message Queuing statistics for a selected computer.

The value you see for memory usage includes the memory space occupied by all messages in local queues on the computer. Because recoverable messages are stored on disk, this memory space is backed up by memory-mapped files on disk, not from the Windows Server 2003 family paged memory pool. For more information about how messages are stored, see "Local message storage" in Message storage.

**MSMQ Queue performance object**
The MSMQ Queue performance object contains performance counters that you can use to monitor message statistics for a selected queue. There can be an instance of the object for each open queue and for each queue containing messages on the computer where the queue resides up to the maximum number of instances allowed on that computer. In addition, there can be an instance for each outgoing queue opened for every destination queue on the computer where the outgoing queue resides up to the maximum number of instances allowed on that computer.

The name given a queue counter is the format name of the queue, unless the queue is an outgoing queue, in which case the name is the format name without the "PRIVATE=", "PUBLIC=", or "DIRECT=" prefix. For example, the following outgoing queues have the following queue counter names.

| Outgoing queue | Queue counter name |
|---|---|
| DIRECT=HTTP://fake/msmq/q1 | http:\\fake\msmq\q1 |

| | |
|---|---|
| DIRECT=OS:fake\q1 | os:fake\q1 |
| DIRECT=TCP:10.0.0.0\q1 | tcp:10.0.0.0\q1 |

Note that there can potentially be multiple outgoing queues (and counter instances) for the same queue, opened with different format names. If a connector application is running on the computer, a counter is available for the connector queue also; the queue name is displayed as **foreign=***GUID*.

Under **Instance**, only the first 97 queues created on the computer, including private queues, are listed. The queue counters for a specific computer appear for each instance. The **Computer Queues** instance represents the source or computer journal and the dead-letter queue for the computer. The **Bytes in Queue** and **Messages in Queue** counters monitor that computer's dead-letter queue. The **Bytes in Journal** and **Messages in Journal** counters then monitor the computer journal (Journal messages in the System Queues folder).

An outgoing queue is identifiable because the computer name listed in the counter instance matches the name of the computer on which the corresponding destination queue resides.

**MSMQ Session performance object**

The MSMQ Session performance object is visible only when the computer has established an active session with another Message Queuing computer. This object contains counters that can be used to monitor statistics about active sessions between computers running Message Queuing. Multiple instances of this object may be listed, one for each session. There can be an instance of this object on both computers involved in each session up to the maximum number of instances allowed on each computer. **Instance** lists the IP address of the computer with which there is an active session.

**Performance objects for HTTP messages**

The MSMQ Incoming HTTP Traffic and MSMQ Outgoing HTTP Session performance objects include counters that monitor messages sent over HTTP transport. These objects contain counters that monitor statistics about incoming HTTP messages, the rates at which the messages and message bytes arrive at the computer in an incoming HTTP connection, the total number of HTTP messages that arrived in the connection, and the total number of message bytes that arrived in the connection as well as counters that monitor the statistics about active outgoing HTTP sessions between the computer and other computers, the rates at which message bytes and messages are sent from the computer in a specific outgoing session, the total number of HTTP messages sent in the session, and the total number of message bytes sent in the session.

**Performance objects for multicast messaging**

The MSMQ Incoming Multicast Session and MSMQ Outgoing Multicast Session performance objects contain counters that monitor messages sent in multicast sessions. These objects contain counters that monitor statistics about active incoming multicast sessions, the rates at which the messages and message bytes arrive at the computer in a specific incoming multicast session, the total number of multicast messages that arrived in the session, and the total number of message bytes that arrived in the session as well as counters that monitor the statistics about active outgoing multicast sessions between the computer and other computers, the rates at which message bytes and messages are sent from the computer in a specific outgoing session, the total number of multicast messages sent in the session, and the total number of message bytes sent in the session.

**Improving messaging performance**

If available processing resources (CPU time) are not limiting messaging performance, it is possible that independent clients and Message Queuing servers can improve messaging performance by storing the various message and log files used to implement messaging across multiple physical disks.

To determine whether your computers are limited by disk access or by processing power, track the **% Processor Time** counter (located in the Processor object) and the **Avg. Disk Queue Length** counter (located in the DiskLength object). If the sustained **% Processor Time** value is above 75 percent during the time messages are being sent, adding processing capacity may improve messaging performance. If the **Avg. Disk Queue Length** value for any drive is greater than 0.6 when messages are being sent, additional disks may improve messaging performance.

For information about how to store the message and log files on separate physical disks, see Store messages on multiple disk drives.

# Monitoring transactional messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring transactional messages**

You can monitor Message Queuing transactions using the Component Services snap-in when the Microsoft Distributed Transaction Coordinator (DTC) is running.

Message Queuing uses the DTC, installed by default with Windows Server 2003 family, for implementing external transactions. You can use the Component Services snap-in to monitor statistics for transactional messages that are sent or received within external transactions and to monitor statistics for all transactions managed by the DTC. For more information, see View external transactions.

When you monitor external transactions, the details pane opened by clicking **Transaction Statistics** in the console tree of the Component Services snap-in provides useful information on active, committed, and aborted transactions. The DTC must be running to perform external transactional messaging for Message Queuing.

For more information on transactional messaging, see Transactional messaging.

For more information on the Microsoft DTC, see Using Component Services.

# Monitoring connectivity

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Monitoring connectivity**

Message Queuing offers an MQPing test, which has some similarity to the **ping** command supported by the TCP/IP protocol. You can use MQPing to determine whether the Message Queuing service is running on the computer being tested and whether that computer is currently connected to the network. When a computer running Message Queuing receives an MQPing request, it returns a response message to a response queue on the computer that sent the MQPing request. Thus, unlike the **ping** command, MQPing does not test for direct IP connectivity between the two computers, but verifies that messages can be sent between them with allowance for the possibility of routing.

For information on how to use MQPing, see Test connectivity using MQPing.

# Sending test messages

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Sending test messages**

The Computer Management snap-in or the Active Directory Users and Computers snap-in is used to administer queues. For more information, see Administration overview.

A test message is a message that is generated by the Message Queuing service on a specified source computer and sent to a target queue on a specified destination computer. The source computer can be any independent client or Message Queuing server, and the specified destination computer hosting the target queue can be any other independent client or Message Queuing server within the same forest. The target queue must be a test queue; that is, a nontransactional public queue with a queue type ID set equal to {55EE8F33-CCE9-11CF-B108-0020AFD61CE9}.

Test messages are sent to verify that messages can be sent from a given source computer and delivered to public queues on a given destination computer and, if message route tracking is enable, to track the route taken by messages sent from the source computer to public queues on the destination computer. For more information on tracking the routes taken by messages, see Tracking messages and routes.

You can either create a new test queue or transform an existing public queue into a test queue. Most existing public queues can be made to function as a test queue by changing the type ID to that of a test queue. However, it is useless to change the type ID of a transactional queue or a queue requiring message authentication to convert it into a test queue, because test messages, which are nontransactional and are not authenticated, will not be delivered to a transactional queue or to a queue requiring message authentication (unless the queue is located on the source computer).

Sending test messages is not enabled by default following Message Queuing installation, and must be enabled before you can send a test message. For instructions, see Enable route tracking and test messages. For information on how to send a test message, see Send test messages.

# Troubleshooting and Additional Resources

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting and Additional Resources**

This section provides help on troubleshooting Message Queuing and links to additional Message Queuing resources.

For help with installation, deployment, and administration issues, see:

- Troubleshooting installation problems
- Troubleshooting administration problems
- Troubleshooting triggers

For information and links to other Message Queuing resources, see:

- Additional Message Queuing resources

# Troubleshooting installation problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting installation problems**
This topic provides guidelines for solving problems associated with installing new Message Queuing software or running Message Queuing Setup.

When encountering installation problems, always inspect the setup log files first. This is especially important when you perform an unattended setup, because you will not know if something went wrong. The Message Queuing setup log file, Msmqinst.log, is located in the Windows folder. If this file does not identify the problem, look at the Windows Server 2003 family setup log file, Setuperr.log, which is located in the Windows folder (typically C:\Windows).

What problem are you having?

- You have completed Windows Server 2003 family Setup, but cannot find Message Queuing.
- You cannot install Message Queuing, or you receive an "Access is Denied" error.
- You have been prompted for the name of a server during Message Queuing Setup in a Windows Server 2003 family enterprise.
- You receive a "Message Queuing application is running" error while uninstalling Message Queuing.
- You are installing a Message Queuing computer as a dependent client and cannot configure a supporting server for it.

**You have completed Windows Server 2003 family Setup, but cannot find Message Queuing.**
**Cause:** Message Queuing is not installed by default during Windows Server 2003 family Setup.

**Solution:** Using **Add or Remove Programs** in Control Panel, install Message Queuing after Windows Server 2003 family is installed.

**See also:** Installation overview

**You cannot install Message Queuing, or you receive an "Access is Denied" error.**
**Cause:** To install Message Queuing clients, you must be logged on with local administrative permissions for the computer on which you want to install software. To install Message Queuing servers or Message Queuing servers with Downlevel Client Support on Windows Server 2003 family domain controllers, you need to have domain administrative permissions. To install Message Queuing servers with Routing Support on nondomain controllers, you need to have enterprise administrative permissions.

**Solution:** Verify that you are logged on with the proper permissions for the computer you want to install Message Queuing on.

**Solution:** Allow Active Directory replication to complete, and then try again.

**See also:** Installation permissions

**You have been prompted for the name of a server during Message Queuing Setup in a Windows Server 2003 family enterprise.**
**Cause:** For a Windows Server 2003 family computer, Setup was unable to automatically locate a Windows Server 2003 family domain controller in the local site or a nearby site.

**Solution:** Verify that both the computer on which you are running Message Queuing Setup and the domain controller have network connectivity.

**See also:** Installation overview

**You receive a "Message Queuing application is running" error while uninstalling Message Queuing.**
**Cause:** A Message Queuing application is currently running.

**Solution:** Close all Message Queuing applications.

**See also:** Start or stop services for Message Queuing

**You are installing a Message Queuing computer as a dependent client and cannot configure a supporting server for it.**
**Cause:** Following installation, the default setting is that Message Queuing server computers do not support dependent clients.

**Solution:** Enable the required Message Queuing server to act as a supporting server for dependent clients. For instructions, see Enable a supporting server.

# Troubleshooting administration problems

Updated: January 21, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting administration problems**
This topic provides guidelines for solving problems associated with viewing or setting properties, accessing objects in Active Directory, or using the snap-ins for Message Queuing.

What problem are you having?

- You cannot find Message Queuing under Services and Applications in Computer Management.
- You cannot find any objects for Message Queuing in Active Directory.
- You cannot access any objects for Message Queuing in Active Directory.
- You are unable to establish a connection with Active Directory.
- Changes you made do not show up in Active Directory.
- Windows NT 4.0 clients and local users cannot access Active Directory.
- You cannot access the contents of a particular queue.
- You cannot create queues.
- You cannot send messages to another site.
- You cannot send or receive authenticated messages.
- Messages sent to a queue are rejected.
- You cannot retrieve messages from a queue.
